Preface

Our main goal in the 15th edition of the *Textbook of Medical Physiology* is to explain, in language easily understood by students, how the different cells, tissues, and organs of the human body work together to maintain life. The *Textbook of Medical Physiology* is not a reference book or a compendium of the most recent advances in physiology. It is a book that continues the tradition of being written mainly for students who wish to learn the basic principles of physiology needed to begin a career in health care professions, such as medicine, dentistry, nursing, or graduate studies in the biological and health sciences. However, it should also be useful to clinicians and health care professionals who wish to review the fundamental mechanisms of human diseases.

Unlike most major medical textbooks that often have 20 or more authors, the first eight editions of the *Textbook of Medical Physiology* were written entirely by Dr. Arthur Guyton, who had a gift for communicating complex ideas in a clear and interesting manner that made studying physiology enjoyable. We have strived to maintain this presentation style in subsequent editions, with a focus on content most relevant to clinical and preclinical students. Although the book has been extensively updated as the science of physiology has advanced, we have maintained the same unified organization to ensure that it useful for students who are beginning their studies of physiology and that it is comprehensive enough for students to continue to use during their professional careers.

Our task has been enjoyable and challenging as advances in understanding the mysteries of body functions continue to emerge with each new edition. New technologies and extensive research have made it possible to explain the molecular and physical bases for many physiology principles, rather than merely summarizing a series of separate and unexplained biological phenomena. However, the molecular events that underpin the molecular functions of the body's cells provide only a partial explanation of human physiology. The total function of the human body requires complex control systems to communicate with each other and to coordinate the molecular functions of the body's cells, tissues, and organs in health and disease.

We hope that the *Textbook of Medical Physiology* conveys the majesty of the human body and its many functions and that it stimulates students to study physiology throughout their careers. Physiology links the basic sciences with clinical medicine. The great beauty of physiology is that it integrates the individual functions of all the body's different cells, tissues, and organs into a functional whole, the human body. Indeed, the human body is much more than the sum of its parts, and life relies upon this total function, not just on the function of individual body parts in isolation from the others.

Fortunately, our bodies are endowed with a vast network of feedback controls that are essential for normal function and for survival. Physiologists call this high level of internal bodily control *homeostasis*. These feedback controls occur at all levels of organization in the body—from the molecular and genetic levels to the cells, tissues, organs, and the whole body. In diseases, these controls are often seriously disturbed, although homeostatic compensations continue to operate and maintain vital functions until a limit is reached and the whole body can no longer live. One of the goals of this text is to emphasize the effectiveness and beauty of the body's homeostatic mechanisms, but we also present some of their abnormal functions in various diseases.

Although we often discuss "normal" values in the text, it is with the understanding that many of the body's control systems are constantly reacting to perturbations, and that variability normally exists in each person, depending on the time of day, activity, and other factors. Physiological variability also occurs among different individuals, depending on factors such as body weight, diet, age, sex, environment, and genetics. In most textbooks, discussion of human physiology often focuses on the "average" 70-kg young man even though the average man no longer weighs 70 kg and it is clear that there are important sex differences in many physiological functions. In this edition, we discuss some of these important differences in male and female physiology, in addition to obvious differences related to reproduction and physical traits. Despite our attempts to outline important sex differences in physiological functions, we must often make generalizations, partly as a result of limited available data but also to avoid creating an excessively lengthy compendium.

Although the chapters have been revised and updated to include new principles of physiology and new figures

to better illustrate these principles, the text length has been closely monitored to limit the book's size so that it can be used effectively in physiology courses for students and health care professionals. New references have been chosen for more extensive presentation of physiological principles, for the quality of their own references, and for their accessibility. The selected bibliography at the end of the chapters lists mainly review papers from recently published scientific journals that can often be freely accessed from the PubMed site at https://www.ncbi.nlm.nih.gov/pubmed/. Use of these references, as well as cross-references from them, provides much more extensive coverage of the entire field of physiology than can be included in this book.

Another feature of the book is that the print is set in two sizes. The material in large print constitutes fundamental physiological information that students will require in virtually all of their medical studies. The material in small print and highlighted with a pale blue background is of several different types: (1) anatomical, chemical, and other information that is needed for immediate discussion but that most students will learn in more detail in other courses; (2) information of special importance to certain fields of clinical medicine; and (3) information that will be of value to those students who wish to study specific physiological mechanisms more deeply.

The electronic version of this book provides links to additional content, including video animations and self-assessment questions that can be accessed with computers, smartphones, and electronic tablets. For additional self-assessment beyond these textbook supplements, the reader may consider using a copy of *Guyton and Hall Physiology Review*, which includes more than 1000 practice questions, with explanations for the questions that are referenced to the parent *Textbook of Medical Physiology*. We have also prepared a *Pocket Companion* that is designed to provide a concise overview of key facts and concepts in the parent *Textbook of Medical Physiology*. Although these ancillary materials do not contain some of the important details that enrich the physiological concepts or the clinical examples of pathophysiology contained in the parent textbook, we anticipate that they will assist readers in understanding the basic principles of physiology.

We sincerely thank the many persons who helped to prepare this book, including our colleagues at the University of Mississippi Medical Center, who provided valuable suggestions. We are especially grateful to Stephanie Lucas for excellent assistance and to James Perkins for excellent illustrations. We also thank Elyse O'Grady, Kathryn DeFrancesco, Angie Breckon, Jodi Willard, and the entire Elsevier team for continued editorial and production excellence. We are also grateful for the many readers who continue to help us improve the *Textbook of Medical Physiology* with their comments and suggestions. We hope that you enjoy the current edition and find it even more useful than previous editions.

John E. Hall
Michael E. Hall

Contents

UNIT I
Introduction to Physiology: The Cell and General Physiology

CHAPTER 1

Functional Organization of the Human Body and Control of the "Internal Environment" 3
Cells Are the Living Units of the Body 3
Extracellular Fluid—The "Internal Environment" 3
Homeostasis—Maintenance of a Stable Internal Environment 4
Control Systems of the Body 7
Physiological Variability 10
Sex Differences in Physiology and Pathophysiology 10
Summary—Automaticity of the Body 11

CHAPTER 2

The Cell and Its Functions 13
Organization of the Cell 13
Cell Structure 14
Functional Systems of the Cell 21
Locomotion of Cells 26

CHAPTER 3

Genetic Control of Protein Synthesis, Cell Function, and Cell Reproduction 31
Cell Nucleus Genes Control Protein Synthesis 31
Transcription—Transfer of Cell Nucleus DNA Code to Cytoplasm RNA Code 33
Translation—Formation of Proteins on the Ribosomes 37
Protein Enzymes Control Synthesis of Other Substances in the Cell 38
Regulation of Gene Function and Biochemical Activity in Cells 39
The DNA–Genetic System Controls Cell Reproduction 41
Cell Differentiation 45
Apoptosis—Programmed Cell Death 46
Cancer 46

UNIT II
Membrane Physiology, Nerve, and Muscle

CHAPTER 4

Transport of Substances Through Cell Membranes 51
The Cell Membrane Is a Lipid Bilayer With Cell Membrane Transport Proteins 51
Diffusion 52
Active Transport of Substances Through Membranes 58

CHAPTER 5

Membrane Potentials and Action Potentials 63
Basic Physics of Membrane Potentials 63
Resting Membrane Potential of Neurons 65
Neuron Action Potential 67
Propagation of the Action Potential 71
Importance of Energy Metabolism for Reestablishing Sodium and Potassium Ionic Gradients After Action Potentials Are Completed 72
Plateau in Some Action Potentials 72
Rhythmicity of Some Excitable Tissues—Repetitive Discharge 73
Special Characteristics of Signal Transmission in Nerve Trunks 74
Excitation—The Process of Eliciting the Action Potential 75

CHAPTER 6

Contraction of Skeletal Muscle 79
Physiological Anatomy of Skeletal Muscle 79
General Mechanism of Muscle Contraction 81
Molecular Mechanisms of Muscle Contraction 82
Energetics of Muscle Contraction 86
Characteristics of Whole Muscle Contraction 87

CHAPTER 7

Excitation of Skeletal Muscle: Neuromuscular Transmission and Excitation-Contraction Coupling **93**

Neuromuscular Junction and Transmission of Impulses From Nerve Endings to Skeletal Muscle Fibers 93

Muscle Action Potential 97

Excitation-Contraction Coupling 97

CHAPTER 8

Excitation and Contraction of Smooth Muscle **101**

Contraction of Smooth Muscle 101

Regulation of Contraction By Calcium Ions 103

Nervous and Hormonal Control of Smooth Muscle Contraction 105

UNIT III

The Heart

CHAPTER 9

Cardiac Muscle; The Heart as a Pump and Function of the Heart Valves **113**

Cardiac Muscle Physiology 113

The Cardiac Cycle 118

Regulation of Heart Pumping 123

CHAPTER 10

Rhythmical Excitation of the Heart **127**

Specialized Excitatory and Conductive System of the Heart 127

Control of Excitation and Conduction in the Heart 131

CHAPTER 11

Fundamentals of Electrocardiography **135**

Waveforms of the Normal Electrocardiogram 135

Flow of Current Around the Heart During the Cardiac Cycle 137

Electrocardiographic Leads 138

CHAPTER 12

Electrocardiographic Interpretation of Cardiac Muscle and Coronary Blood Flow Abnormalities: Vectorial Analysis **143**

Vectorial Analysis of Electrocardiograms 143

Vectorial Analysis of the Normal Electrocardiogram 145

Mean Electrical Axis of the Ventricular QRS and Its Significance 148

Conditions That Cause Abnormal Voltages of the QRS Complex 150

Prolonged and Bizarre Patterns of the QRS Complex 151

Current of Injury on the Electrocardiogram 152

Abnormalities in the T Wave 155

CHAPTER 13

Cardiac Arrhythmias and Their Electrocardiographic Interpretation **159**

Abnormal Sinus Rhythms 159

Heart Block Within the Intracardiac Conduction Pathways 160

Premature Contractions 162

Paroxysmal Tachycardia 164

Ventricular Fibrillation 165

Atrial Fibrillation 168

Atrial Flutter 169

Cardiac Arrest 170

UNIT IV

The Circulation

CHAPTER 14

Overview of the Circulation: Pressure, Flow, and Resistance **173**

Physical Characteristics of the Circulation 173

Basic Principles of Circulatory Function 175

Interrelationships of Pressure, Flow, and Resistance 175

CHAPTER 15

Vascular Distensibility and Functions of the Arterial and Venous Systems **183**

Vascular Distensibility 183

Arterial Pressure Pulsations 184

Veins and Their Functions 188

CHAPTER 16

The Microcirculation and Lymphatic System: Capillary Fluid Exchange, Interstitial Fluid, and Lymph Flow **193**

Structure of the Microcirculation and Capillary System 193

Vasomotion Causes Intermittent Capillary Blood Flow 194

Exchange of Substances Between the Blood and Interstitial Fluid 195

Interstitium and Interstitial Fluid 196

Fluid Filtration Across Capillaries 197

Lymphatic System 201

CHAPTER 17

Local and Humoral Control of Tissue Blood Flow **207**

Local Blood Flow Is Controlled in Response to Tissue Needs 207
Mechanisms of Local Blood Flow Control 207
Humoral Control of the Circulation 216

CHAPTER 18

Nervous Regulation of the Circulation and Rapid Control of Arterial Pressure **219**

Nervous Regulation of the Circulation 219
Special Features of Nervous Control of Arterial Pressure 228

CHAPTER 19

Role of the Kidneys in Long-Term Control of Arterial Pressure and in Hypertension: The Integrated System for Arterial Pressure Regulation **231**

Renal–Body Fluid System for Arterial Pressure Control 231
Role of the Renin-Angiotensin System in Arterial Pressure Control 238
Summary of Integrated Multifaceted Systems for Arterial Pressure Regulation 245

CHAPTER 20

Cardiac Output, Venous Return, and Their Regulation **249**

Normal Values for Cardiac Output at Rest and During Activity 249
Control of Cardiac Output By Venous Return—Frank-Starling Mechanism of the Heart 249
Methods for Measuring Cardiac Output 260

CHAPTER 21

Muscle Blood Flow and Cardiac Output During Exercise; The Coronary Circulation and Ischemic Heart Disease **263**

Blood Flow Regulation in Skeletal Muscle at Rest and During Exercise 263
Coronary Circulation 266

CHAPTER 22

Heart Failure **275**

Circulatory Dynamics in Heart Failure 275
Unilateral Left Heart Failure 279
Low-Output Cardiac Failure—Cardiogenic Shock 279
Edema in Patients With Heart Failure 280
Cardiac Reserve 282
Quantitative Graphic Analysis of Cardiac Failure 282
Heart Failure With Preserved Ejection Fraction 284
High-Output Heart Failure 285

CHAPTER 23

Heart Valves and Heart Sounds; Valvular and Congenital Heart Defects **287**

Heart Sounds 287
Abnormal Circulatory Dynamics in Valvular Heart Disease 291
Abnormal Circulatory Dynamics in Congenital Heart Defects 293
Use of Extracorporeal Circulation During Cardiac Surgery 295
Hypertrophy of the Heart in Valvular and Congenital Heart Disease 295

CHAPTER 24

Circulatory Shock and Its Treatment **297**

Physiological Causes of Shock 297
Hypovolemic Shock Due to Hemorrhage 298
Distributive Shock Is Characterized By Severe Peripheral Vasodilation 303
Obstructive Shock Is Usually Due to Noncardiac Causes of Reduced Cardiac Output 305
Physiology of Treatment in Shock 305
Circulatory Arrest 306

UNIT V

The Body Fluids and Kidneys

CHAPTER 25

Regulation of Body Fluid Compartments: Extracellular and Intracellular Fluids; Edema **309**

Intake and Output of Fluids and Solutes Are Balanced During Long-Term Steady-State Conditions 309
Body Fluid Compartments 310
Constituents of Extracellular and Intracellular Fluids 311
Measurement of Body Fluid Compartment Volumes—Indicator-Dilution Principle 312
Fluid Exchange and Osmotic Equilibrium Between Intracellular and Extracellular Fluid 314
Volume and Osmolality of Extracellular and Intracellular Fluids in Abnormal States 316
Glucose and Other Solutions Administered for Nutritive Purposes 317
Clinical Abnormalities of Fluid Volume Regulation: Hyponatremia and Hypernatremia 318
Edema: Excess Fluid in the Tissues 320
Fluids in Potential Spaces of the Body 324

CHAPTER 26

The Urinary System: Functional Anatomy and Urine Formation By the Kidneys 325
Multiple Functions of the Kidneys 325
Physiological Anatomy of the Kidneys 326
Urine Formation Results From Glomerular Filtration, Tubular Reabsorption, and Tubular Secretion 328
Micturition 331

CHAPTER 27

Glomerular Filtration, Renal Blood Flow, and Their Control 335
Glomerular Filtration—The First Step in Urine Formation 335
Determinants of GFR 337
Renal Blood Flow 340
Physiological Control of GFR and Renal Blood Flow 341
Autoregulation of GFR and Renal Blood Flow 343

CHAPTER 28

Renal Tubular Reabsorption and Secretion 349
Tubular Reabsorption Is Quantitatively Large and Highly Selective 349
Tubular Reabsorption Includes Passive and Active Mechanisms 349
Reabsorption and Secretion Along Different Parts of the Nephron 355
Regulation of Tubular Reabsorption 361
Use of Clearance Methods to Quantify Kidney Function 367

CHAPTER 29

Urine Concentration and Dilution; Regulation of Extracellular Fluid Osmolarity and Sodium Concentration 373
Kidneys Excrete Excess Water By Forming Dilute Urine 373
Kidneys Conserve Water By Excreting Concentrated Urine 374
Countercurrent Multiplier Mechanism 376
Control of Extracellular Fluid Osmolarity and Sodium Concentration 383

CHAPTER 30

Renal Regulation of Potassium, Calcium, Phosphate, and Magnesium; Integration of Renal Mechanisms for Control of Blood Volume and Extracellular Fluid Volume 391
Regulation of Internal Potassium Distribution 391
Regulation of Renal Potassium Excretion 392
Regulation of Renal Calcium Excretion and Extracellular Calcium Ion Concentration 397
Regulation of Renal Phosphate Excretion 400
Regulation of Renal Magnesium Excretion and Extracellular Magnesium Ion Concentration 401
Integration of Renal Mechanisms for Control of Extracellular Fluid 401
Distribution of Extracellular Fluid Between Interstitial Spaces and Vascular System 404
Nervous and Hormonal Factors Increase Effectiveness of Renal–Body Fluid Feedback Control 405
Integrated Responses to Changes in Sodium Intake 407
Conditions That Cause Large Increases in Blood Volume and Extracellular Fluid Volume 408
Conditions That Cause Large Increases in Extracellular Fluid Volume With Normal or Reduced Blood Volume 409

CHAPTER 31

Acid–Base Regulation 411
Hydrogen Ion Concentration Is Precisely Regulated 411
Acids and Bases—Definitions and Meanings 411
Defending Against Changes in H^+ Concentration: Buffers, Lungs, and Kidneys 412
Buffering of H^+ in the Body Fluids 412
Bicarbonate Buffer System 413
Phosphate Buffer System 415
Proteins Are Important Intracellular Buffers 415
Respiratory Regulation of Acid–Base Balance 416
Renal Control of Acid–Base Balance 417
Secretion of H^+ and Reabsorption of HCO_3^- By the Renal Tubules 418
Combination of Excess H^+ With Phosphate and Ammonia Buffers in the Tubule Generates "New" HCO_3^- 420
Quantifying Renal Acid–Base Excretion 422
Regulation of Renal Tubular H^+ Secretion 422
Renal Correction of Acidosis—Increased Excretion of H^+ and Addition of HCO_3^- to the Extracellular Fluid 423
Renal Correction of Alkalosis—Decreased Tubular Secretion of H^+ and Increased Excretion of HCO_3^- 424

CHAPTER 32

Diuretics and Kidney Diseases 429
Diuretics and Their Mechanisms of Action 429
Kidney Diseases 431
Acute Kidney Injury 432
CKD Is Often Associated With Irreversible Loss of Functional Nephrons 434

UNIT VI

Blood Cells, Immunity, and Blood Coagulation

CHAPTER 33

Red Blood Cells, Anemia, and Polycythemia **447**
Red Blood Cells (Erythrocytes) 447
Iron Metabolism 452
Anemias 454
Polycythemia 455

CHAPTER 34

Resistance of the Body to Infection: I. Leukocytes, Granulocytes, the Monocyte-Macrophage System, and Inflammation **457**
Leukocytes (White Blood Cells) 457
Neutrophils and Macrophages Defend Against Infections 459
Monocyte-Macrophage Cell System (Reticuloendothelial System) 460
Inflammation: Role of Neutrophils and Macrophages 462
Eosinophils 464
Basophils 465
Leukopenia 465
Leukemias 465

CHAPTER 35

Resistance of the Body to Infection: II. Immunity and Allergy **467**
Acquired (Adaptive) Immunity 467
Allergy and Hypersensitivity 477
Sex Differences in Innate and Adaptive Immunity 479

CHAPTER 36

Blood Types, Transfusion, and Tissue and Organ Transplantation **481**
Antigenicity Causes Immune Reactions of Blood 481
O-A-B Blood Types 481
Rh Blood Types 483
Transfusion Reactions Resulting From Mismatched Blood Types 484
Transplantation of Tissues and Organs 485

CHAPTER 37

Hemostasis and Blood Coagulation **487**
Hemostasis Events 487
Mechanism of Blood Coagulation 489
Conditions That Cause Excessive Bleeding in Humans 494
Thromboembolic Conditions 496
Anticoagulants for Clinical Use 497
Blood Coagulation Tests 497

UNIT VII

Respiration

CHAPTER 38

Pulmonary Ventilation **501**
Mechanics of Pulmonary Ventilation 501
Pulmonary Volumes and Capacities 504
Alveolar Ventilation 507

CHAPTER 39

Pulmonary Circulation, Pulmonary Edema, and Pleural Fluid **513**
Physiological Anatomy of the Pulmonary Circulatory System 513
Pressures in the Pulmonary Circulatory System 513
Blood Volume of the Lungs 514
Blood Flow Through the Lungs and Its Distribution 514
Effect of Hydrostatic Pressure Gradients in the Lungs on Regional Pulmonary Blood Flow 515
Pulmonary Capillary Dynamics 517
Fluid in the Pleural Cavity 519

CHAPTER 40

Principles of Gas Exchange; Diffusion of Oxygen and Carbon Dioxide Through Respiratory Membranes **521**
Compositions of Alveolar Air and Atmospheric Air Are Different 523
Diffusion of Gases Through the Respiratory Membrane 525

CHAPTER 41

Transport of Oxygen and Carbon Dioxide in Blood and Tissue Fluids **531**
Transport of Oxygen From the Lungs to the Body Tissues 531
Transport of CO_2 in Blood 538
Respiratory Exchange Ratio 540

CHAPTER 42

Regulation of Respiration **541**
Respiratory Center 541
Chemical Control of Respiration 543
Peripheral Chemoreceptor System—Role of Oxygen in Respiratory Control 544
Regulation of Respiration During Exercise 547

CHAPTER 43

Respiratory Insufficiency—Pathophysiology, Diagnosis, Oxygen Therapy **551**
Methods for Studying Respiratory Abnormalities 551

Pathophysiology of Specific Pulmonary Abnormalities 553
Hypoxia and Oxygen Therapy 556
Hypercapnia—Excess Carbon Dioxide in the Body Fluids 558
Respiratory Resuscitation and Mechanical Ventilators 558

UNIT VIII
Aviation, Space, and Deep-Sea Diving Physiology

CHAPTER 44
Aviation, High Altitude, and Space Physiology 563
Effects of Low Oxygen Pressure on the Body 563

CHAPTER 45
Physiology of Deep-Sea Diving and Other Hyperbaric Conditions 571
Effect of High Partial Pressures of Individual Gases on the Body 571
Self-Contained Underwater Breathing Apparatus (SCUBA) Diving 575

UNIT IX
The Nervous System: A. General Principles and Sensory Physiology

CHAPTER 46
Organization of the Nervous System, Basic Functions of Synapses and Neurotransmitters 579
General Design of the Nervous System 579
Major Levels of Central Nervous System Function 581
Comparison of the Nervous System to a Computer 582
Central Nervous System Synapses 582
Special Characteristics of Synaptic Transmission 595

CHAPTER 47
Sensory Receptors and Neuronal Circuits for Processing Information 597
Types of Sensory Receptors and the Stimuli They Detect 597
Transduction of Sensory Stimuli Into Nerve Impulses 598
Signal Intensity Transmission in Nerve Tracts—Spatial and Temporal Summation 602
Transmission and Processing of Signals in Neuronal Pools 603
Instability and Stability of Neuronal Circuits 607

CHAPTER 48
Somatic Sensations: I. General Organization, Tactile and Position Senses 609
Classification of Somatic Senses 609
Detection and Transmission of Tactile Sensations 609
Sensory Pathways for Transmitting Somatic Signals Into the Central Nervous System 611
Transmission in the Dorsal Column–Medial Lemniscal System 611
Transmission of Sensory Signals in the Anterolateral Pathway 619

CHAPTER 49
Somatic Sensations: II. Pain, Headache, and Thermal Sensations 623
Fast Pain and Slow Pain and Their Qualities 623
Pain Receptors (Nociceptors) and Their Stimulation 623
Dual Pathways for Transmission of Pain Signals Into the Central Nervous System 624
Pain Suppression (Analgesia) System in the Brain and Spinal Cord 626
Referred Pain 628
Visceral Pain 628
Thermal Sensations 632

UNIT X
The Nervous System: B. The Special Senses

CHAPTER 50
The Eye: I. Optics of Vision 637
Physical Principles of Optics 637
Optics of the Eye 640
Fluid System of the Eye—Intraocular Fluid 646

CHAPTER 51
The Eye: II. Receptor and Neural Function of the Retina 649
Anatomy and Function of Structural Elements of the Retina 649
Photochemistry of Vision 651
Color Vision 655
Neural Function of the Retina 656

CHAPTER 52
The Eye: III. Central Neurophysiology of Vision 663
Visual Pathways 663
Organization and Function of the Visual Cortex 664
Neuronal Patterns of Stimulation During Analysis of Visual Images 666

Eye Movements and Their Control 667
Autonomic Control of Accommodation and Pupillary Aperture 671

CHAPTER 53
The Sense of Hearing 675
Tympanic Membrane and the Ossicular System 675
Cochlea 676
Central Auditory Mechanisms 681

CHAPTER 54
The Chemical Senses—Taste and Smell 687
Sense of Taste 687
Sense of Smell 691

UNIT XI
The Nervous System: C. Motor and Integrative Neurophysiology

CHAPTER 55
Spinal Cord Motor Functions; The Cord Reflexes 697
Organization of the Spinal Cord for Motor Functions 697
Muscle Sensory Receptors—Muscle Spindles and Golgi Tendon Organs—and Their Roles in Muscle Control 699
Flexor Reflex and the Withdrawal Reflexes 703
Crossed Extensor Reflex 705
Reciprocal Inhibition and Reciprocal Innervation 705
Reflexes of Posture and Locomotion 705

CHAPTER 56
Cortical and Brain Stem Control of Motor Function 709
Motor Cortex and Corticospinal Tract 709
Control of Motor Functions By the Brain Stem 715
Vestibular Sensations and Maintenance of Equilibrium 716

CHAPTER 57
Cerebellum and Basal Ganglia Contributions to Overall Motor Control 723
The Cerebellum and Its Motor Functions 723
The Basal Ganglia and Their Motor Functions 732
Integration of the Many Parts of the Entire Motor Control System 736

CHAPTER 58
Cerebral Cortex, Intellectual Functions of the Brain, Learning, and Memory 739
Physiological Anatomy of the Cerebral Cortex 739
Functions of Specific Cortical Areas 740
The Corpus Callosum and Anterior Commissure Transfer Thoughts, Memories, Training, and Other Information Between the Two Cerebral Hemispheres 746
Thoughts, Consciousness, and Memory 747

CHAPTER 59
The Limbic System and the Hypothalamus—Behavioral and Motivational Mechanisms of the Brain 753
Activating—Driving Systems of the Brain 753
Limbic System 756
The Hypothalamus, a Major Control Headquarters for the Limbic System 757
Specific Functions of Other Parts of the Limbic System 761

CHAPTER 60
States of Brain Activity—Sleep, Brain Waves, Epilepsy, Psychoses, and Dementia 765
Sleep 765

CHAPTER 61
The Autonomic Nervous System and the Adrenal Medulla 777
General Organization of the Autonomic Nervous System 777
Basic Characteristics of Sympathetic and Parasympathetic Function 779
Selective Stimulation of Target Organs By Sympathetic and Parasympathetic Systems or "Mass Discharge" 787

CHAPTER 62
Cerebral Blood Flow, Cerebrospinal Fluid, and Brain Metabolism 791

CHAPTER 1

Functional Organization of the Human Body and Control of the "Internal Environment"

Physiology is a branch of biology that seeks to explain the *function* of living organisms and their parts, including the physical and chemical mechanisms that are responsible for the origin, development, and progression of life. Each type of life, from the simplest virus to the largest tree or the complicated human being, has its own functional characteristics. Therefore, the vast field of physiology can be divided into viral physiology, bacterial physiology, cellular physiology, plant physiology, invertebrate physiology, vertebrate physiology, mammalian physiology, human physiology, and many more subdivisions.

Human Physiology. The science of human physiology attempts to explain the specific characteristics and mechanisms of the human body that make it a living being. The fact that we remain alive is the result of complex control systems. Hunger makes us seek food, and fear makes us seek refuge. Sensations of cold make us look for warmth. Other forces cause us to seek fellowship and to reproduce. The fact that we are sensing, feeling, and knowledgeable beings is part of this automatic sequence of life; these special attributes allow us to exist under widely varying conditions that otherwise would make life impossible.

Human physiology links the basic life sciences with medicine and integrates multiple functions of the cells, tissues, and organs into the functions of the living human being. This integration requires communication and coordination by a vast array of control systems that operate at every level—from the genes that program synthesis of molecules to the complex nervous and hormonal systems that coordinate functions of cells, tissues, and organs throughout the body. Thus, the coordinated functions of the human body are much more than the sum of its parts, and life relies on this total function. Although the main focus of this book is on normal human physiology, we also discuss, to some extent, *pathophysiology*, which is the study of disordered body function and the basis for clinical medicine.

CELLS ARE THE LIVING UNITS OF THE BODY

Each tissue or organ is an aggregate of many different cells held together by intercellular supporting structures.

Each type of cell is specially adapted to perform one or a few particular functions. For example, the red blood cells, numbering about 25 trillion in each person, transport oxygen from the lungs to the tissues. Although the red blood cells are the most abundant cell type in the body, there are also trillions of additional cells of other types that perform functions different from those of the red blood cell. The entire human body contains about 35 to 40 trillion cells.

The many cells of the body often differ markedly from one another but all have certain basic characteristics that are alike. For example, oxygen reacts with carbohydrate, fat, and protein to release the energy required for all cells to function. Furthermore, the general chemical mechanisms for changing nutrients into energy are basically the same in all cells, and all cells deliver products of their chemical reactions into the surrounding fluids.

Almost all cells also have the ability to reproduce additional cells of their own type. Fortunately, when cells of a particular type are destroyed, the remaining cells of this type usually generate new cells until the supply is replenished.

Communities of Microorganisms Living in the Body Outnumber Human Cells. In addition to human cells, trillions of microbes inhabit the body, living on the skin and in the mouth, gut, and nose. The gastrointestinal tract, for example, normally contains a complex, dynamic population of 400 to 1000 species of microorganisms that outnumber our human cells. Communities of microorganisms that inhabit the body, often called *microbiota*, can cause diseases, but most of the time they live in harmony with their human hosts and provide vital functions that are essential for survival of their hosts. Although the importance of gut microbiota for digestion of foodstuffs is widely recognized, additional roles for the body's microbes in nutrition, immunity, and other functions are just beginning to be appreciated and represent an intensive area of biomedical research.

EXTRACELLULAR FLUID—THE "INTERNAL ENVIRONMENT"

About 50% to 70% of the adult human body is fluid, mainly a water solution of ions and other substances. Although

most of this fluid is inside the cells (*intracellular fluid*), about one-third is in the spaces outside the cells (*extracellular fluid*). The extracellular fluid is in constant motion throughout the body. It is transported rapidly in the circulating blood and then mixed between the blood and tissue fluids by diffusion through the capillary walls.

In the extracellular fluid are the ions and nutrients needed by the cells to maintain life. Thus, all cells live in essentially the same environment—the extracellular fluid. For this reason, the extracellular fluid is also called the *internal environment* of the body, or the *milieu intérieur*, a term introduced by the great 19th-century French physiologist Claude Bernard (1813–1878).

Maintenance of the proper concentrations of oxygen, glucose, different ions, amino acids, fatty substances, and other constituents in this internal environment is required for the cells to perform their special functions.

Differences in Extracellular and Intracellular Fluids. The extracellular fluid contains large amounts of sodium, chloride, and bicarbonate ions plus nutrients for the cells, such as oxygen, glucose, fatty acids, and amino acids. It also contains carbon dioxide that is transported from the cells to the lungs to be excreted, plus other cellular waste products that are transported to the kidneys for excretion.

The intracellular fluid contains large amounts of potassium, magnesium, and phosphate ions instead of the sodium and chloride ions found in the extracellular fluid. Special mechanisms for transporting ions through the cell membranes maintain the ion concentration differences between the extracellular and intracellular fluids. These transport processes are discussed in Chapter 4.

HOMEOSTASIS—MAINTENANCE OF A STABLE INTERNAL ENVIRONMENT

In 1929, the American physiologist Walter Cannon (1871–1945) coined the term *homeostasis* to describe the *maintenance of stable conditions in the internal environment*. Homeostasis is a dynamic, rather than static, process that is continually adjusting the body's functions to maintain internal stability despite the challenges of daily life in health, as well as in disease.

Homeostasis occurs at all levels of organization in the body—from the molecular and genetic levels to the cells, tissues, organs, and the whole body. For example, the process of deoxyribonucleic acid (DNA) replication, which is necessary for production of new cells, requires assembly of around 3 to 6 billion nucleotides in correct order to form 20,000 to 25,000 genes that control formation of approximately 100,000 proteins. Each type of cell has different mechanisms that control its gene expression and protein formation. The human body has around 25 to 30 trillion cells, not including another 25 to 30 trillion microorganisms living in the body, usually in symbiosis with the body's cells. Each cell of the body, in turn, has many separate control mechanisms that regulate its function. The cells that make up a tissue communicate with each other via chemical signals and in some cases form organs that have their own internal controls. The organs communicate with each other via the *nervous system* and by releasing different substances, including *hormones* and *extracellular vesicles*; these vesicles are bound by lipids, secreted by cells into the extracellular space, and contain cargo that can alter the function of other cells and organs. How is all of this beautiful complexity that sustains life coordinated? This overall coordination is called homeostasis.

A fundamental principle of homeostasis is that *the function of the whole body is much more than the sum of its parts*. All of the organs and tissues of the body perform their functions, which together help maintain the stable conditions necessary for life. For example, the lungs provide oxygen to the extracellular fluid to replenish the oxygen used by the cells, the kidneys maintain stable ion concentrations, and the gastrointestinal system provides nutrients while eliminating waste from the body.

Body Fluid Constituents Are Normally Regulated Within a Tolerable Range of Values. The various ions, nutrients, waste products, and other constituents of the body are normally regulated within a tolerable range of values, rather than at fixed values. For some of the body's constituents, this range is extremely small. Variations in the blood hydrogen ion concentration, for example, are normally less than 5 *nanomoles/L* (0.000000005 moles/L). The blood sodium concentration is also tightly regulated, normally varying only a few *millimoles* per liter, even with large changes in sodium intake, but these variations of sodium concentration are at least 1 million times greater than for hydrogen ions.

Powerful control systems exist for maintaining concentrations of sodium and hydrogen ions, as well as for most of the other ions, nutrients, and substances in the body at levels that permit the cells, tissues, and organs to perform their normal functions, despite wide environmental variations and challenges from injury and diseases.

Much of this text is concerned with how each organ or tissue contributes to homeostasis. Normal body functions require integrated actions of cells, tissues, organs, and multiple nervous, hormonal, and local control systems that together contribute to homeostasis and good health.

Homeostatic Compensations in Diseases. *Disease* is often considered to be a state of disrupted homeostasis. However, even with diseases, homeostatic mechanisms continue to operate and maintain vital functions through multiple compensations. In some cases, these compensations may lead to major deviations of the body's functions from the normal range, making it difficult to distinguish the primary cause of the disease from the compensatory responses. For example, diseases that impair the kidneys'

ability to excrete salt and water may lead to high blood pressure, which initially helps return excretion to normal so that a balance between intake and renal excretion can be maintained. This balance is needed to maintain life, but, over long periods of time, the high blood pressure can damage various organs, including the kidneys, causing even greater increases in blood pressure and more renal damage. Thus, homeostatic compensations that ensue after injury, disease, or major environmental challenges to the body may represent trade-offs that are necessary to maintain life but that, in the long term, contribute to additional abnormalities of body function. The discipline of *pathophysiology* seeks to explain how the various physiological processes are altered in diseases or injury.

This chapter outlines the different functional systems of the body and their contributions to homeostasis. We then briefly discuss the basic theory of the body's control systems that allow the functional systems to operate in support of one another.

CIRCULATION OF THE BLOOD PROVIDES MIXING AND TRANSPORT OF EXTRACELLULAR FLUID

Extracellular fluid is transported through the body in two stages. The first stage is movement of blood through the body in the blood vessels. The second is movement of fluid between the blood capillaries and the *intercellular spaces* between the tissue cells.

Fig. 1.1 shows the overall circulation of blood. All the blood in the circulation traverses the entire circuit an average of once each minute when the body is at rest and as many as six times each minute when a person is extremely active.

As blood passes through blood capillaries, continual exchange of extracellular fluid occurs between the plasma portion of the blood and the interstitial fluid that fills the intercellular spaces. This process is shown in **Fig. 1.2**. The capillary walls are permeable to most molecules in the blood plasma, with the exception of plasma proteins, which are too large to pass through capillaries readily. Therefore, large amounts of fluid and its dissolved constituents *diffuse* back and forth between the blood and the tissue spaces, as shown by the arrows in **Fig. 1.2**.

This process of diffusion is caused by kinetic motion of the molecules in the plasma and the interstitial fluid. That is, the fluid and dissolved molecules are continually moving and bouncing in all directions in the plasma and fluid in the intercellular spaces, as well as through capillary pores. Few cells are located more than 50 micrometers from a capillary, which ensures diffusion of almost any substance from the capillary to the cell within a few seconds. Thus, the extracellular fluid everywhere in the body—including plasma and interstitial fluid—is continually being mixed, thereby maintaining homogeneity of extracellular fluid throughout the body.

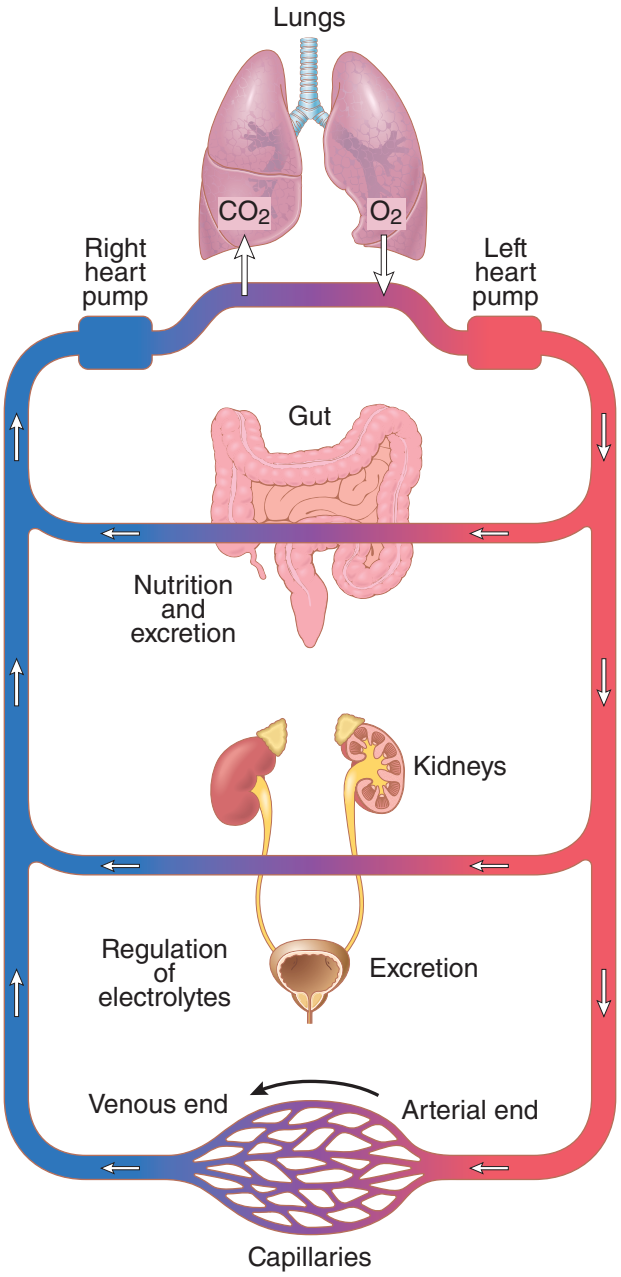

Figure 1.1 General organization of the circulatory system.

ORIGIN OF NUTRIENTS IN THE EXTRACELLULAR FLUID

Respiratory System. **Fig. 1.1** shows that each time blood passes through the body, it also flows through the lungs, picking up *oxygen* in alveoli and acquiring oxygen needed by cells. The membrane between the alveoli and the lumen of the pulmonary capillaries, the *alveolar membrane*, is only 0.4 to 2.0 micrometers thick, and oxygen rapidly diffuses by molecular motion through this membrane into the blood.

Gastrointestinal Tract. A large portion of the blood pumped by the heart also passes through the walls of the gastrointestinal tract. Here different dissolved nutrients,

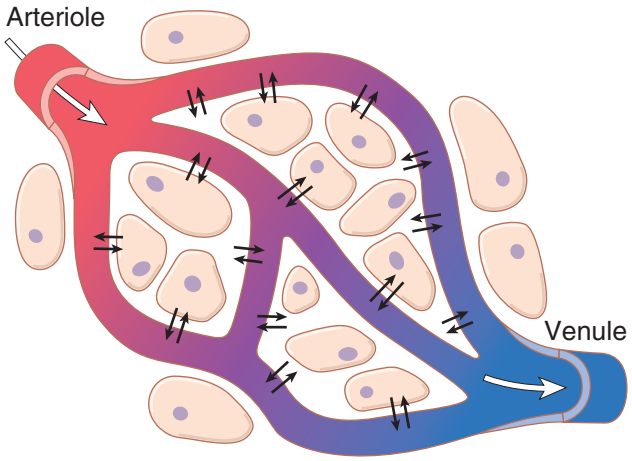

Figure 1.2 Diffusion of fluid and dissolved constituents through the capillary walls and interstitial spaces.

including *carbohydrates*, *fatty acids*, and *amino acids*, are absorbed from ingested food into the extracellular fluid of the blood.

Liver and Other Organs That Perform Primarily Metabolic Functions. Not all substances absorbed from the gastrointestinal tract can be used in their absorbed form by the cells. The liver changes the chemical compositions of many of these substances to more usable forms, and other tissues of the body—fat cells, gastrointestinal mucosa, kidneys, and endocrine glands—help modify the absorbed substances or store them until they are needed. The liver also eliminates certain waste products produced in the body and toxic substances that are ingested.

Musculoskeletal System. How does the musculoskeletal system contribute to homeostasis? Were it not for the muscles, the body could not move to obtain the foods required for nutrition. The musculoskeletal system also provides motility that, along with its other homeostatic mechanisms, protects the entire body against adverse surroundings.

REMOVAL OF METABOLIC END PRODUCTS

The Lungs Remove Carbon Dioxide. At the same time that blood picks up oxygen in the lungs, *carbon dioxide* is released from the blood into lung alveoli; the respiratory movement of air into and out of the lungs carries carbon dioxide to the atmosphere. Carbon dioxide is the most abundant of all the metabolism products.

Kidneys. Passage of blood through the kidneys removes most of the other substances from the plasma besides carbon dioxide that are not needed by cells. These substances include different end products of cellular metabolism, such as urea and uric acid, as well as excesses of ions and water from the food that accumulate in the extracellular fluid.

The kidneys perform these functions first by filtering large quantities of plasma through the glomerular capillaries into the tubules and then reabsorbing into the blood substances needed by the body, such as glucose, amino acids, appropriate amounts of water, and many of the ions. Most of the other substances that are not needed by the body, especially metabolic waste products such as urea and creatinine, are reabsorbed poorly and pass through the renal tubules into the urine.

Gastrointestinal Tract. Undigested material that enters the gastrointestinal tract and some waste products of metabolism are eliminated in the feces.

Liver. Among the many functions of the liver is detoxification or removal of ingested drugs and chemicals. The liver secretes many of these wastes into the bile to be eventually eliminated in the feces.

REGULATION OF BODY FUNCTIONS

Nervous System. The nervous system is composed of three major parts—the *sensory input portion*, the *central nervous system* (or *integrative portion*), and the *motor output portion*. Sensory receptors detect the state of the body and its surroundings. For example, receptors in the skin alert us whenever an object touches the skin. The eyes are sensory organs that give us a visual image of the surrounding area. The ears permit us to detect sounds. The central nervous system is composed of the brain and spinal cord. The brain stores information, generates thoughts, creates ambition, and determines reactions that the body performs in response to the sensations. Appropriate signals are then transmitted through the motor output portion of the nervous system to carry out one's desires.

An important segment of the nervous system is called the *autonomic system*. It operates at a subconscious level and controls many functions of internal organs, including the level of pumping activity by the heart, movements of the gastrointestinal tract, and secretion by many of the body's glands.

Hormone Systems. Located in the body are *endocrine glands*, organs and tissues that secrete chemical substances called *hormones*. Hormones are transported in the extracellular fluid to other parts of the body to help regulate cellular function. For example, *thyroid hormone* increases the rates of most chemical reactions in all cells, thus helping set the tempo of bodily activity. *Insulin* controls glucose metabolism, *adrenocortical hormones* control sodium and potassium ions and protein metabolism, and *parathyroid hormone* controls bone calcium and phosphate. Thus, the hormones provide a regulatory system that complements the nervous system. The nervous system controls many muscular and secretory activities of the body, whereas the hormonal system regulates many metabolic functions. The nervous and hormonal systems normally work together in a coordinated manner to control essentially all the organ systems of the body.

PROTECTIVE SYSTEMS OF THE BODY

Immune System. The immune system includes white blood cells, tissue cells derived from white blood cells, the thymus, lymph nodes, and lymph vessels that protect the body from pathogens such as bacteria, viruses, parasites, and fungi. The immune system provides a mechanism for the body to carry out the following: (1) distinguish its own cells from harmful foreign cells and substances; and (2) destroy the invader by *phagocytosis* or by producing *sensitized lymphocytes* or specialized proteins (e.g., *antibodies*) that destroy or neutralize the invader.

Integumentary System. The skin and its various appendages (including the hair, nails, glands, and other structures) cover, cushion, and protect the deeper tissues and organs of the body and generally provide a boundary between the body's internal environment and the outside world. The integumentary system is also important for temperature regulation and excretion of wastes, and it provides a sensory interface between the body and the external environment. The skin generally comprises about 12% to 15% of body weight.

REPRODUCTION

Although reproduction may not seem to be a homeostatic function, it helps maintain homeostasis by generating new beings to take the place of those that are dying. This may sound like a permissive usage of the term *homeostasis*, but it illustrates that in the final analysis, essentially all body structures are organized to help maintain the automaticity and continuity of life.

CONTROL SYSTEMS OF THE BODY

The human body has thousands of control systems. Some of the most intricate of these systems are genetic control systems that operate in all cells to help regulate intracellular and extracellular functions. This subject is discussed in Chapter 3.

Many other control systems operate *within the organs* to regulate functions of the individual parts of the organs; others operate throughout the entire body *to control the communication and interrelationships among the organs*. For example, the respiratory system, operating in association with the nervous system, regulates carbon dioxide concentration in the extracellular fluid. The liver and pancreas control glucose concentration in the extracellular fluid, and the kidneys regulate concentrations of hydrogen, sodium, potassium, phosphate, and other ions in the extracellular fluid.

EXAMPLES OF CONTROL MECHANISMS

Regulation of Oxygen and Carbon Dioxide Concentrations in the Extracellular Fluid. Because oxygen is required for chemical reactions in cells, the body has a special control mechanism to maintain an almost exact and constant oxygen concentration in the extracellular fluid. This mechanism depends principally on the chemical characteristics of *hemoglobin*, which is present in red blood cells. Hemoglobin combines with oxygen as blood passes through the lungs. Then, as blood passes through the tissue capillaries, hemoglobin, because of its own strong chemical affinity for oxygen, does not release oxygen into the tissue fluid if too much oxygen is already there. However, if oxygen concentration in the tissue fluid is too low, sufficient oxygen is released to reestablish an adequate concentration. Thus, regulation of oxygen concentration in the tissues relies to a great extent on the chemical characteristics of hemoglobin. This regulation is called the *oxygen-buffering function of hemoglobin*.

Carbon dioxide concentration in the extracellular fluid is regulated in a much different way. Carbon dioxide is a major end product of oxidative reactions in cells. If all the carbon dioxide formed in the cells continued to accumulate in the tissue fluids, all energy-giving reactions of the cells would cease. Fortunately, a higher than normal carbon dioxide concentration in the blood *excites the respiratory center*, causing a person to breathe rapidly and deeply. This deep rapid breathing increases expiration of carbon dioxide and removes excess carbon dioxide from the blood and tissue fluids. This process continues until the concentration returns to normal.

Regulation of Arterial Blood Pressure. Several systems contribute to arterial blood pressure regulation. One of these, the *baroreceptor system*, is an excellent example of a rapidly acting control mechanism (**Fig. 1.3**). In the walls of the bifurcation region of the carotid arteries in the neck and in the arch of the aorta in the thorax, are many nerve receptors called *baroreceptors* that are stimulated

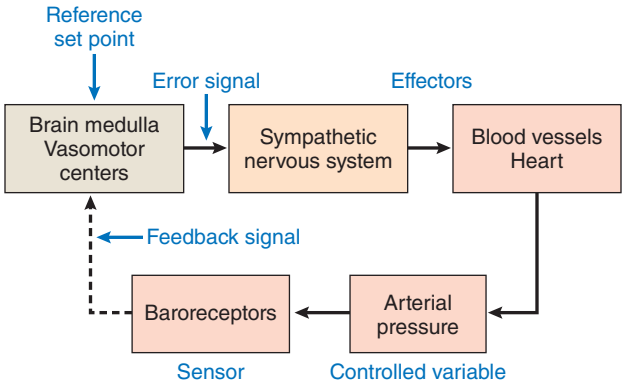

Figure 1.3 Negative feedback control of arterial pressure by the arterial baroreceptors. Signals from the sensor (baroreceptors) are sent to the medulla of the brain, where they are compared with a reference set point. When arterial pressure increases above normal, this abnormal pressure increases nerve impulses from the baroreceptors to the medulla of the brain, where the input signals are compared with the set point, generating an error signal that leads to decreased sympathetic nervous system activity. Decreased sympathetic activity causes dilation of blood vessels and reduced pumping activity of the heart, which return arterial pressure toward normal.

by stretch of the arterial wall. When arterial pressure rises too high, the baroreceptors send increased nerve impulses to the medulla of the brain. Here, these impulses inhibit the *vasomotor center*, which in turn decreases the number of impulses transmitted from the vasomotor center through the sympathetic nervous system to the heart and blood vessels. Reduced sympathetic nervous activity diminishes pumping activity of the heart and dilates peripheral blood vessels. Both these effects decrease the arterial pressure, moving it back toward normal.

Conversely, a decrease in arterial pressure below normal relaxes the stretch receptors, allowing the vasomotor center to become more active than usual, thereby causing vasoconstriction and increased heart pumping. The initial decrease in arterial pressure thus initiates negative feedback mechanisms that raise arterial pressure back toward normal.

Normal Ranges and Physical Characteristics of Important Extracellular Fluid Constituents

Table 1.1 lists some important constituents of extracellular fluid, along with their normal values, normal ranges, and maximum limits without causing death. Note the narrowness of the normal range for most of these constituents. Values outside these ranges are often caused by illness, injury, or major environmental challenges.

Most important are the limits beyond which abnormalities can cause death. For example, an increase in the body temperature of only 11°F (7°C) above normal can lead to a vicious cycle of increasing cellular metabolism that destroys the cells. Note also the narrow range for acid–base balance in the body, with a normal pH value of 7.4 yet lethal values only about 0.5 higher or lower than the normal value. Whenever the potassium ion concentration decreases to less than one-third normal, paralysis may result from the inability of the nerves to carry signals. Alternatively, if potassium ion concentration increases to two or more times normal, the heart muscle is likely to be severely depressed. Also, when the calcium ion concentration falls below about one-half normal, a person is likely to experience tetanic contraction of muscles throughout the body because of the spontaneous generation of excess nerve impulses in peripheral nerves. When the glucose concentration falls below one-half normal, a person frequently exhibits extreme mental irritability and sometimes even has convulsions.

These examples give one an appreciation for the necessity of the vast numbers of control systems that keep the body operating in health. In the absence of any one of these controls, serious body malfunction or death can result.

CHARACTERISTICS OF CONTROL SYSTEMS

The aforementioned examples of homeostatic control mechanisms are only a few of the many thousands in the body, all of which have some common characteristics, as explained in this section.

Many Control Systems Operate By Negative Feedback

Most control systems of the body act by *negative feedback*, which can be explained by reviewing some of the homeostatic control systems mentioned previously. In the regulation of carbon dioxide concentration, a high concentration of carbon dioxide in the extracellular fluid increases pulmonary ventilation. This, in turn, decreases extracellular fluid carbon dioxide concentration because the lungs expire greater amounts of carbon dioxide from the body. Thus, the high concentration of carbon dioxide initiates events that decrease the concentration toward normal, which is *negative* to the initiating stimulus. Conversely, a carbon dioxide concentration that falls too low results in feedback to increase the concentration. This response is also negative to the initiating stimulus.

In the arterial pressure–regulating mechanisms, a high pressure causes a series of reactions that promote compensatory reductions in pressure, whereas a low pressure causes a series of reactions that promote increased pressure. In both cases, these effects are negative with respect to the initiating stimulus.

Table 1.1 Important Constituents and Physical Characteristics of Extracellular Fluid

Constituent	Normal Value	Normal Range	Approximate Short-Term Nonlethal Limit	Unit
Oxygen (venous)	40	25–40	10–1000	mm Hg
Carbon dioxide (venous)	45	41–51	5–80	mm Hg
Sodium ion	142	135–145	115–175	mmol/L
Potassium ion	4.2	3.5–5.3	1.5–9.0	mmol/L
Calcium ion	1.2	1.0–1.4	0.5–2.0	mmol/L
Chloride ion	106	98–108	70–130	mmol/L
Bicarbonate ion	24	22–29	8–45	mmol/L
Glucose	90	70–115	20–1500	mg/dL
Body temperature	98.4 (37.0)	98–98.8 (37.0)	65–110 (18.3–43.3)	°F (°C)
Acid–base (venous)	7.4	7.3–7.5	6.9–8.0	pH

Therefore, in general, if some factor becomes excessive or deficient, a control system initiates *negative feedback*, which consists of a series of changes that return the factor toward a certain mean value, thus maintaining homeostasis.

Gain of a Control System. The degree of effectiveness with which a control system maintains constant conditions is determined by the *gain* of negative feedback. For example, let us assume that a large volume of blood is transfused into a person whose baroreceptor pressure control system is not functioning, and the arterial pressure rises from the normal level of 100 mm Hg up to 175 mm Hg. Then, let us assume that the same volume of blood is injected into the same person when the baroreceptor system is functioning, and this time the pressure increases by only 25 mm Hg. Thus, the feedback control system has caused a "correction" of −50 mm Hg, from 175 mm Hg to 125 mm Hg. There remains an increase in pressure of +25 mm Hg, called the "error," which means that the control system is not 100% effective in preventing change. The gain of the system is then calculated by using the following formula:

$$\text{Gain} = \frac{\text{Correction}}{\text{Error}}$$

Thus, in the baroreceptor system example, the correction is −50 mm Hg, and the error persisting is +25 mm Hg. Therefore, the gain of the person's baroreceptor system for control of arterial pressure is −50 divided by +25, or −2. Thus, the baroreceptor system corrects about two-thirds of the initial disturbance and increases or decreases in arterial pressure are only one-third as much as would occur if this control system were not present.

The gains of some other physiological control systems are much greater than that of the baroreceptor system. For example, the gain of the system controlling internal body temperature when a person is exposed to moderately cold weather is about −33. Therefore, one can see that the temperature control system is much more effective than the baroreceptor pressure control system.

Feed-Forward and Adaptive Control Systems Anticipate Changes

Later in this text, when we study the nervous system, we shall see that this system contains great numbers of interconnected control mechanisms. Some are simple feedback systems similar to those already discussed. Many are not. For example, some movements of the body occur so rapidly that there is not enough time for nerve signals to travel from the peripheral parts of the body all the way to the brain and then back to the periphery again to control the movement. Therefore, the brain uses a mechanism called *feed-forward control* to cause required muscle contractions. Sensory nerve signals from the moving parts apprise the brain about whether the movement is performed correctly. If not, the brain corrects the feed-forward signals that it sends to the muscles the *next* time the movement is required. Then, if still further correction is necessary, this process will be performed again for subsequent movements. This process is called *adaptive control*. Adaptive control, in a sense, is delayed negative feedback.

Positive Feedback May Cause Vicious Cycles and Death

Why do most control systems of the body operate by negative feedback or feed-forward rather than by positive feedback? If one considers the nature of positive feedback, it is obvious that positive feedback leads to instability rather than stability and, in some cases, can cause death.

Fig. 1.4 shows an example in which death can ensue from positive feedback. This figure depicts the pumping effectiveness of the heart, showing the heart of a healthy human pumping about 5 liters of blood per minute. If the person suddenly bleeds a total of 2 liters, the amount of blood in the body is decreased to such a low level that not enough blood is available for the heart to pump effectively. As a result, the arterial pressure falls, and the flow of blood to the heart muscle through the coronary vessels diminishes. This scenario results in weakening of the heart, further diminished pumping, further decrease in coronary blood flow, and still more weakness of the heart; the cycle repeats itself again and again until death occurs. Note that each cycle in the feedback results in further weakening of the heart. In other words, the initiating stimulus causes more of the same, which is *positive feedback*.

Positive feedback is sometimes known as a "vicious cycle," but a mild degree of positive feedback can be overcome by the negative feedback control mechanisms of the body, and the vicious cycle then fails to develop. For example, if the person in the aforementioned example bleeds only 1 liter instead of 2 liters, the normal negative feedback mechanisms for controlling cardiac output and arterial pressure can counterbalance the positive feedback, and the person can recover, as shown by the dashed curve of **Fig. 1.4**.

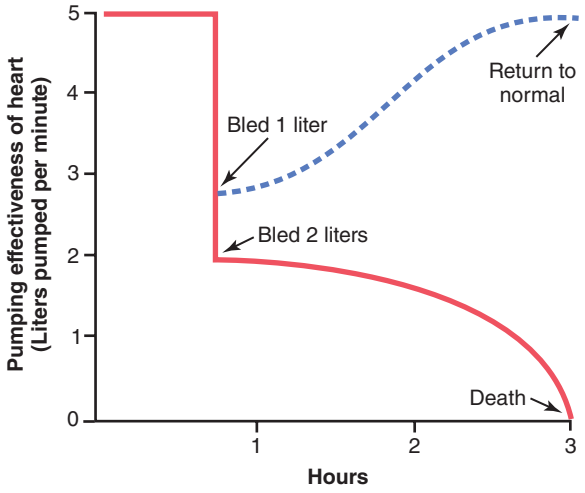

Figure 1.4 Recovery of heart pumping caused by negative feedback after 1 liter of blood is removed from the circulation. Death is caused by positive feedback when 2 or more liters of blood are removed.

Positive Feedback Can Sometimes Be Useful. The body sometimes uses positive feedback to its advantage. Blood clotting is an example of a valuable use of positive feedback. When a blood vessel is ruptured, and a clot begins to form, multiple enzymes called *clotting factors* are activated within the clot. Some of these enzymes act on other inactivated enzymes of the immediately adjacent blood, thus causing more blood clotting. This process continues until the hole in the vessel is plugged and bleeding stops. On occasion, this mechanism can get out of hand and cause the formation of unwanted clots. In fact, this is what initiates most acute heart attacks, which can be caused by a clot beginning on the inside surface of an atherosclerotic plaque in a coronary artery and then growing until the artery is blocked.

Childbirth is another situation in which positive feedback is valuable. When uterine contractions become strong enough for the baby's head to begin pushing through the cervix, the stretched cervix sends signals through the uterine muscle back to the body of the uterus, causing even more powerful contractions. Thus, the uterine contractions stretch the cervix, and cervical stretch causes stronger contractions. When this process becomes powerful enough, the baby is born. If they are not powerful enough, the contractions usually die out, and a few days pass before they begin again.

Another important use of positive feedback is for the generation of nerve signals. Stimulation of the membrane of a nerve fiber causes slight leakage of sodium ions through sodium channels in the nerve membrane to the fiber's interior. The sodium ions entering the fiber then change the membrane potential, which, in turn, causes more opening of channels, more change of potential, still more opening of channels, and so forth. Thus, a slight leak becomes an explosion of sodium entering the interior of the nerve fiber, which creates the nerve action potential. This action potential, in turn, causes electrical current to flow along the outside and inside of the fiber and initiates additional action potentials. This process continues until the nerve signal goes all the way to the end of the fiber.

In each case in which positive feedback is useful, the positive feedback is part of an overall negative feedback process. For example, in the case of blood clotting, the positive feedback clotting process is a negative feedback process for the maintenance of normal blood volume. Also, the positive feedback that causes nerve signals allows the nerves to participate in thousands of negative feedback nervous control systems.

Thus, one can see how complex the feedback control systems of the body can be. A person's life depends on all of them. Therefore, much of this text is devoted to discussing these life-giving mechanisms, as well as some of the positive feedbacks that can lead to progressive diseases or even death.

PHYSIOLOGICAL VARIABILITY

Although some physiological variables, such as plasma concentrations of potassium, calcium, and hydrogen ions, are tightly regulated, others, such as body weight and adiposity, show wide variation among different individuals and even in the same individual at different stages of life. Blood pressure, cardiac pumping, metabolic rate, nervous system activity, hormones, and other physiological variables change throughout the day as we move about and engage in normal daily activities. Some variables follow a *circadian rhythm*, a regular recurring cycle of changes every 24 hours, as discussed in Chapter 59. Therefore, when we discuss "normal" values, it is with the understanding that many of the body's control systems are constantly reacting to perturbations and that variability may exist even in the same individual, depending on the time of day, and among different individuals, depending on body weight and height, diet, age, sex, environment, genetics, and other factors.

For simplicity, discussion of physiological functions often focuses on the "average" 70-kg lean young male. However, the American male no longer weighs an average of 70 kg; he now weighs over 88 kg, and the average American female weighs over 76 kg, more than the average male in the 1960s. Body weight has also increased substantially in most other industrialized countries during the past 40 to 50 years.

Age-related and ethnic or racial differences in physiology also have important influences on body composition, physiological control systems, and pathophysiology of diseases. For example, total body water is about 60% to 65% of body weight in lean young males and about 50% to 55% in lean young females, although there is considerable variation among individuals. As a person grows and ages, this percentage gradually decreases, partly because aging is usually associated with declining skeletal muscle mass and increasing fat mass. Aging may also cause a decline in the function and effectiveness of some organs and physiological control systems.

These sources of physiological variability—sex differences, aging, and ethnic differences—are complex but important considerations when discussing normal physiology and the pathophysiology of diseases.

SEX DIFFERENCES IN PHYSIOLOGY AND PATHOPHYSIOLOGY

The term *sexual dimorphism* has traditionally been used to describe two distinct and nonoverlapping traits of males and females from the same species. In humans, sexually dimorphic anatomical features include, for example, the gonads (e.g., testes and ovaries) and the internal and external genitals. However, beyond obvious differences related to reproduction and some physical traits, important sex differences exist for a broad range of physiological

characteristics and diseases that may change over the lifespan. For example, females have a lower incidence of hypertension (high blood pressure) and cardiovascular diseases before menopause, after which the incidences of these disorders may surpass those found in males. Some diseases (e.g., hemophilia) are much more common in males, whereas others (e.g., systemic lupus erythematosus) primarily affect females.

Although much of our knowledge of physiology has been derived from studies conducted on male subjects, there is increasing emphasis on the role of sex differences in normal physiology and the pathophysiology of diseases. In fact, consideration of sex as a key biological variable has become a fundamental principle in designing basic research and clinical studies.

Some differences in the physiology of males and females are related to the levels of sex hormones discussed in Chapters 81 and 82. A common misconception, however, is that male-female differences are caused entirely by variations in the sex hormones. Although the hormonal milieu has important effect on many physiological functions, sex differences also occur as a result of cell-specific effects of the sex chromosomes (X and Y) on gene expression. For example, there are genes on the Y chromosome that have no counterpart on X chromosomes and some genes on the X chromosome may be expressed at higher levels in female than in male subjects. Another misconception is that sex hormones exert their effects only following puberty. However, exposure early in life to different levels of sex steroids can program variations in gene expression and responses to various physiological signals in adults.

In addition to sex differences, defined by biological factors, *gender* differences related to sociocultural factors may also contribute to differences in male and female physiology and susceptibility to disease. Although we consider some of the sex differences in male and female physiology in subsequent chapters, generalizations are often made about normal values and fundamental principles of physiological regulation based on available data and to avoid creating an excessively lengthy compendium. Recognizing the importance of sex differences, however, is essential for understanding normal physiology and diseases in males and females.

SUMMARY—AUTOMATICITY OF THE BODY

The main purpose of this chapter has been to discuss briefly the overall organization of the body and the means by which different parts of the body operate in harmony. To summarize, the body is actually a *social order of about 35 to 40 trillion cells* organized into different functional structures, some of which are called *organs*. Each functional structure contributes its share to maintaining homeostasis in the extracellular fluid, which is called the *internal environment*. As long as normal conditions are maintained in this internal environment, the body's cells continue to live and function properly. Each cell benefits from homeostasis and, in turn, each cell contributes toward the maintenance of homeostasis. This reciprocal interplay provides continuous automaticity of the body until one or more functional systems lose their ability to contribute their share of function. When this happens, all the cells of the body suffer. Extreme dysfunction leads to death; moderate dysfunction leads to sickness.

CHAPTER 2

The Cell and Its Functions

Each of the trillions of human cells in the body is a living structure that can survive for months or years, provided its surrounding fluids contain appropriate nutrients and other constituents. Cells are the building blocks of the body, providing structure for the body's tissues and organs, ingesting nutrients and converting them to energy, and performing specialized functions. Cells also contain the body's hereditary code, which controls the substances synthesized by the cells and permits them to make copies of themselves.

ORGANIZATION OF THE CELL

A schematic drawing of a typical cell, as seen by the light microscope, is shown in **Fig. 2.1**. Its two major parts are the *nucleus* and the *cytoplasm*. The nucleus is separated from the cytoplasm by a *nuclear membrane*, and the cytoplasm is separated from the surrounding fluids by a *cell membrane*, also called the *plasma membrane*.

The different substances that make up the cell are collectively called *protoplasm*. Protoplasm is composed mainly of five basic substances—water, electrolytes, proteins, lipids, and carbohydrates.

Water. Most cells, except for fat cells, are composed mainly of water in a concentration of 70% to 85%. Many cellular chemicals are dissolved in the water. Others are suspended in the water as solid particulates. Chemical reactions take place among the dissolved chemicals or at the surfaces of the suspended particles or membranes.

Ions. Some of the important ions in the cell include *potassium, magnesium, phosphate, sulfate, bicarbonate*, and smaller quantities of *sodium, chloride*, and *calcium*. These ions are all discussed in Chapter 4, which considers the interrelations between the intracellular and extracellular fluids.

The ions provide inorganic chemicals for cellular reactions and are necessary for the operation of some cellular control mechanisms. For example, ions acting at the cell membrane are required for transmission of electrochemical impulses in nerve and muscle fibers.

Proteins. After water, the most abundant substances in most cells are proteins, which normally constitute 10% to 20% of the cell mass. These proteins can be divided into two main types, *structural proteins* and *functional proteins*.

Structural proteins are present in the cell mainly in the form of long filaments that are polymers of many individual protein molecules. A prominent use of such intracellular filaments is to form *microtubules*, which provide the cytoskeletons of cellular organelles such as cilia, nerve axons, the mitotic spindles of cells undergoing mitosis, and a tangled mass of thin filamentous tubules that hold parts of the cytoplasm and nucleoplasm together in their respective compartments. Fibrillar proteins are found outside the cell, especially in the collagen and elastin fibers of connective tissue, and elsewhere, such as in blood vessel walls, tendons, and ligaments.

The *functional proteins* are usually composed of combinations of a few molecules in tubular-globular form. These proteins are mainly the *enzymes* of the cell and, in contrast to the fibrillar proteins, are often mobile in the cell fluid. Also, many of them adhere to membranous structures inside the cell and catalyze specific intracellular chemical reactions. For example, a series of protein enzymes catalyze the chemical reactions that split glucose into its component parts and then combine these with oxygen to form carbon dioxide and water while simultaneously providing energy for cellular function.

Lipids. Lipids are several types of substances grouped together because of their common property of being soluble in fat solvents. Especially important lipids are *phospholipids* and *cholesterol*, which together constitute only

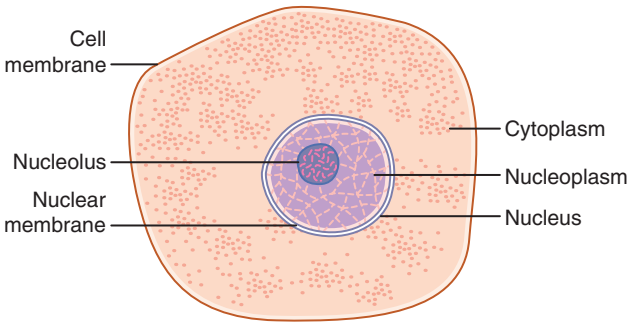

Figure 2.1 Illustration of cell structures visible with a light microscope.

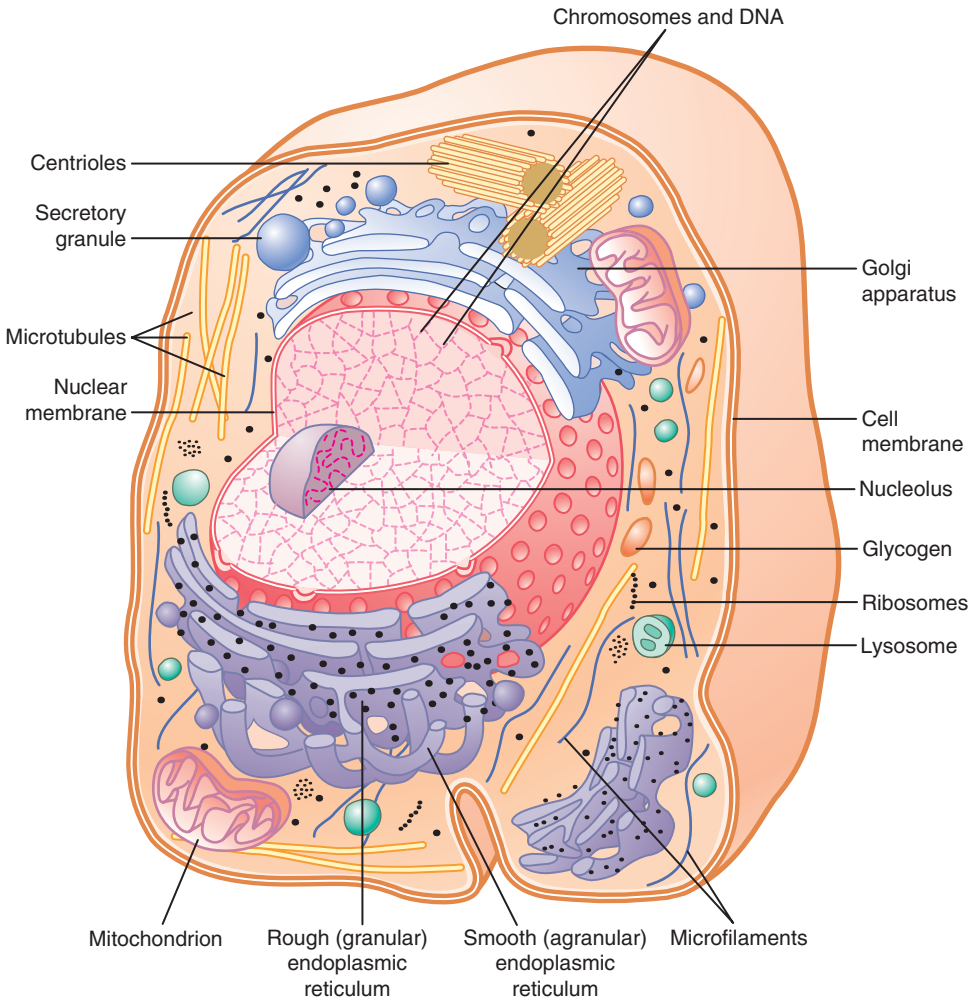

Figure 2.2 Reconstruction of a typical cell, showing the internal organelles in the cytoplasm and nucleus.

about 2% of the total cell mass. Phospholipids and cholesterol are mainly insoluble in water and therefore are used to form the cell membrane and intracellular membrane barriers that separate the different cell compartments.

In addition to phospholipids and cholesterol, some cells contain large quantities of *triglycerides*, also called *neutral fats*. In *fat cells (adipocytes)*, triglycerides often account for as much as 95% of the cell mass. The fat stored in these cells represents the body's main storehouse of energy-giving nutrients that can later be used to provide energy wherever it is needed in the body.

Carbohydrates. Carbohydrates play a major role in cell nutrition and, as parts of glycoprotein molecules, have structural functions. Most human cells do not maintain large stores of carbohydrates; the amount usually averages only about 1% of their total mass but increases to as much as 3% in muscle cells and, occasionally, to 6% in liver cells. However, carbohydrate in the form of dissolved glucose is always present in the surrounding extracellular fluid so that it is readily available to the cell. Also, a small amount of carbohydrate is stored in cells as *glycogen*, an insoluble polymer of glucose that can be depolymerized and used rapidly to supply the cell's energy needs.

CELL STRUCTURE

The cell contains highly organized physical structures called *intracellular organelles*, which are critical for cell function. For example, without one of the organelles, the *mitochondria*, more than 95% of the cell's energy release from nutrients would cease immediately. Some of the most important organelles and other structures of the cell are shown in **Fig. 2.2**.

MEMBRANOUS STRUCTURES OF THE CELL

Most organelles of the cell are covered by membranes composed primarily of lipids and proteins. These membranes include the *cell membrane* surrounding the entire cell, *nuclear membrane, membrane of the endoplasmic reticulum (ER)*, and *membranes of the mitochondria, lysosomes, peroxisomes*, and *Golgi apparatus*.

The lipids in membranes provide a barrier that impedes movement of water and water-soluble substances from one cell compartment to another because water is not soluble in lipids. However, protein molecules often penetrate all the way through membranes, thus providing specialized pathways, often organized into *pores*, for passage

of specific substances through membranes. Also, many other membrane proteins are *enzymes*, which catalyze a multitude of different chemical reactions, discussed here and in subsequent chapters.

The Cell Membrane Is a Lipid Bilayer Inserted With Proteins. The cell membrane (also called the *plasma membrane*) envelops the cell and is a thin, pliable, elastic structure only 7.5 to 10 nanometers thick. It is composed almost entirely of proteins and lipids. The approximate composition is 55% proteins, 25% phospholipids, 13% cholesterol, 4% other lipids, and 3% carbohydrates.

Fig. 2.3 shows the structure of the cell membrane. Its basic structure is a *lipid bilayer*, which is a thin, double-layered film of lipids—each layer only one molecule thick—that is continuous over the entire cell surface. Interspersed in this lipid film are large globular proteins.

The basic lipid bilayer is composed of three main types of lipids—*phospholipids, sphingolipids*, and *cholesterol*. Phospholipids are the most abundant cell membrane lipids. The phosphate end of each phospholipid molecule is *hydrophilic* and soluble in water. The other end is the fatty acid portion and is *hydrophobic* and soluble only in fats.

Because the hydrophobic portions of the phospholipid molecules are repelled by water but are mutually attracted to one another, they have a natural tendency to attach to one another in the middle of the membrane, as shown in **Fig. 2.3**. The hydrophilic phosphate portions then constitute the two surfaces of the complete cell membrane, in contact with *intracellular* water on the inside of the membrane and *extracellular* water on the outside surface.

The lipid layer in the middle of the membrane is impermeable to the usual water-soluble substances, such as ions, glucose, and urea. Conversely, fat-soluble substances, such as oxygen, carbon dioxide, and alcohol, can penetrate this portion of the membrane with ease.

Sphingolipids, derived from the amino alcohol *sphingosine*, also have hydrophobic and hydrophilic groups and are present in small amounts in the cell membranes, especially nerve cells. Complex sphingolipids in cell membranes serve several functions, including protection from harmful environmental factors, signal transmission, and adhesion sites for extracellular proteins.

Cholesterol molecules in membranes are also lipids because their steroid nuclei are highly fat-soluble. These molecules, in a sense, are dissolved in the bilayer of the membrane. They mainly help determine the degree of permeability (or impermeability) of the bilayer to water-soluble constituents of body fluids. Cholesterol controls much of the fluidity of the membrane as well.

Integral and Peripheral Cell Membrane Proteins. **Fig. 2.3** also shows globular masses floating in the lipid bilayer. These membrane proteins are mainly *glycoproteins*. There are two types of cell membrane proteins, *integral proteins*, which protrude all the way through the membrane, and *peripheral proteins*, which are attached to an integral protein or only to one surface of the membrane and do not penetrate all the way through.

Many of the integral proteins provide structural *channels* (or *pores*) through which water molecules and water-soluble substances, especially ions, can diffuse between

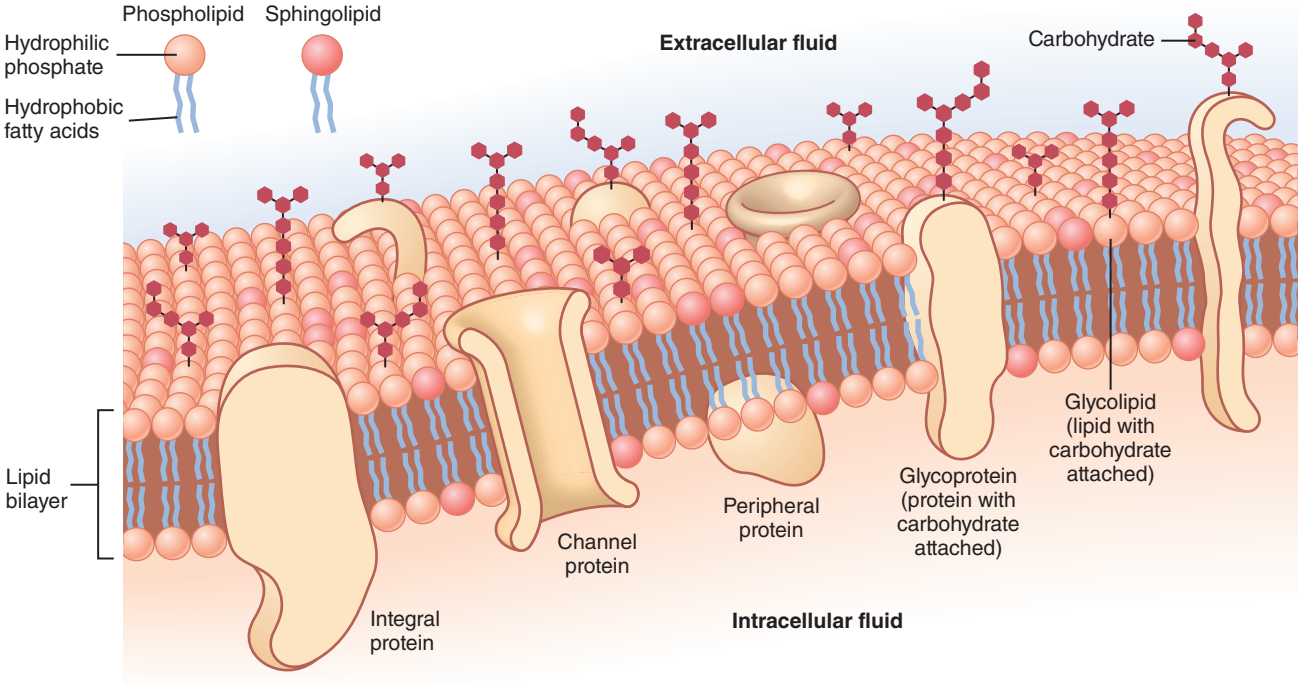

Figure 2.3 Structure of the cell membrane showing that it is composed of a bilayer of phospholipid molecules and large numbers of protein molecules protruding through the layer (integral proteins) or attached to the surfaces of the membrane (peripheral proteins). Carbohydrate moieties are attached to some of the protein and lipid molecules of the membrane.

extracellular and intracellular fluids. These protein channels also have selective properties that allow preferential diffusion of some substances over others.

Other integral proteins act as *carrier proteins* for transporting substances that otherwise could not penetrate the lipid bilayer. Sometimes, these carrier proteins even transport substances in the direction opposite to their electrochemical gradients for diffusion, which is called *active transport*. Still others act as *enzymes*.

Integral membrane proteins can also serve as *receptors* for water-soluble chemicals, such as peptide hormones, that do not easily penetrate the cell membrane. Interaction of cell membrane receptors with specific *ligands* that bind to the receptor causes conformational changes in the receptor protein. This process, in turn, enzymatically activates the intracellular part of the protein or induces interactions between the receptor and proteins in the cytoplasm that act as *second messengers*, relaying the signal from the extracellular part of the receptor to the interior of the cell. In this way, integral proteins spanning the cell membrane provide a means of conveying information about the environment to the cell interior.

Peripheral protein molecules are often attached to integral proteins. These peripheral proteins function almost entirely as enzymes or as controllers of transport of substances through cell membrane *pores*.

Membrane Carbohydrates—The Cell "Glycocalyx." Membrane carbohydrates occur almost invariably in combination with proteins or lipids in the form of *glycoproteins* or *glycolipids*. In fact, most of the integral proteins are glycoproteins, and about one-tenth of the membrane lipid molecules are glycolipids. The *glyco-* portions of these molecules almost invariably protrude to the outside of the cell, dangling outward from the cell surface. Many other carbohydrate compounds, called *proteoglycans*—which are mainly carbohydrates bound to small protein cores—are loosely attached to the outer surface of the cell as well. Thus, the entire outside surface of the cell often has a loose carbohydrate coat called the *glycocalyx*.

The carbohydrate moieties attached to the outer surface of the cell have several important functions:

1. Many of them have a negative electrical charge, which gives most cells an overall negative surface charge that repels other negatively charged objects.
2. The glycocalyx of some cells attaches to the glycocalyx of other cells, thus attaching cells to one another.
3. Many of the carbohydrates act as *receptors* for binding hormones, such as insulin. When bound, this combination activates attached internal proteins that in turn activate a cascade of intracellular enzymes.
4. Some carbohydrate moieties enter into immune reactions, as discussed in Chapter 35.

CYTOPLASM AND ITS ORGANELLES

The cytoplasm is filled with minute and large dispersed particles and organelles. The jelly-like fluid portion of the cytoplasm in which the particles are dispersed is called *cytosol* and contains dissolved proteins, electrolytes, glucose, and other substances.

Dispersed in the cytoplasm are neutral fat globules, glycogen granules, ribosomes, secretory vesicles, and five especially important organelles—the *ER*, the *Golgi apparatus, mitochondria, lysosomes*, and *peroxisomes*.

Endoplasmic Reticulum

Fig. 2.2 shows the *ER*, a network of tubular structures called *cisternae* and flat vesicular structures in the cytoplasm. This organelle helps process molecules made by the cell and transports them for their specific uses inside or outside the cell. The tubules and vesicles interconnect. Also, their walls are constructed of lipid bilayer membranes that contain large amounts of proteins, similar to the cell membrane. The total surface area of this structure in some cells—the liver cells, for example—can be as much as 30 to 40 times the cell membrane area.

The detailed structure of a small portion of ER is shown in **Fig. 2.4**. The space inside the tubules and vesicles, usually referred to as the *cisternal space*, is filled with *endoplasmic matrix*, a watery medium that is different from fluid in the cytosol outside the ER. The space inside the ER is connected with the space between the two membrane surfaces of the nuclear membrane, providing a pipeline between the nucleus and the cytoplasm.

Substances formed in some parts of the cell enter the space of the ER and are then directed to other parts of the cell. Also, the vast surface area of the ER and the multiple

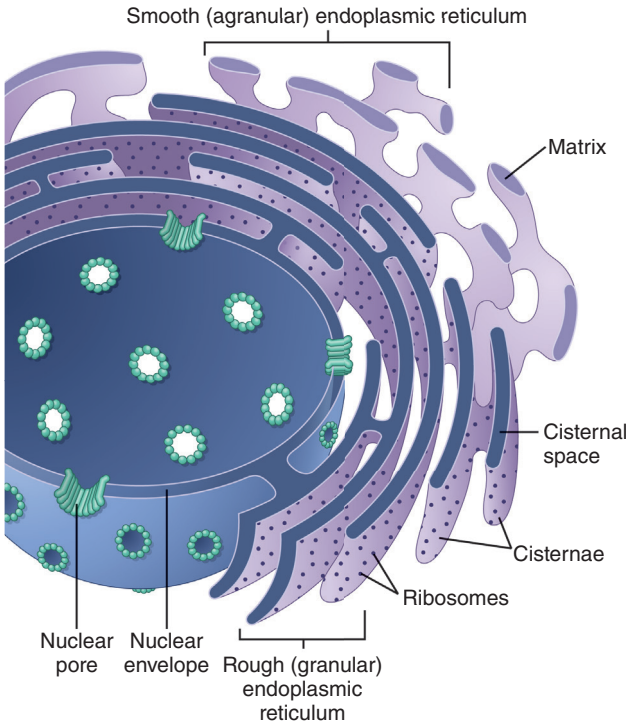

Figure 2.4 Structure of the endoplasmic reticulum and its close association with the nuclear membrane.

enzyme systems attached to its membranes provide the mechanisms for a major share of the cell's metabolic functions.

Ribosomes and the Rough (Granular) Endoplasmic Reticulum. Attached to the outer surfaces of many parts of the ER are large numbers of minute granular particles called *ribosomes*. Where these particles are present, the reticulum is called the *rough (granular) ER*. The ribosomes are composed of a mixture of RNA and proteins; they function to synthesize new protein molecules in the cell, as discussed later in this chapter and in Chapter 3.

As shown in **Fig. 2.4**, the rough ER is directly continuous with the nuclear membrane. This close association enables the ER and the nucleus to efficiently exchange information. For example, if ER function is impaired and proteins that are not completely processed begin to accumulate within the organelle, the ER sends a signal to the nucleus, which then slows ribosomal translation via a multistep process. This gives the ER additional time to catch up on its processing of proteins and helps maintain cellular health.

Smooth (Agranular) Endoplasmic Reticulum. Part of the ER has no attached ribosomes. This part is called the *smooth*, or *agranular, ER*, which is less extensive than the rough ER. The smooth ER functions for the synthesis of lipid substances, detoxification of drugs and poisons, and other processes of the cells promoted by intrareticular enzymes.

Golgi Apparatus

The Golgi apparatus, shown in **Fig. 2.5**, is closely related to the ER. It has membranes similar to those of the smooth ER. The Golgi apparatus is usually composed of four or more stacked layers of thin, flat, enclosed vesicles lying near one side of the nucleus. This apparatus is prominent in secretory cells, where it is located on the side of the cell from which secretory substances are extruded.

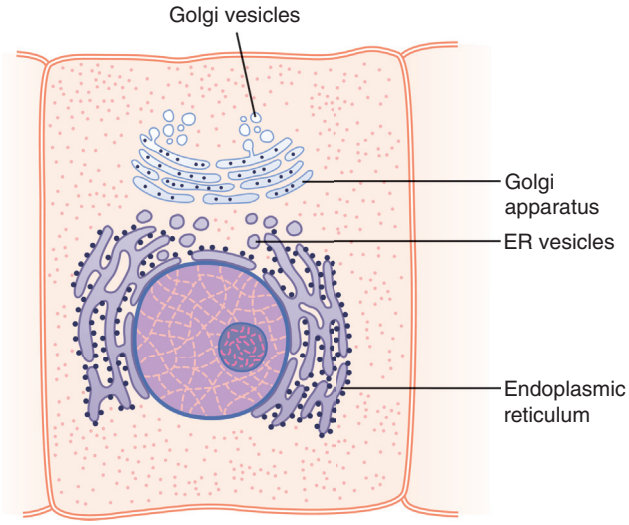

Figure 2.5 A typical Golgi apparatus and its relationship to the endoplasmic reticulum (ER) and the nucleus.

The Golgi apparatus functions in association with the ER. As shown in **Fig. 2.5**, small *transport vesicles* (also called *ER vesicles*) continually pinch off from the ER and shortly thereafter fuse with the Golgi apparatus. In this way, substances entrapped in ER vesicles are transported from the ER to the Golgi apparatus, which prepares them for export outside of the cell or for transport to other locations in the cell. Some of these substances processed in the Golgi apparatus are used to form lysosomes, secretory vesicles, and other cytoplasmic components (discussed later in this chapter).

Lysosomes

Lysosomes, shown in **Fig. 2.2** and **Fig. 2.6**, are vesicular organelles that form by budding off from the membrane of the Golgi apparatus; they then disperse throughout the cytoplasm. The lysosomes provide an *intracellular digestive system* that allows the cell to digest the following: (1) damaged cellular structures; (2) food particles that have been ingested by the cell; and (3) unwanted matter such as bacteria and viruses.

Lysosomes are found in all cells but are more numerous in disease-fighting cells, such as white blood cells, that must digest greater amounts of material from bacteria and viruses. Lysosomes are usually 250 to 750 nanometers in diameter. They are surrounded by typical lipid bilayer membranes and are filled with large numbers of small granules, 5 to 8 nanometers in diameter, which are protein aggregates of as many as 40 different *hydrolase (digestive) enzymes*. A hydrolytic enzyme can split an organic compound into two or more parts by combining hydrogen from a water molecule with one part of the compound and combining the hydroxyl portion of the water molecule with the other part of the compound. For example, protein is hydrolyzed to form amino acids, glycogen is hydrolyzed to form glucose, and lipids are hydrolyzed to form fatty acids and glycerol.

Hydrolytic enzymes are highly concentrated in lysosomes. Ordinarily, the membrane surrounding the lysosome prevents the enclosed hydrolytic enzymes from coming into contact with other substances in the cell and therefore prevents their digestive actions. The cell is also protected from exposure to the lysosome's hydrolytic enzymes by their dependency on an acidic environment for activity. The lysosomal matrix, with a pH of about 4.8, is favorable for enzymatic activity, but the cytosol's neutral pH renders most of the digestive enzymes inactive. However, some conditions of the cell break the membranes of lysosomes, allowing release of the digestive enzymes. These enzymes then split the organic substances with which they come in contact into small, highly diffusible substances such as amino acids and glucose. Some of the specific functions of lysosomes are discussed later in this chapter.

Lysosome enzyme disorders that impair cellular digestion can cause several human diseases. For example, *Tay-Sachs disease* is a rare genetic disorder caused by mutation

of the gene for a lysosomal enzyme (*hexosaminidase A*) that breaks down complex lipids called *gangliosides* in the brain and nerve cells. Excessive accumulation of these lipids damages the nervous system, causing cognitive deficits, impaired motor skills, and often premature death. In the infantile form of Tay-Sachs disease, characterized by almost complete lack of hexosaminidase A enzyme activity, symptoms usually start when a child is 3 to 6 months old, and the condition may be fatal by around 3 to 5 years of age. When there is some residual enzyme activity, symptoms of the disease develop later in life.

Peroxisomes

Peroxisomes (**Fig. 2.6**) are physically similar to lysosomes, but are different in two important ways. First, they are formed mainly by self-replication, or perhaps also by budding off from the smooth ER rather than from the Golgi apparatus. Peroxisomes do not have their own internal DNA for self-replication and must import proteins from the surrounding cytosol to make copies of themselves. Second, they contain *oxidases* rather than hydrolases. Several of the oxidases combine oxygen with hydrogen ions derived from different intracellular chemicals to form hydrogen peroxide (H_2O_2). Hydrogen peroxide is a highly oxidizing substance and is used in association with *catalase*, another oxidase enzyme present in large quantities in peroxisomes, to oxidize many substances that might otherwise be poisonous to the cell. For example, about half the alcohol that a person drinks is detoxified into acetaldehyde by the peroxisomes of the liver cells in this manner. A major function of peroxisomes is to catabolize long-chain fatty acids.

Approximately one in every 20,000 people has some type of a peroxisomal disorder caused by molecular defects of a single peroxisomal enzyme or that impair peroxisome development and cause defects of several proteins. For example, *Zellweger syndrome* is associated with a decreased number of cell peroxisomes and leads to severe disorders of the nervous system and metabolism. Zellweger syndrome is present at birth, has no effective treatment, and is usually fatal in the first year of life.

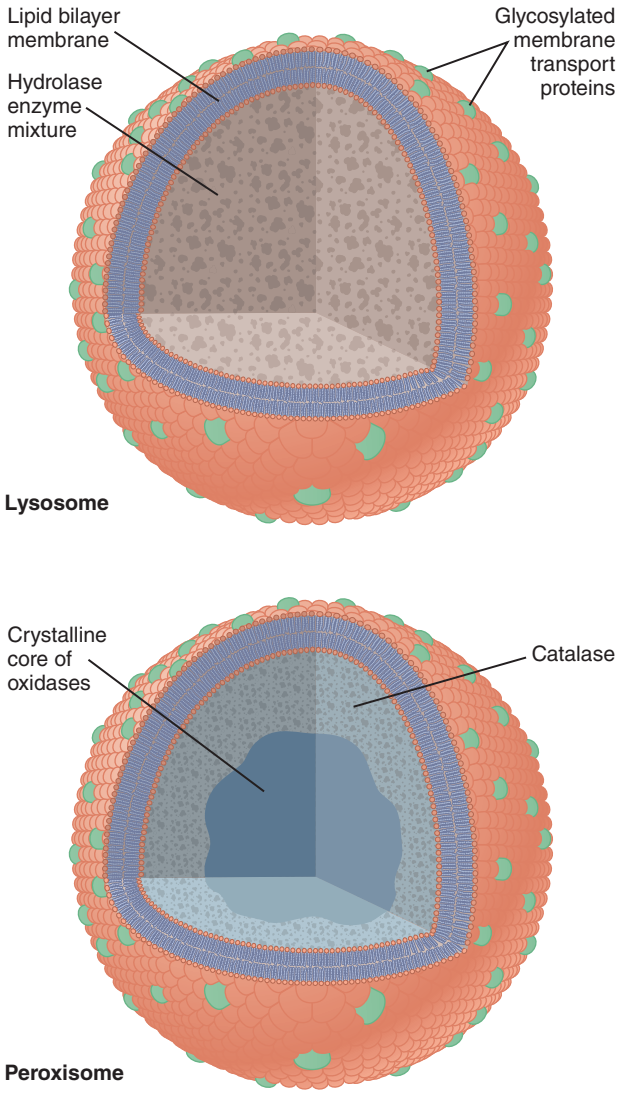

Figure 2.6 Structure of a lysosome and a perioxisome.

Secretory Vesicles

One of the important functions of many cells is secretion of special chemical substances. Almost all such secretory substances are formed by the ER–Golgi apparatus system and are then released from the Golgi apparatus into the cytoplasm in the form of storage vesicles called *secretory vesicles* or *secretory granules*. **Fig. 2.7** shows typical secretory vesicles inside pancreatic acinar cells; these vesicles store protein proenzymes (enzymes that are not yet activated). The proenzymes are secreted later through the outer cell membrane into the pancreatic duct and then into the duodenum, where they become activated and perform digestive functions on the food in the intestinal tract.

Mitochondria

The mitochondria, shown in **Fig. 2.2** and **Fig. 2.8**, are the *powerhouses* of the cell. Without them, cells would be unable to extract enough energy from the nutrients, and essentially all cellular functions would cease.

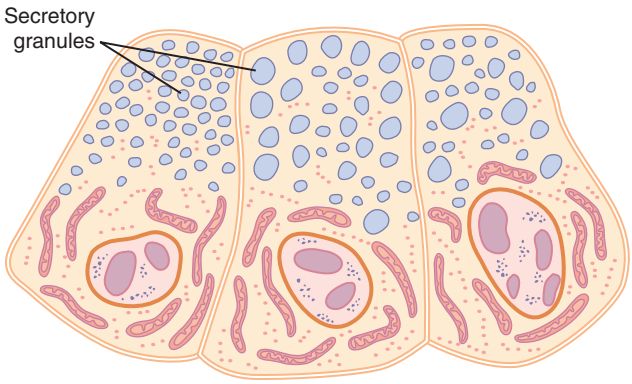

Figure 2.7 Secretory granules (secretory vesicles) in acinar cells of the pancreas.

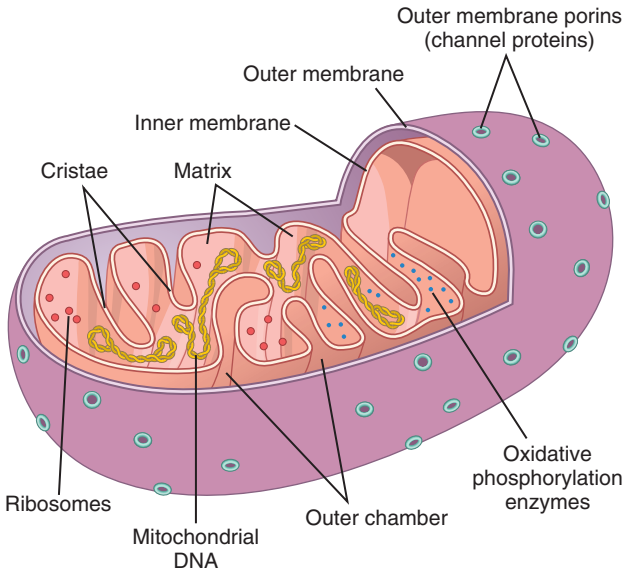

Figure 2.8 Structure of a mitochondrion.

Mitochondria are present in all areas of each cell's cytoplasm, but the total number per cell varies from less than 100 up to several thousand, depending on the cell's energy requirements. Cardiac muscle cells (cardiomyocytes), for example, use large amounts of energy and have far more mitochondria than fat cells (adipocytes), which use much less energy. Furthermore, mitochondria are concentrated in portions of the cell responsible for most of its energy metabolism. Mitochondria are also variable in size and shape. Some mitochondria are only a few hundred nanometers in diameter and are globular in shape, whereas others are elongated and are as large as 1 micrometer in diameter and 10 micrometers long.

The basic structure of a mitochondrion, shown in **Fig. 2.8**, is composed mainly of two lipid bilayer-protein membranes, an *outer membrane* and an *inner membrane*. The outer membrane contains channel proteins (*porins*) that regulate the flow of ions and metabolites across the membrane. The inner membrane has many infoldings that form shelves or tubules called *cristae* onto which oxidative enzymes are attached. The cristae provide a large surface area for chemical reactions to occur. In addition, the inner cavity of the mitochondrion is filled with a *matrix* that contains large quantities of dissolved enzymes necessary for extracting energy from nutrients. These enzymes operate in association with oxidative enzymes on the cristae to cause oxidation of nutrients, thereby forming carbon dioxide and water and, at the same time, releasing energy. The liberated energy is used to synthesize a high-energy substance called *adenosine triphosphate* (ATP). ATP is then transported out of the mitochondrion and diffuses throughout the cell to release its own energy wherever it is needed for performing cellular functions. The chemical details of ATP formation by the mitochondrion are provided in Chapter 68, but some basic functions of ATP in the cell are introduced later in this chapter.

Mitochondria are self-replicative, which means that one mitochondrion can form a second one, a third one, and so on whenever the cell needs increased amounts of ATP. Indeed, the mitochondria contain DNA. In Chapter 3, we will see that DNA is the basic constituent of the nucleus that controls replication of the cell. The DNA of the mitochondrion plays a similar role, controlling replication of the mitochondrion. Mitochondrial DNA is localized to the matrix, which also contains enzymes and ribosomes for protein synthesis. Cells that are faced with increased energy demands—for example, in skeletal muscles subjected to chronic exercise training—may increase the density of mitochondria to supply the additional energy required.

Mitochondrial DNA (mtDNA) contains 37 genes that are essential for mitochondrial function and is primarily inherited from the mother, although some evidence suggests that in rare instances mtDNA may also be inherited from the father. Mitochondria of sperm are usually carried in the tail, which drops off when the sperm attaches to the egg during fertilization. Thus, the only mtDNA the new organism usually receives is from its mother's egg. This means that mtDNA, unlike nuclear DNA which comes from both parents, does not get reordered every generation.

Mutations of mtDNA can occur, leading to inherited mitochondrial disorders that impair energy production. In diseases caused by mtDNA mutations, normal and mutant mtDNA molecules typically coexist in cells, a condition termed *heteroplasmy*. The severity of mitochondrial diseases caused by genetic changes in mtDNA is partly determined by the amount of mutant mtDNA in the cells, which, in turn, is dictated by the number of copies of mutant mtDNA in the mother's fertilized egg. However, mitochondrial diseases can also be caused by mutations of approximately 1300 nuclear genes that encode proteins that regulate mitochondrial function. There is considerable heterogeneity of mitochondrial diseases, with onset occurring from early childhood to adulthood, depending on the specific cause.

Cell Cytoskeleton—Filament and Tubular Structures

The cell cytoskeleton is a network of fibrillar proteins organized into filaments or tubules. These originate as precursor proteins synthesized by ribosomes in the cytoplasm. The precursor molecules then polymerize to form *filaments* (**Fig. 2.9**). As an example, large numbers of actin *microfilaments* frequently occur in the outer zone of the cytoplasm, called the *ectoplasm*, to form an elastic support for the cell membrane. Also, in muscle cells, actin and myosin filaments are organized into a special contractile machine that is the basis for muscle contraction, as discussed in Chapter 6.

Intermediate filaments are generally strong ropelike filaments that often work together with microtubules, providing strength and support for the fragile tubulin

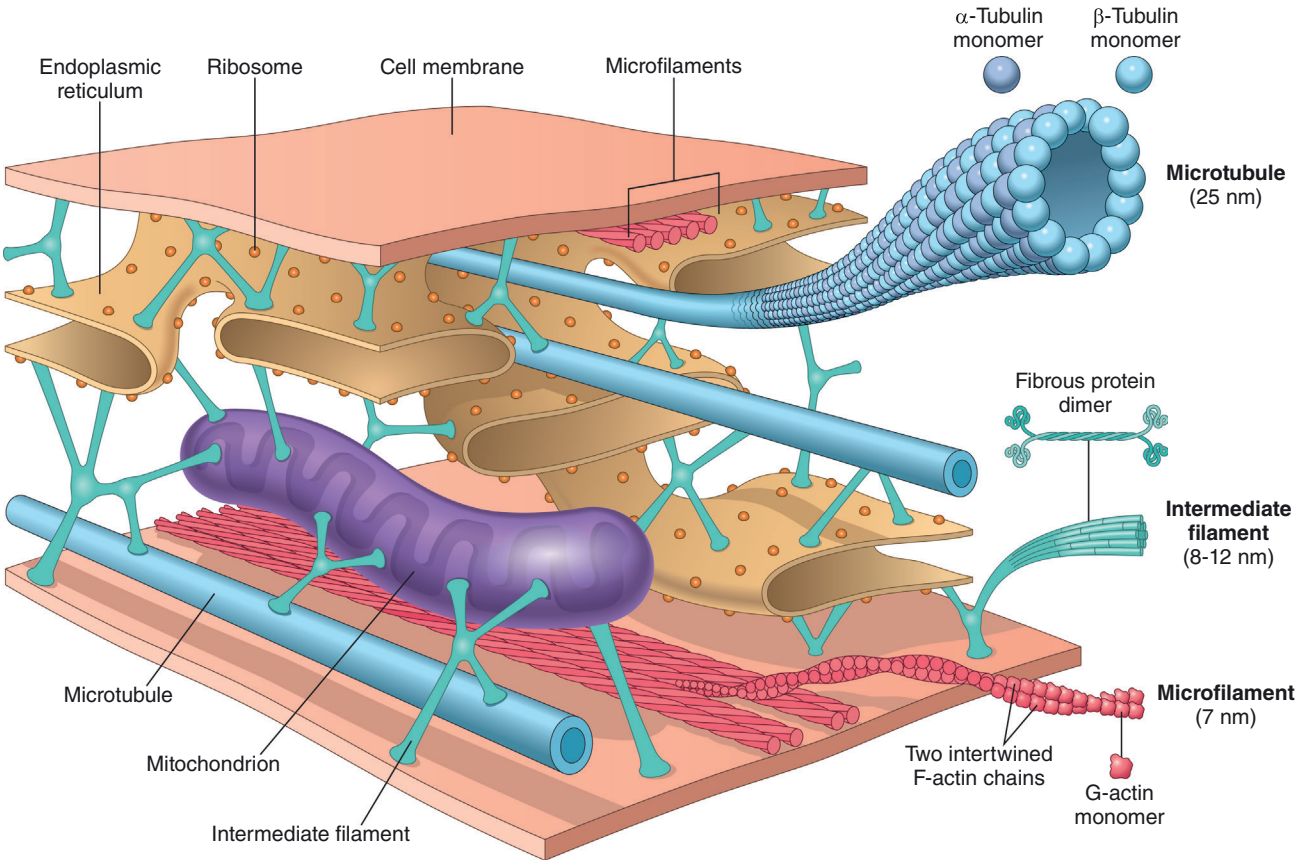

Figure 2.9 Cell cytoskeleton composed of protein fibers called microfilaments, intermediate filaments, and microtubules.

structures. They are called *intermediate* because their average diameter is between that of narrower actin microfilaments and wider myosin filaments found in muscle cells. Their functions are mainly mechanical, and they are less dynamic than actin microfilaments or microtubules. All cells have intermediate filaments, although the protein subunits of these structures vary, depending on the cell type. Specific intermediate filaments found in various cells include *desmin filaments* in muscle cells, *neurofilaments* in neurons, and *keratins* in epithelial cells.

A special type of stiff filament composed of polymerized *tubulin* molecules is used in all cells to construct strong tubular structures, the *microtubules*. **Fig. 2.9** shows typical microtubules of a cell.

Another example of microtubules is the tubular skeletal structure in the center of each cilium that radiates upward from the cell cytoplasm to the tip of the cilium. This structure is discussed later in the chapter (see **Fig. 2.18**). Also, both the *centrioles* and *mitotic spindles* of cells undergoing mitosis are composed of stiff microtubules.

A major function of microtubules is to act as a *cytoskeleton*, providing rigid physical structures for certain parts of cells. The cell cytoskeleton not only determines cell shape but also participates in cell division, allows cells to move, and provides a tracklike system that directs movement of organelles in the cells. Microtubules serve as the conveyor belts for the intracellular transport of vesicles, granules, and organelles such as mitochondria.

Nucleus

The nucleus is the control center of the cell and sends messages to the cell to grow and mature, replicate, or die. Briefly, the nucleus contains large quantities of DNA, which comprise the *genes*. The genes determine the characteristics of the cell's proteins, including structural proteins and the intracellular enzymes that control cytoplasmic and nuclear activities.

The genes also control and promote cell reproduction. The genes first reproduce to create two identical sets of genes; then the cell splits by a special process called *mitosis* to form two daughter cells, each of which receives one of the two sets of DNA genes. All these activities of the nucleus are discussed in Chapter 3.

Fig. 2.10 illustrates the appearance of the nucleus during *interphase* (the period between mitoses), revealing darkly staining *chromatin material* throughout the nucleoplasm. During mitosis, the chromatin material organizes in the form of highly structured *chromosomes*, which can be easily identified using the light microscope, as illustrated in Chapter 3.

Nuclear Membrane. The *nuclear membrane*, also called the *nuclear envelope*, is actually two separate bilayer membranes, one inside the other. The outer membrane is continuous with the ER of the cell cytoplasm, and the space between the two nuclear membranes is also continuous with the space inside the ER, as shown in **Figs. 2.4 and 2.10**.

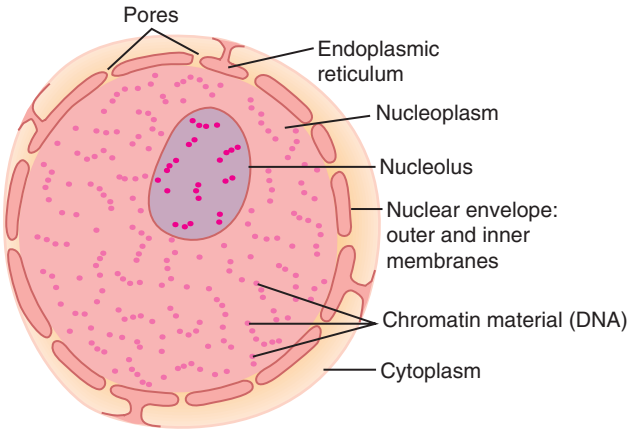

Figure 2.10 Structure of the nucleus.

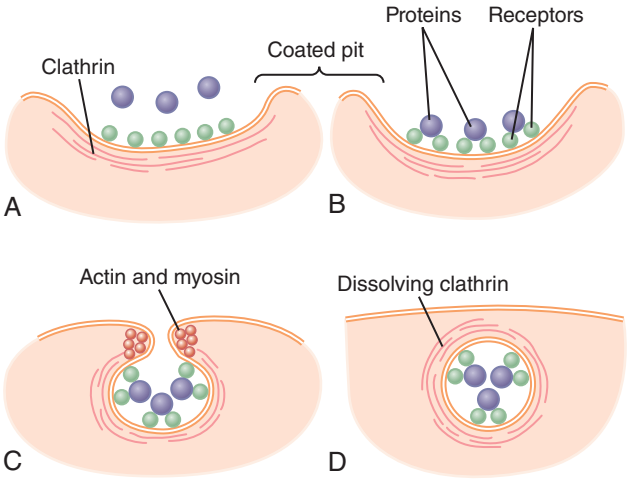

Figure 2.11 Mechanism of pinocytosis.

The nuclear membrane is penetrated by several thousand *nuclear pores*. Large complexes of proteins are attached at the edges of the pores so that the central area of each pore is only about 9 nanometers in diameter, permitting molecules up to a molecular weight of 44,000 to pass through with reasonable ease. Even larger molecules can cross nuclear pore complexes through selective, receptor-mediated transport.

Nucleoli and Formation of Ribosomes. The nuclei of most cells contain one or more highly staining structures called *nucleoli*. The nucleolus, unlike most other organelles discussed here, does not have a limiting membrane. Instead, it is simply an accumulation of large amounts of RNA and the types of proteins found in ribosomes. The nucleolus enlarges considerably when the cell is actively synthesizing proteins.

Formation of the nucleoli (and of the ribosomes in the cytoplasm outside the nucleus) begins in the nucleus. First, specific DNA genes in the chromosomes cause RNA to be synthesized. Some of this synthesized RNA is stored in the nucleoli, but most of it is transported outward through the nuclear pores into the cytoplasm. Here it is used in conjunction with specific proteins to assemble "mature" ribosomes that play an essential role in forming cytoplasmic proteins, as discussed in Chapter 3.

FUNCTIONAL SYSTEMS OF THE CELL

Although the cells of different tissues and organs of the human body are highly specialized, they share many common functions. In the remainder of this chapter, we discuss some functional systems of the cell that make it a living organism.

ENDOCYTOSIS—INGESTION BY THE CELL

For cells to live, grow and reproduce, they must obtain nutrients and other substances from the surrounding fluids. Most substances pass through the cell membrane by the processes of *diffusion* and *active transport*.

Diffusion involves simple movement through the membrane caused by the random motion of the molecules of the substance. Substances move through cell membrane pores or, in the case of lipid-soluble substances, through the lipid matrix of the membrane.

Active transport involves actually carrying a substance through the membrane by a physical protein structure that penetrates all the way through the membrane. These active transport mechanisms are so important to cell function that they are presented in detail in Chapter 4.

Large particles enter the cell by a specialized function of the cell membrane called *endocytosis* (**Video 2.1**). The principal forms of endocytosis are *pinocytosis* and *phagocytosis*. Pinocytosis means the ingestion of minute particles that form vesicles of extracellular fluid and particulate constituents inside the cell cytoplasm. Phagocytosis means the ingestion of large particles, such as bacteria, whole cells, or portions of degenerating tissue.

Pinocytosis. Pinocytosis occurs continually in the cell membranes of most cells, but is especially rapid in some cells. For example, it occurs so rapidly in macrophages that about 3% of the total macrophage membrane is engulfed in the form of vesicles each minute. Even so, the pinocytotic vesicles are so small—usually only 100 to 200 nanometers in diameter—that most of them can be seen only with an electron microscope.

Pinocytosis is a means whereby most large macromolecules, such as most proteins, can enter cells. In fact, the rate at which pinocytotic vesicles form is usually enhanced when such macromolecules attach to the cell membrane.

Fig. 2.11A–D demonstrates the successive steps of pinocytosis, showing three molecules of protein attaching to the membrane. These molecules usually attach to specialized protein *receptors* on the surface of the membrane that are specific for the type of protein that is to be absorbed. The receptors generally are concentrated in small pits on the outer surface of the cell membrane, called *coated pits*. On the inside of the cell membrane beneath these pits is a latticework of fibrillar protein

called *clathrin*, as well as other proteins, perhaps including contractile filaments of *actin* and *myosin*. Once the protein molecules have bound with the receptors, the surface properties of the local membrane change in such a way that the entire pit invaginates inward, and fibrillar proteins surrounding the invaginating pit cause its borders to close over the attached proteins, as well as over a small amount of extracellular fluid. Immediately thereafter, the invaginated portion of the membrane breaks away from the surface of the cell, forming a *pinocytotic vesicle* inside the cytoplasm of the cell.

This pinocytotic process requires energy from within the cell, which is supplied by ATP, a high-energy substance discussed later in this chapter. This process also requires the presence of calcium ions (Ca^{2+}) in the extracellular fluid, which react with contractile protein filaments beneath the coated pits to provide the force for pinching the vesicles away from the cell membrane.

Phagocytosis. Phagocytosis occurs in much the same way as pinocytosis, except that it involves large particles rather than molecules. Only certain cells have the capability of phagocytosis—notably, tissue macrophages and some white blood cells.

Phagocytosis is initiated when a particle such as a bacterium, dead cell, or tissue debris binds with receptors on the surface of the phagocyte. In the case of bacteria, each bacterium is usually attached to a specific antibody, and it is the antibody that attaches to the phagocyte receptors, dragging the bacterium along with it. This intermediation of antibodies is called *opsonization*, as discussed in Chapters 34 and 35.

Phagocytosis occurs in the following steps:

1. The cell membrane receptors attach to the surface ligands of the particle.
2. The edges of the membrane around the points of attachment evaginate outward within a fraction of a second to surround the entire particle; then, progressively more and more membrane receptors attach to the particle ligands. All this occurs suddenly in a zipper-like manner to form a closed *phagocytic vesicle*.
3. Actin and other contractile fibrils in the cytoplasm surround the phagocytic vesicle and contract around its outer edge, pushing the vesicle to the interior.
4. The contractile proteins then pinch the stem of the vesicle so completely that the vesicle separates from the cell membrane, leaving the vesicle in the cell interior in the same way that pinocytotic vesicles are formed.

LYSOSOMES DIGEST PINOCYTOTIC AND PHAGOCYTIC FOREIGN SUBSTANCES INSIDE THE CELL

Almost immediately after a pinocytotic or phagocytic vesicle appears inside a cell, one or more *lysosomes* become attached to the vesicle and empty their *acid hydrolases* to the inside of the vesicle, as shown in **Fig. 2.12**. Thus, a *digestive vesicle* is formed inside the cell cytoplasm in which the vesicular hydrolases begin hydrolyzing the proteins, carbohydrates, lipids, and other substances in the vesicle. The products of digestion are small molecules of substances such as amino acids, glucose, and phosphates that can diffuse through the membrane of the vesicle into the cytoplasm. What is left of the digestive vesicle, called the *residual body*, represents indigestible substances. In most cases, the residual body is finally excreted through the cell membrane by a process called *exocytosis*, which is essentially the opposite of endocytosis. Thus, the pinocytotic and phagocytic vesicles containing lysosomes can be called the *digestive organs* of the cells.

Lysosomes and Regression of Tissues and Autolysis of Damaged Cells. Tissues of the body often regress to a smaller size. For example, this regression occurs in the uterus after pregnancy, in muscles during long periods of inactivity, and in mammary glands at the end of lactation. Lysosomes are responsible for much of this regression.

Another special role of the lysosomes is removal of damaged cells or damaged portions of cells from tissues. Damage to the cell—caused by heat, cold, trauma, chemicals, or any other factor—induces lysosomes to release hydrolases, which digest the surrounding organic substances. If the damage is slight, only a portion of the cell is removed, and the cell is then repaired. If the damage is severe, the entire cell is digested, a process called *autolysis*. In this way, the cell is completely removed, and a new cell of the same type is formed, ordinarily by mitotic reproduction of an adjacent cell to take the place of the old one.

The lysosomes also contain bactericidal agents that can kill phagocytized bacteria before they cause cellular damage. These agents include the following: (1) *lysozyme*, which dissolves the bacterial cell wall; (2) *lysoferrin*, which binds iron and other substances before they can promote bacterial growth; and (3) acid at a pH of about

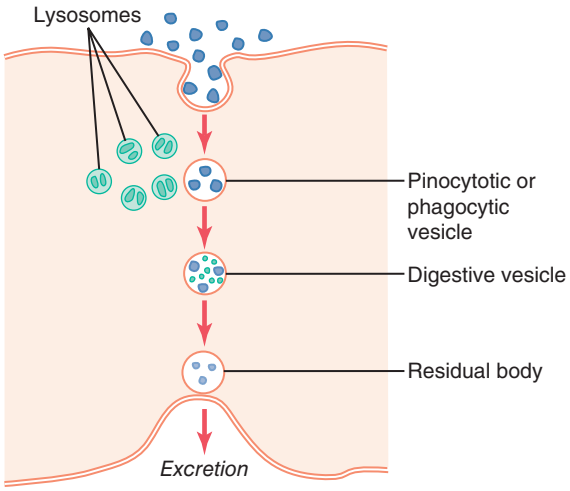

Figure 2.12 Digestion of substances in pinocytotic or phagocytic vesicles by enzymes derived from lysosomes.

4.8, which activates the hydrolases and inactivates bacterial metabolic systems.

Autophagy and Recycling of Cell Organelles. Lysosomes play a key role in the process of *autophagy*, which literally means "to eat oneself." Autophagy is a housekeeping process whereby obsolete organelles and large protein aggregates are degraded and recycled (**Fig. 2.13**). Worn-out cell organelles are transferred to lysosomes by double-membrane structures called *autophagosomes*, which are formed in the cytosol. Invagination of the lysosomal membrane and the formation of vesicles provide another pathway for cytosolic structures to be transported into the lumen of lysosomes. Once inside the lysosomes, the organelles are digested, and the nutrients are reused by the cell. Autophagy contributes to the routine turnover of cytoplasmic components; it is a key mechanism for tissue development, cell survival when nutrients are scarce, and homeostasis. In liver cells, for example, the average mitochondrion normally has a life span of only about 10 days before it is destroyed.

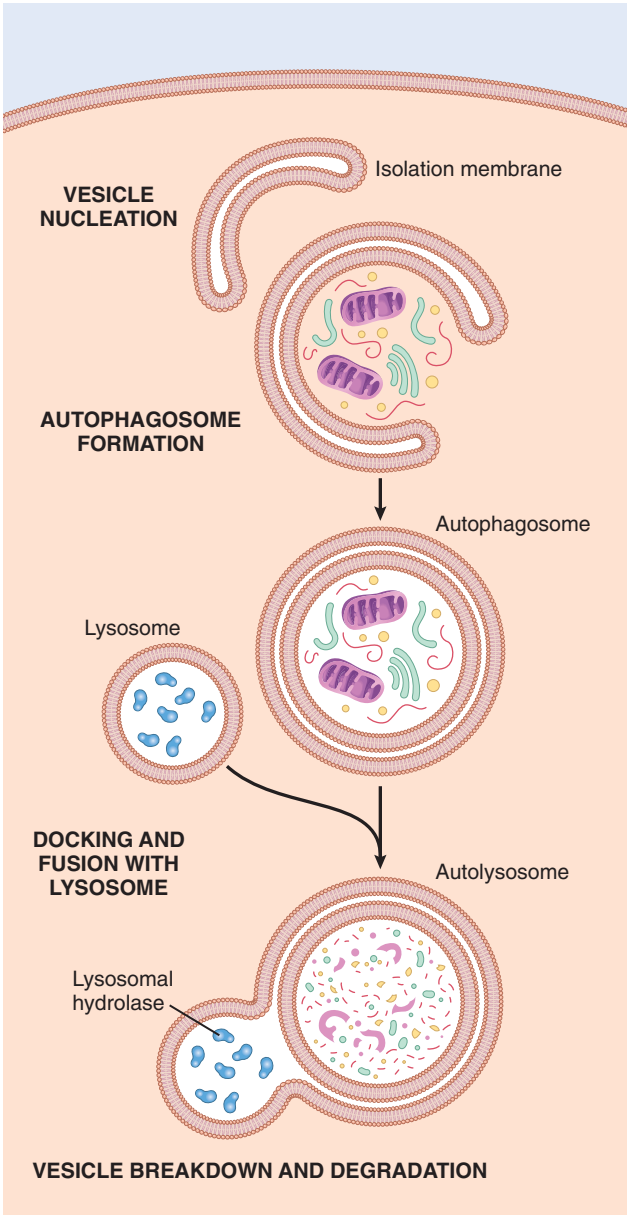

Figure 2.13 Schematic diagram of autophagy steps.

SYNTHESIS OF CELLULAR STRUCTURES BY ENDOPLASMIC RETICULUM AND GOLGI APPARATUS

Endoplasmic Reticulum Functions

The extensiveness of the ER and Golgi apparatus in secretory cells has already been emphasized. These structures are formed primarily of lipid bilayer membranes, similar to the cell membrane, and their walls are loaded with protein enzymes that catalyze the synthesis of many substances required by the cell.

Most synthesis begins in the ER. The products formed there are then passed on to the Golgi apparatus, where they are further processed before being released into the cytoplasm. First, however, let us note the products that are synthesized in specific portions of the ER and Golgi apparatus.

Proteins Synthesis By the Rough Endoplasmic Reticulum. The rough ER has large numbers of ribosomes attached to the outer surfaces of the ER membrane. As discussed in Chapter 3, proteins are synthesized within the structures of the ribosomes. The ribosomes extrude some of the synthesized proteins directly into the cytosol, but they also extrude many more through the wall of the ER to the interior of the endoplasmic vesicles and tubules into the *endoplasmic matrix*.

Lipid Synthesis By the Smooth Endoplasmic Reticulum. The ER also synthesizes lipids, especially phospholipids and cholesterol. These lipids are rapidly incorporated into the lipid bilayer of the ER, thus causing the ER to grow more extensive. This process occurs mainly in the smooth portion of the ER.

To keep the ER from growing beyond the cell's needs, small vesicles called *ER vesicles* or *transport vesicles* continually break away from the smooth reticulum; most of these vesicles then migrate rapidly to the Golgi apparatus.

Other Functions of the Endoplasmic Reticulum. Other significant functions of the ER, especially the smooth reticulum, include the following:

1. It provides the enzymes that control glycogen breakdown when glycogen is to be used for energy.
2. It provides a vast number of enzymes that are capable of detoxifying substances, such as drugs, that might damage the cell. It achieves detoxification by processes such as coagulation, oxidation, hydrolysis, and conjugation with glycuronic acid.

Golgi Apparatus Functions

Synthetic Functions of the Golgi Apparatus. Although a major function of the Golgi apparatus is to provide

additional processing of substances already formed in the ER, it can also synthesize certain carbohydrates that cannot be formed in the ER. This is especially true for the formation of large saccharide polymers bound with small amounts of protein; important examples include *hyaluronic acid* and *chondroitin sulfate*.

A few of the many functions of hyaluronic acid and chondroitin sulfate in the body are as follows: (1) they are major components of proteoglycans secreted in mucus and other glandular secretions; (2) they are major components of the *ground substance*, or nonfibrous components of the extracellular matrix, outside the cells in the interstitial spaces, which serve several important functions, including acting as fillers between collagen fibers and cells; (3) they are principal components of the organic matrix in both cartilage and bone; and (4) they are important in many cell activities, including migration and proliferation.

Processing of Endoplasmic Reticulum Secretions By the Golgi Apparatus—Formation of Vesicles. **Fig. 2.14** summarizes the major functions of the ER and Golgi apparatus. As substances are formed in the ER, especially proteins, they are transported through the tubules toward portions of the smooth ER that lie nearest to the Golgi apparatus. At this point, *transport vesicles* composed of small envelopes of smooth ER continually break away and diffuse to the *deepest layer* of the Golgi apparatus. Inside these vesicles are synthesized proteins and other products from the ER.

The transport vesicles fuse with the Golgi apparatus and empty their contained substances into the vesicular spaces of the Golgi apparatus. Here, additional carbohydrate moieties are added to the secretions. Also, an important function of the Golgi apparatus is to compact the ER secretions into highly concentrated packets. As the secretions pass toward the outermost layers of the Golgi apparatus, the compaction and processing proceed. Finally, small and large vesicles continually break away from the Golgi apparatus, carrying with them the compacted secretory substances and diffusing throughout the cell.

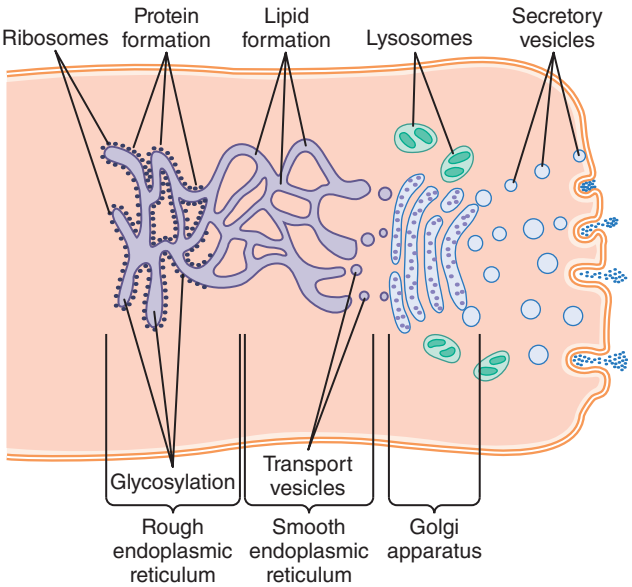

Figure 2.14 Formation of proteins, lipids, and cellular vesicles by the endoplasmic reticulum and Golgi apparatus.

The following example provides an idea of the timing of these processes. When a glandular cell is bathed in amino acids, newly formed protein molecules can be detected in the granular ER within 3 to 5 minutes. Within 20 minutes, newly formed proteins are already present in the Golgi apparatus and, within 1 to 2 hours, the proteins are secreted from the surface of the cell.

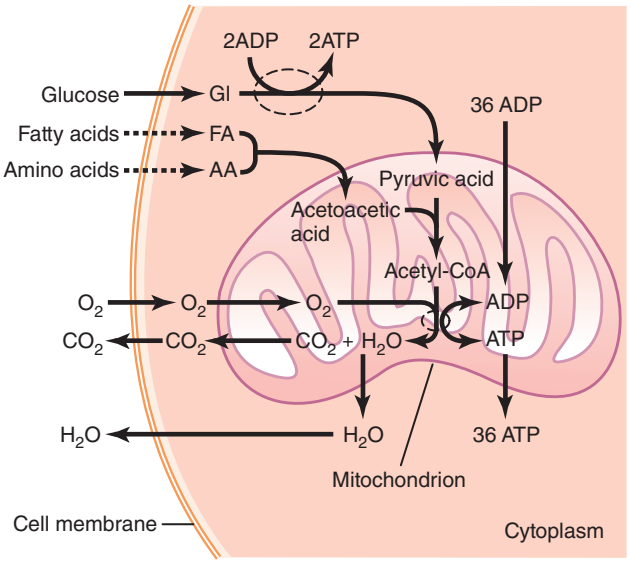
Secretory Vesicles Are Formed By the Golgi Apparatus. In a highly secretory cell, the vesicles formed by the Golgi apparatus are mainly *secretory vesicles* containing proteins that are secreted through the surface of the cell membrane. These secretory vesicles first diffuse to the cell membrane and then fuse with it and empty their substances to the exterior by the mechanism called *exocytosis*. Exocytosis, in most cases, is stimulated by entry of Ca^{2+} into the cell. Calcium ions interact with the vesicular membrane and cause its fusion with the cell membrane, followed by exocytosis—opening of the membrane's outer surface and extrusion of its contents outside the cell. Some vesicles, however, are destined for intracellular use.

Use of Intracellular Vesicles to Replenish Cellular Membranes. Some intracellular vesicles formed by the Golgi apparatus fuse with the cell membrane or with the membranes of intracellular structures such as the mitochondria and even the ER. This fusion increases the expanse of these membranes and replenishes the membranes as they are used. For example, the cell membrane loses much of its substance every time it forms a phagocytic or pinocytotic vesicle, and the vesicular membranes of the Golgi apparatus continually replenish the cell membrane.

In summary, the membranous system of the ER and Golgi apparatus is highly metabolic and capable of forming new intracellular structures and secretory substances to be extruded from the cell.

MITOCHONDRIA EXTRACT ENERGY FROM NUTRIENTS

The principal substances from which cells extract energy are foods that react chemically with oxygen—carbohydrates, fats, and proteins. In the human body, essentially all carbohydrates are converted into *glucose* by the digestive tract and liver before they reach the other cells of the body. Similarly, proteins are converted into *amino acids*, and fats are converted into *fatty acids*. **Fig. 2.15** shows oxygen and the foodstuffs—glucose, fatty acids, and amino acids—all entering the cell. Inside the cell, they react chemically with oxygen under the influence of enzymes that control the reactions and channel the energy released in the proper direction. The details of all



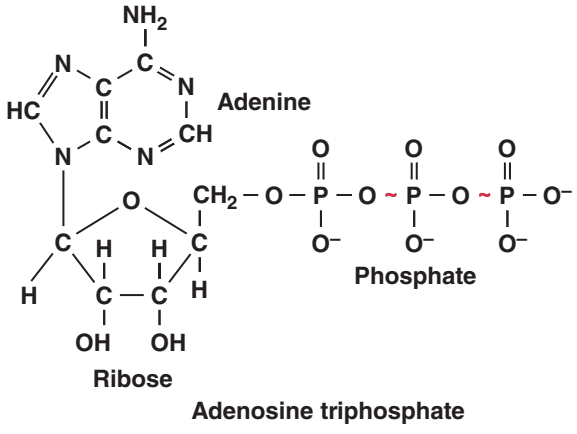


Figure 2.15 Formation of adenosine triphosphate (ATP) in the cell, showing that most of the ATP is formed in the mitochondria. *ADP*, Adenosine diphosphate; *CoA*, coenzyme A.

these digestive and metabolic functions are provided in Chapters 63 through 73.

Briefly, almost all these oxidative reactions occur inside the mitochondria, and the energy that is released is used to form the high-energy compound ATP. Then, ATP, not the original food, is used throughout the cell to energize almost all the subsequent intracellular metabolic reactions.

Functional Characteristics of Adenosine Triphosphate

ATP is a nucleotide composed of the following: (1) the nitrogenous base *adenine;* (2) the pentose sugar *ribose;* and (3) three *phosphate radicals*. The last two phosphate radicals are connected with the remainder of the molecule by *high-energy phosphate bonds*, which are represented in the formula shown by the symbol ~. *Under the physical and chemical conditions of the body*, each of these high-energy bonds contains about 12,000 calories of energy per mole of ATP, which is many times greater than the energy stored in the average chemical bond, thus giving rise to the term *high-energy bond*. Furthermore, the high-energy phosphate bond is very labile and can be split instantly on demand whenever energy is required to promote other intracellular reactions.

When ATP releases its energy, a phosphoric acid radical is split away, and *adenosine diphosphate* (ADP) is formed. This released energy is used to energize many of the cell's other functions, such as syntheses of substances and muscular contraction.

To reconstitute the cellular ATP as it is used, energy derived from the cellular nutrients causes ADP and phosphoric acid to recombine to form new ATP, and the entire process is repeated over and over. For these reasons, ATP has been called the *energy currency* of the cell because it can be spent and reformed continually, having a turnover time of only a few minutes.

Role of Mitochondria in Forming ATP. On entry into the cells, glucose is converted by enzymes in the *cytoplasm* into *pyruvic acid* (a process called *glycolysis*). A small amount of ADP is changed into ATP by the energy released during this conversion, but this amount accounts for less than 5% of the overall energy metabolism of the cell.

About 95% of the cell's ATP formation occurs in the mitochondria. Pyruvic acid derived from carbohydrates, fatty acids from lipids, and amino acids from proteins are eventually converted into the compound *acetyl-coenzyme A* (CoA) in the matrix of mitochondria. This substance, in turn, is further dissolved to extract its energy by another series of enzymes in the mitochondrion matrix, undergoing a sequence of chemical reactions called the *citric acid cycle*, or *Krebs cycle*. These chemical reactions are so important that they are explained in detail in Chapter 68.

In this citric acid cycle, acetyl-CoA is split into its component parts, *hydrogen atoms* and *carbon dioxide*. The carbon dioxide diffuses out of the mitochondria and the cell; finally, it is excreted from the body through the lungs. The hydrogen atoms, however, are highly reactive and combine with oxygen that has also diffused into the mitochondria. This combination releases a tremendous amount of energy, which is used by mitochondria to convert large amounts of ADP to ATP.

The processes of these reactions are complex, requiring participation of many protein enzymes that are integral parts of mitochondrial *membranous shelves* that protrude into the mitochondrial matrix. The initial event is the removal of an electron from the hydrogen atom, thus converting it to a hydrogen ion. The terminal event is the combination of hydrogen ions with oxygen to form water and the release of large amounts of energy to globular proteins called *ATP synthetase* that protrude like knobs from the membranes of the mitochondrial shelves. The enzyme ATP synthetase then uses the energy from the hydrogen ions to convert ADP to ATP. The newly formed ATP is transported out of the mitochondria into all parts of the cell cytoplasm and nucleoplasm, where it energizes multiple cell functions.

This overall process for formation of ATP is called the *chemiosmotic mechanism* of ATP formation. The chemical and physical details of this mechanism are presented in Chapter 68, and many of the detailed metabolic functions of ATP in the body are discussed in Chapters 68 through 72.

Uses of ATP for Cellular Function. Energy from ATP is used to promote three major categories of cellular functions: (1) *transport* of substances through multiple cell membranes; (2) *synthesis of chemical compounds* throughout the cell; and (3) *mechanical work*. These uses of ATP are illustrated by the examples in **Fig. 2.16**: (1) to supply energy for sodium transport through the cell membrane; (2) to promote protein synthesis by the ribosomes; and (3) to supply energy needed for muscle contraction.

In addition to membrane transport of sodium, energy from ATP is required for membrane transport of potassium, calcium, magnesium, phosphate, chloride, urate, and hydrogen ions and many other ions, as well as various organic substances. Membrane transport is so important to cell function that some cells—the renal tubular cells, for example—use as much as 80% of the ATP that they form for this purpose alone.

In addition to synthesizing proteins, cells make phospholipids, cholesterol, purines, pyrimidines, and many other substances. Synthesis of almost any chemical compound requires energy. For example, a single protein molecule might be composed of as many as several thousand amino acids attached to one another by peptide linkages. The formation of each of these linkages requires energy derived from the breakdown of four high-energy bonds; thus, many thousand ATP molecules must release their energy as each protein molecule is formed. Indeed, some cells use as much as 75% of all the ATP formed in the cell simply to synthesize new chemical compounds, especially proteins during the growth phase of cells.

Another use of ATP is to supply energy for special cells to perform mechanical work. We discuss in Chapter 6 that each contraction of a muscle fiber requires expenditure of large quantities of ATP energy. Other cells perform mechanical work in different ways, especially by *ciliary* and *ameboid motion*, described later in this chapter. The source of energy for all these types of mechanical work is ATP.

In summary, ATP is readily available to release its energy rapidly wherever it is needed in the cell. To replace ATP used by the cell, much slower chemical reactions break down carbohydrates, fats, and proteins and use the energy derived from these processes to form new ATP. More than 95% of this ATP is formed in the mitochondria, which is why the mitochondria are called the *powerhouses* of the cell.

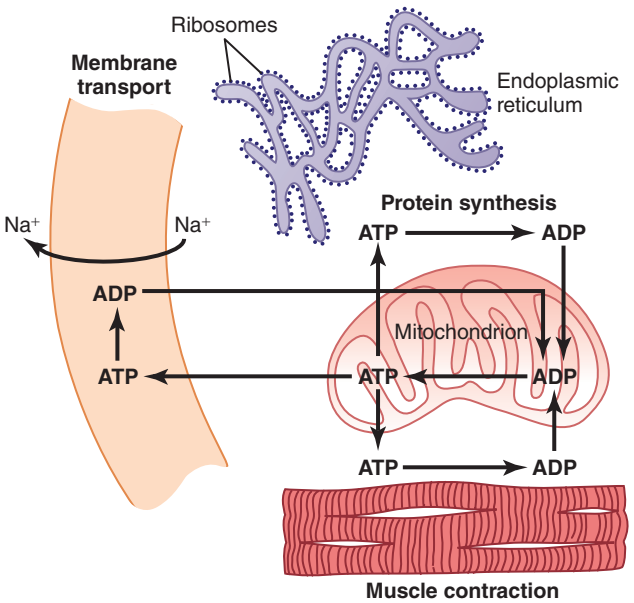

Figure 2.16 Use of adenosine triphosphate (ATP; formed in the mitochondrion) to provide energy for three major cellular functions—membrane transport, protein synthesis, and muscle contraction. *ADP*, Adenosine diphosphate.

LOCOMOTION OF CELLS

The most obvious types of movement in the body occur in skeletal, cardiac, and smooth muscle cells, which constitute almost 50% of the entire body mass. The specialized functions of these cells are discussed in Chapters 6 through 9. Two other types of movement—*ameboid locomotion* and *ciliary movement*—occur in other cells.

Ameboid Movement

Ameboid movement is a crawling-like movement of an entire cell, such as movement of white blood cells through tissues. This type of movement gets its name from the fact that amebae move in this manner, and amebae have provided an excellent tool for studying the phenomenon.

Typically, ameboid locomotion begins with the protrusion of a *pseudopodium* from one end of the cell. The pseudopodium projects away from the cell body and partially secures itself in a new tissue area; then the remainder of the cell is pulled toward the pseudopodium. **Fig. 2.17** demonstrates this process, showing an elongated cell, the right-hand end of which is a protruding pseudopodium.

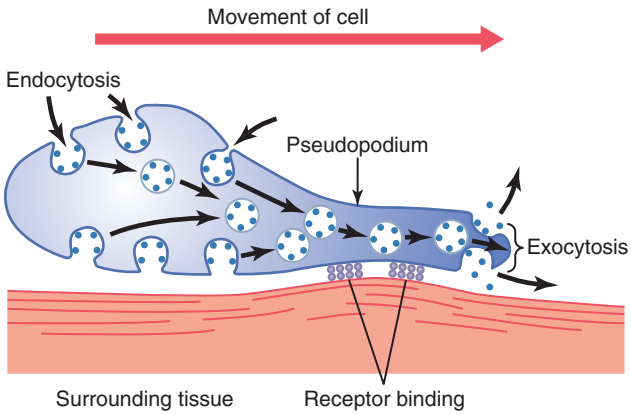

Figure 2.17 Ameboid motion by a cell.

The membrane of this end of the cell is continually moving forward, and the membrane at the left-hand end of the cell is continually following along as the cell moves.

Mechanism of Ameboid Locomotion. Fig. 2.17 shows the general principle of ameboid motion. Basically, this results from the continual formation of new cell membrane at the leading edge of the pseudopodium and continual absorption of the membrane in the mid and rear portions of the cell. Two other effects are also essential for forward movement of the cell. The first is attachment of the pseudopodium to surrounding tissues so that it becomes fixed in its leading position while the remainder of the cell body is being pulled forward toward the point of attachment. This attachment is caused by *receptor proteins* that line the insides of exocytotic vesicles. When the vesicles become part of the pseudopodial membrane, they open so that their insides evert to the outside, and the receptors now protrude to the outside and attach to ligands in the surrounding tissues.

At the opposite end of the cell, the receptors pull away from their ligands and form new endocytotic vesicles. Then, inside the cell, these vesicles stream toward the pseudopodial end of the cell, where they are used to form new membrane for the pseudopodium.

The second essential requirement for locomotion is the energy to pull the cell body in the direction of the pseudopodium. A moderate to large amount of the protein *actin* is in the cytoplasm of all cells. Much of the actin is in the form of single molecules that do not provide any motive power; however, these molecules polymerize to form a filamentous network, and the network contracts when it binds with an actin-binding protein such as *myosin*. The entire process is energized by the high-energy compound ATP. This is what occurs in the pseudopodium of a moving cell, where such a network of actin filaments forms anew inside the enlarging pseudopodium. Contraction also occurs in the ectoplasm of the cell body, where a preexisting actin network is already present beneath the cell membrane.

Cells That Exhibit Ameboid Locomotion. The most common cells to exhibit ameboid locomotion in the human body are the *white blood cells* when they move out of the blood into the tissues to form *tissue macrophages*. Other types of cells can also move by ameboid locomotion under certain circumstances. For example, fibroblasts move into a damaged area of tissues to help repair the damage. Even the germinal cells of the skin, although ordinarily completely sessile cells, move toward a cut area to repair the opening. Cell locomotion is also especially important in development of the embryo and fetus after fertilization of an ovum. For example, embryonic cells often must migrate long distances from their sites of origin to new areas during the development of special structures.

Some types of cancer cells, such as sarcomas, which arise from connective tissue cells, are especially proficient at ameboid movement. This partially explains their relatively rapid spreading from one part of the body to another, known as *metastasis*.

Control of Ameboid Locomotion—Chemotaxis. An important initiator of ameboid locomotion is the process called *chemotaxis*, which results from the appearance of certain *chemotactic substance*s in the tissues. Most cells that exhibit ameboid locomotion move toward the source of a chemotactic substance—that is, from an area of lower concentration toward an area of higher concentration. This is called *positive chemotaxis*. Some cells move away from the source, which is called *negative chemotaxis*. The side of the cell most exposed to the chemotactic substance develops membrane changes that cause pseudopodial protrusion.

Cilia and Ciliary Movements

There are two types of cilia, *motile* and *nonmotile (primary)* cilia. Motile cilia can undergo a whiplike movement on the surfaces of cells. This movement occurs mainly in two places in the human body, on the surfaces of the respiratory airways and on the inside surfaces of the uterine tubes (fallopian tubes) of the reproductive tract. In the nasal cavity and lower respiratory airways, the whiplike motion of motile cilia causes a layer of mucus to move at a rate of about 1 cm/min toward the pharynx, in this way continually clearing these passageways of mucus and particles that become trapped in the mucus. In the uterine tubes, cilia cause slow movement of fluid from the ostium of the uterine tube toward the uterus cavity; this movement of fluid transports the ovum from the ovary to the uterus.

Fig. 2.18 shows a cilium with the appearance of a sharp-pointed straight or curved hair that projects 2 to 4 micrometers from the surface of the cell. Often, many motile cilia project from a single cell—for example, as many as 200 cilia on the surface of each epithelial cell inside the respiratory passageways. The cilium is covered by an outcropping of the cell membrane, and it is supported by 11 microtubules—nine double tubules located around the periphery of the cilium and two single tubules down the center, as demonstrated in the cross section shown in Fig. 2.18. Each cilium is an outgrowth of a structure that lies immediately beneath the cell membrane, called the *basal body* of the cilium.

The *flagellum of a sperm* is similar to a motile cilium; in fact, it has much the same type of structure and same type of contractile mechanism. The flagellum, however, is much longer and moves in quasi sinusoidal waves instead of whiplike movements.

In the inset of Fig. 2.18, movement of the motile cilium is shown. The cilium moves forward with a sudden, rapid whiplike stroke 10 to 20 times per second, bending sharply where it projects from the surface of the cell. Then it moves backward slowly to its initial position. The rapid, forward-thrusting, whiplike movement pushes the fluid

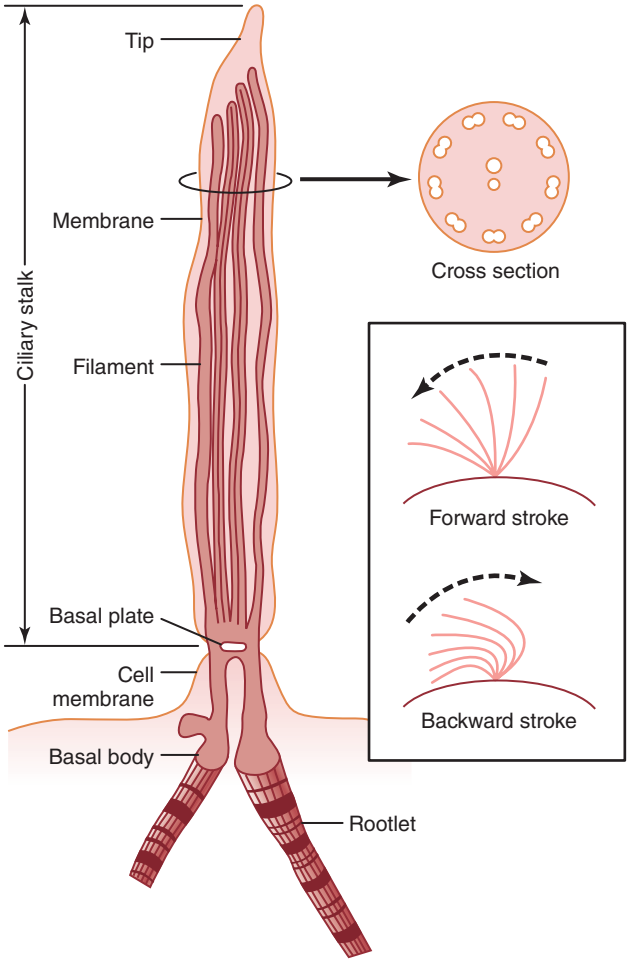

Figure 2.18 Structure and function of the cilium. *(Modified from Satir P. Cilia.* Sci Am. *1961;204:108.)*

lying adjacent to the cell in the direction that the cilium moves; the slow dragging movement in the backward direction has almost no effect on fluid movement. As a result, the fluid is continually propelled in the direction of the fast-forward stroke. Because most motile ciliated cells have large numbers of cilia on their surfaces, and because all the cilia are oriented in the same direction, this is an effective means for moving fluids from one part of the surface to another.

Mechanism of Ciliary Movement. The nine double tubules and two single tubules of cilia are all linked to one another by a complex of protein cross-linkages; this total complex of tubules and cross-linkages is called the *axoneme*. Even after removal of the membrane and destruction of other elements of the cilium in addition to the axoneme, the cilium can still beat under appropriate conditions. Two conditions are necessary for continued beating of the axoneme after removal of the other structures of the cilium: (1) the availability of ATP; and (2) appropriate ionic conditions, especially appropriate concentrations of magnesium and calcium. During forward motion of the cilium, the double tubules on the front edge of the cilium slide outward toward the tip of the cilium, whereas those on the back edge remain in place. Multiple protein arms composed of the protein *dynein*, which has adenosine triphosphatase (ATPase) enzymatic activity, project from each double tubule toward an adjacent double tubule.

Given this basic information, it has been determined that the release of energy from ATP in contact with the ATPase dynein arms causes the heads of these arms to "crawl" rapidly along the surface of the adjacent double tubule. If the front tubules crawl outward while the back tubules remain stationary, bending occurs.

The cilia of some genetically abnormal cells do not have the two central single tubules, and these cilia fail to beat. Therefore, it is presumed that some signal, perhaps an electrochemical signal, is transmitted along these two central tubules to activate the dynein arms.

Nonmotile Primary Cilia Serve as Cell Sensory "Antennae." *Primary cilia* are nonmotile and generally occur only as a single cilium on each cell. Current evidence indicates that they function as cellular "sensory antennae," which coordinate cellular signaling pathways involved in chemical and mechanical sensation, signal transduction, and cell growth. In the kidneys, for example, primary cilia are found in most epithelial cells of the tubules, projecting into the tubule lumen and acting as a flow sensor. In response to fluid flow over the tubular epithelial cells, the primary cilia bend and cause flow-induced changes in intracellular calcium signaling. These signals, in turn, initiate multiple effects on the cells. Defects in signaling by primary cilia in renal tubular epithelial cells are thought to contribute to various disorders, including the development of large fluid-filled cysts, a condition called *polycystic kidney disease*.

Genetic Control of Protein Synthesis, Cell Function, and Cell Reproduction

Genes, which are located in the nuclei of all cells of the body, control heredity from parents to children, as well as the daily functioning of all the body's cells. The genes control cell function by determining which structures, enzymes, and chemicals are synthesized within the cell.

Fig. 3.1 shows the general schema of genetic control. Each gene, which is composed of *deoxyribonucleic acid* (DNA), controls the formation of another nucleic acid, *ribonucleic acid* (RNA); this RNA then spreads throughout the cell to control formation of a specific protein. The entire process, from *transcription* of the genetic code in the nucleus to *translation* of the RNA code and the formation of proteins in the cell cytoplasm, is often referred to as *gene expression*.

Because the human body has approximately 20,000 to 25,000 different genes that code for proteins in each cell, it is possible to form a large number of different cellular proteins. In fact, RNA molecules transcribed from the same segment of DNA—the same gene—can be processed in more than one way by the cell, giving rise to alternate versions of the protein. The total number of different proteins produced by the various cell types in humans is estimated to be at least 100,000. However, not all of these proteins are produced by all of the cells all of the time. Depending on their function, different cell types have different *proteomes* (the entire complement of proteins produced by a cell).

Some of the cellular proteins are *structural proteins*, which, in association with various lipids and carbohydrates, form structures of the various intracellular organelles discussed in Chapter 2. However, most of the proteins are *enzymes* that catalyze different chemical reactions in the cells. For example, enzymes promote all the oxidative reactions that supply energy to the cell, along with synthesis of all the cell chemicals, such as lipids, glycogen, and adenosine triphosphate (ATP).

CELL NUCLEUS GENES CONTROL PROTEIN SYNTHESIS

In the cell nucleus, large numbers of genes are attached end on end in extremely long, double-stranded helical molecules of DNA having molecular weights measured in the billions. A very short segment of such a molecule is shown in **Fig. 3.2**. This molecule is composed of several simple chemical compounds bound together in a regular pattern, the details of which are explained in the next few paragraphs.

Building Blocks of DNA

Fig. 3.3 shows the basic chemical compounds involved in the formation of DNA. These compounds include the following: (1) *phosphoric acid;* (2) a sugar called *deoxyribose;* and (3) four nitrogenous *bases* (two purines, *adenine* and *guanine*, and two pyrimidines, *thymine* and *cytosine*). The phosphoric acid and deoxyribose form the two helical strands that are the backbone of the DNA molecule, and the nitrogenous bases lie between the two strands and connect them, as illustrated in **Fig. 3.2**.

Nucleotides

The first stage of DNA formation is to combine one molecule of phosphoric acid, one molecule of deoxyribose, and one of the four bases to form an acidic nucleotide. Four separate nucleotides are thus formed, one for each of the

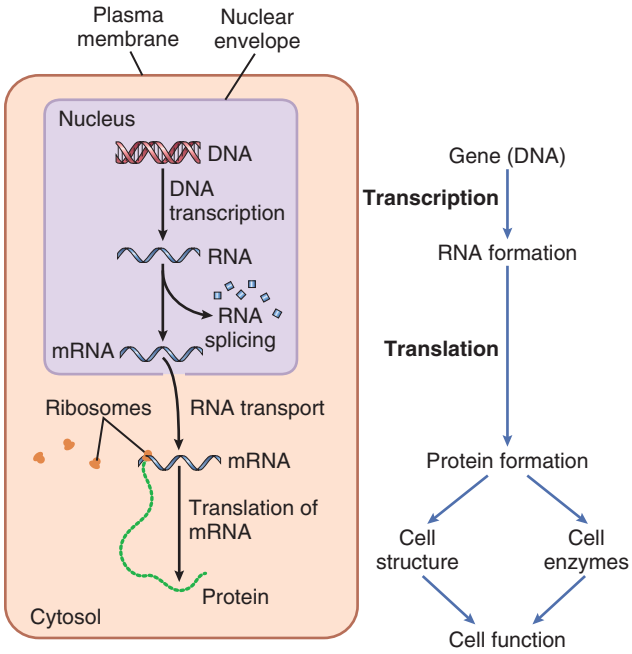

Figure 3.1 The general schema whereby genes control cell function. *mRNA*, Messenger RNA.

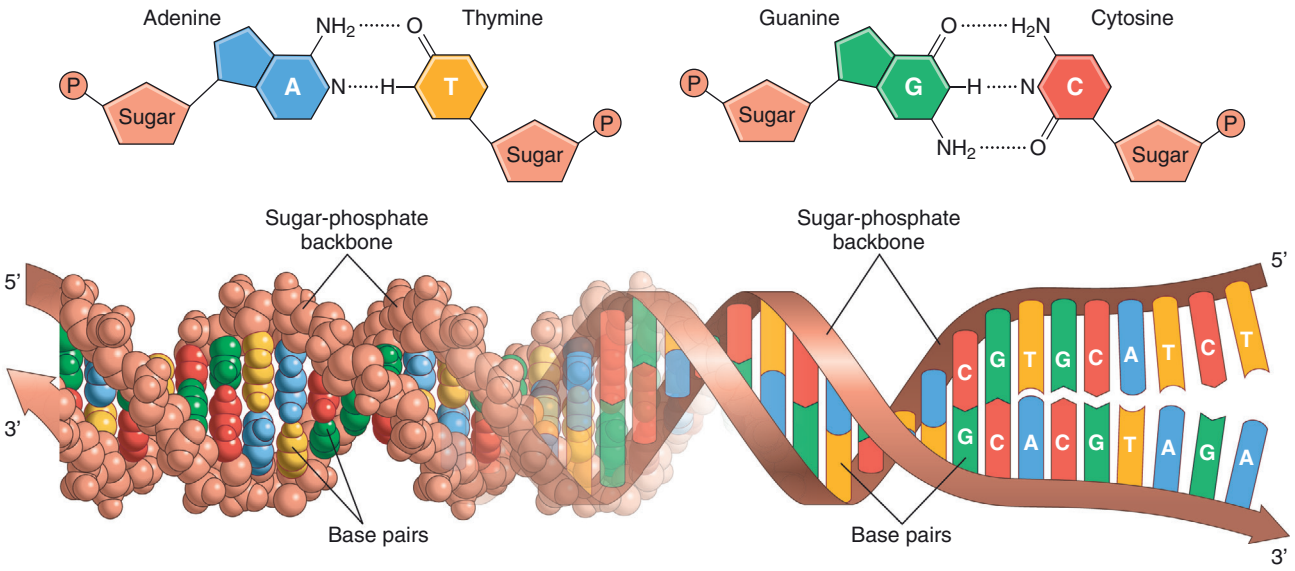

Figure 3.2 The helical double-stranded structure of the gene. The outside strands are composed of phosphoric acid and the sugar deoxyribose. The internal molecules connecting the two strands of the helix are purine and pyrimidine bases, which determine the "code" of the gene.

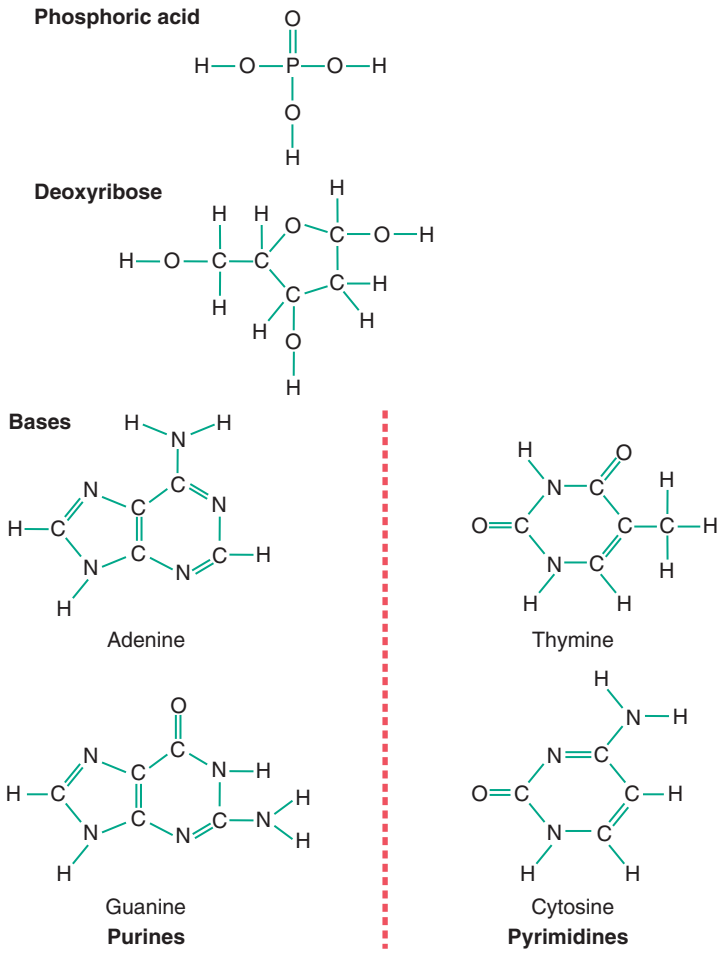

Figure 3.3 The basic building blocks of DNA.

four bases: *deoxyadenylic, deoxythymidylic, deoxyguanylic*, and *deoxycytidylic acids*. **Fig. 3.4** shows the chemical structure of deoxyadenylic acid, and **Fig. 3.5** shows simple symbols for the four nucleotides that form DNA.

Nucleotides Are Organized to Form Two Strands of DNA Loosely Bound to Each Other

Fig. 3.2 shows the manner in which multiple nucleotides are bound together to form two strands of DNA. The two strands are, in turn, loosely bonded with each other by weak cross-linkages, as illustrated in **Fig. 3.6** by the central dashed lines. Note that the backbone of each DNA strand is composed of alternating phosphoric acid and deoxyribose molecules. In turn, purine and pyrimidine bases are attached to the sides of the deoxyribose molecules. Then, by means of loose *hydrogen bonds* (dashed lines) between the purine and pyrimidine bases, the two respective DNA strands are held together. Note the following caveats, however:

1. Each purine base *adenine* of one strand always bonds with a pyrimidine base *thymine* of the other strand.
2. Each purine base *guanine* always bonds with a pyrimidine base *cytosine*.

Thus, in **Fig. 3.6**, the sequence of complementary pairs of bases is CG, CG, GC, TA, CG, TA, GC, AT, and AT. Because of the looseness of the hydrogen bonds, the two strands can pull apart with ease, and they do so many times during the course of their function in the cell.

To put the DNA of **Fig. 3.6** into its proper physical perspective, one could merely pick up the two ends and twist them into a helix. Ten pairs of nucleotides are present in each full turn of the helix in the DNA molecule.

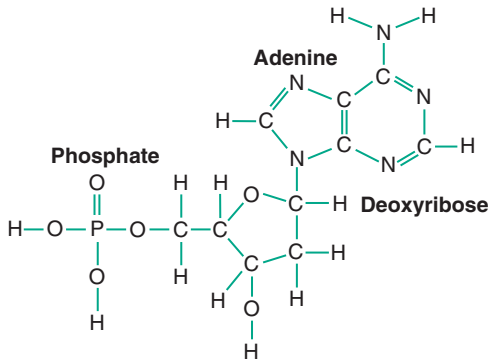

Figure 3.4 Deoxyadenylic acid, one of the nucleotides that make up DNA.

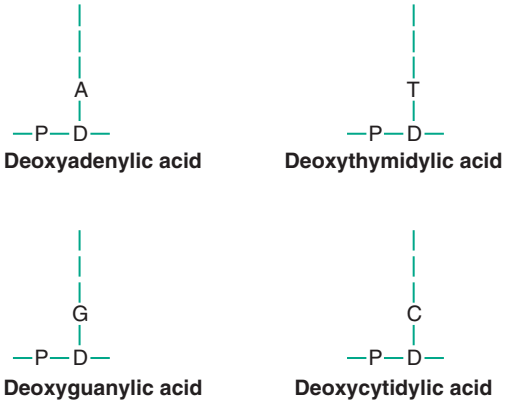

Figure 3.5 Symbols for the four nucleotides that combine to form DNA. Each nucleotide contains phosphoric acid (P), deoxyribose (D), and one of the four nucleotide bases: adenine (A); thymine (T); guanine (G); or cytosine (C).

Genetic Code

The importance of DNA lies in its ability to control the formation of proteins in the cell, which it achieves by means of a *genetic code*. That is, when the two strands of a DNA molecule are split apart, the purine and pyrimidine bases projecting to the side of each DNA strand are exposed, as shown by the top strand in **Fig. 3.7**. It is these projecting bases that form the genetic code.

The genetic code consists of successive "triplets" of bases—that is, each three successive bases is a *code word*. The successive triplets eventually control the sequence of amino acids in a protein molecule that is to be synthesized in the cell. Note in **Fig. 3.6** that the top strand of DNA, reading from left to right, has the genetic code GGC, AGA, CTT, with the triplets being separated from one another by the arrows. As we follow this genetic code through **Fig. 3.7** and **Fig. 3.8**, we see that these three respective triplets are responsible for successive placement of the three amino acids, *proline, serine*, and *glutamic acid*, in a newly formed molecule of protein.

TRANSCRIPTION—TRANSFER OF CELL NUCLEUS DNA CODE TO CYTOPLASM RNA CODE

Because DNA is located in the cell nucleus, yet most of the cell functions are carried out in the cytoplasm, there

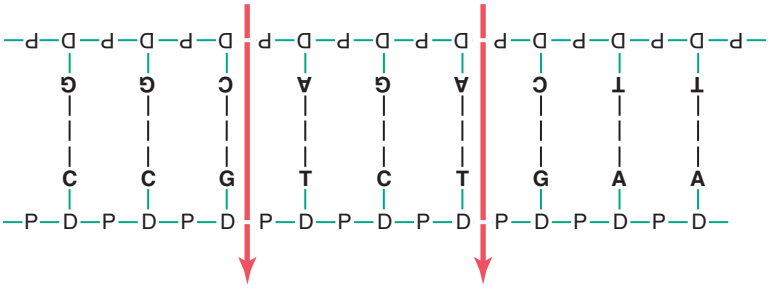

Figure 3.6 Arrangement of deoxyribose nucleotides in a double strand of DNA.

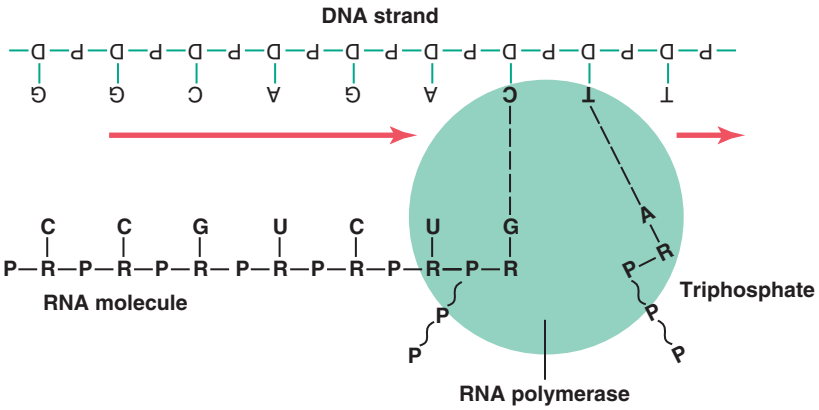

Figure 3.7 Combination of ribose nucleotides with a strand of DNA to form a molecule of RNA that carries the genetic code from the gene to the cytoplasm. The *RNA polymerase* enzyme moves along the DNA strand and builds the RNA molecule.

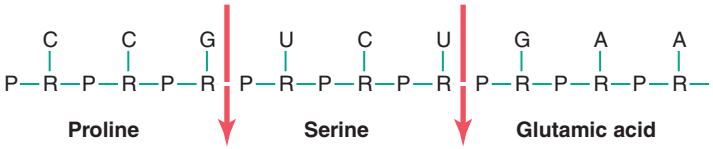

Figure 3.8 A portion of an RNA molecule showing three RNA codons—CCG, UCU, and GAA—that control attachment of the three amino acids, proline, serine, and glutamic acid, respectively, to the growing RNA chain.

must be some means for the DNA to control chemical reactions of the cytoplasm. This control is achieved through the intermediary of another type of nucleic acid, RNA, the formation of which is controlled by DNA of the nucleus. Thus, as shown in **Fig. 3.7**, the code is transferred to RNA in a process called *transcription*. The RNA, in turn, diffuses from the nucleus through nuclear pores into the cytoplasmic compartment, where it controls protein synthesis.

RNA IS SYNTHESIZED IN THE NUCLEUS FROM A DNA TEMPLATE

During RNA synthesis, the two strands of DNA separate temporarily; one of these strands is used as a template for synthesis of an RNA molecule. The code triplets in the DNA result in the formation of *complementary* code triplets (called *codons*) in the RNA. These codons, in turn, will control the sequence of amino acids in a protein to be synthesized in the cell cytoplasm.

Building Blocks of RNA. The basic building blocks of RNA are almost the same as those of DNA, except for two differences. First, the sugar deoxyribose is not used in RNA formation. In its place is another sugar of slightly different composition, *ribose*, which contains an extra hydroxyl ion appended to the ribose ring structure. Second, thymine is replaced by another pyrimidine, *uracil*.

Formation of RNA Nucleotides. The basic building blocks of RNA form *RNA nucleotides*, exactly as described previously for DNA synthesis. Here again, four separate nucleotides are used to form RNA. These nucleotides contain the bases *adenine, guanine, cytosine*, and *uracil*. Note that these bases are the same as in DNA, except that uracil in RNA replaces thymine in DNA.

"Activation" of RNA Nucleotides. The next step for synthesis of RNA is "activation" of RNA nucleotides by an enzyme, *RNA polymerase*. This activation occurs by adding two extra phosphate radicals to each nucleotide to form triphosphates (shown in **Fig. 3.7** by the two RNA nucleotides to the far right during RNA chain formation). These last two phosphates are combined with the nucleotide by *high-energy phosphate bonds* derived from ATP in the cell.

The result of this activation process is that large quantities of ATP energy are made available to each of the nucleotides. This energy is used to promote chemical reactions that add each new RNA nucleotide at the end of the developing RNA chain.

RNA CHAIN IS ASSEMBLED FROM ACTIVATED NUCLEOTIDES USING THE DNA STRAND AS A TEMPLATE

As shown in **Fig. 3.7**, assembly of RNA is accomplished under the influence of an enzyme, *RNA polymerase*. This large protein enzyme has many functional properties necessary for formation of RNA, as follows:

1. In the DNA strand immediately ahead of the gene to be transcribed is a sequence of nucleotides called the *promoter*. The RNA polymerase has an appropriate complementary structure that recognizes this promoter and becomes attached to it, which is the essential step for initiating the formation of RNA.
2. After the RNA polymerase attaches to the promoter, the polymerase causes unwinding of about two turns of the DNA helix and separation of the unwound portions of the two strands.
3. The polymerase then moves along the DNA strand, temporarily unwinding and separating the two DNA strands at each stage of its movement. As it moves along, at each stage it adds a new activated RNA nucleotide to the end of the newly forming RNA chain through the following steps:

a. First, it causes a hydrogen bond to form between the end base of the DNA strand and the base of an RNA nucleotide in the nucleoplasm.
b. Then, one at a time, the RNA polymerase breaks two of the three phosphate radicals away from each of these RNA nucleotides, liberating large amounts of energy from the broken high-energy phosphate bonds. This energy is used to cause covalent linkage of the remaining phosphate on the nucleotide with the ribose on the end of the growing RNA chain.
c. When the RNA polymerase reaches the end of the DNA gene, it encounters a new sequence of DNA nucleotides called the *chain-terminating sequence*, which causes the polymerase and the newly formed RNA chain to break away from the DNA strand. The polymerase then can be used again and again to form more new RNA chains.
d. As the new RNA strand is formed, its weak hydrogen bonds with the DNA template break away because the DNA has a high affinity for rebonding with its own complementary DNA strand. Thus, the RNA chain is forced away from the DNA and is released into the nucleoplasm.

Therefore, the code that is present in the DNA strand is eventually transmitted in *complementary* form to the RNA chain. The ribose nucleotide bases always combine with the deoxyribose bases in the following combinations:

DNA Base	RNA Base
guanine	cytosine
cytosine	guanine
adenine	uracil
thymine	adenine

There Are Several Different Types of RNA. Many different types of RNA have been discovered. Some RNAs are involved in protein synthesis, whereas other types serve gene regulatory functions or are involved in post-transcriptional modification of RNA. The functions of some types of RNA, especially those that do not appear to code for proteins, are still mysterious. The following six types of RNA play independent and different roles in protein synthesis:

1. *Precursor messenger RNA* (pre-mRNA) is a large, immature, single strand of RNA that is processed in the nucleus to form mature messenger RNA (mRNA). The pre-RNA includes two different types of segments, called *introns*, which are removed by a process called splicing, and *exons*, which are retained in the final mRNA.
2. *Small nuclear RNA* (snRNA) directs the splicing of pre-mRNA to form mRNA.
3. *Messenger RNA* (mRNA) carries the genetic code to the cytoplasm for controlling the type of protein formed.
4. *Transfer RNA* (tRNA) transports activated amino acids to the ribosomes to be used in assembling the protein molecule.
5. *Ribosomal RNA*, along with about 75 different proteins, forms *ribosomes*, the physical and chemical structures on which protein molecules are actually assembled.
6. *MicroRNAs* (miRNAs) are single-stranded RNA molecules of 21 to 23 nucleotides that can regulate gene transcription and translation.

MESSENGER RNA—THE CODONS

Messenger RNA molecules are long single RNA strands that are suspended in the cytoplasm. These molecules are composed of several hundred to several thousand RNA nucleotides in unpaired strands, and they contain *codons* that are exactly complementary to the code triplets of the DNA genes. **Fig. 3.8** shows a small segment of mRNA. Its codons are CCG, UCU, and GAA, which are the codons for the amino acids proline, serine, and glutamic acid. The transcription of these codons from the DNA molecule to the RNA molecule is shown in **Fig. 3.7**.

RNA Codons for the Different Amino Acids. **Table 3.1** lists the RNA codons for the 20 common amino acids found in protein molecules. Note that most of the amino acids are represented by more than one codon; also, one codon represents the signal "start manufacturing the protein molecule," and three codons represent "stop manufacturing the protein molecule." In **Table 3.1**, these two types of codons are designated CI for "chain-initiating" or "start" codon and CT for "chain-terminating" or "stop" codon.

TRANSFER RNA—THE ANTICODONS

Another type of RNA that is essential for protein synthesis is transfer RNA (tRNA), which transfers amino acids to protein molecules as the protein is being synthesized. Each type of tRNA combines specifically with 1 of the 20 amino acids that are to be incorporated into proteins. The tRNA then acts as a *carrier* to transport its specific type of amino acid to the ribosomes, where protein molecules are forming. In the ribosomes, each specific type of tRNA recognizes a particular codon on the mRNA (described later) and thereby delivers the appropriate amino acid to the appropriate place in the chain of the newly forming protein molecule.

Transfer RNA, which contains only about 80 nucleotides, is a relatively small molecule in comparison with mRNA. It is a folded chain of nucleotides with a cloverleaf appearance similar to that shown in **Fig. 3.9**. At one end of the molecule there is always an adenylic acid to which the transported amino acid attaches at a hydroxyl group of the ribose in the adenylic acid.

Because the function of tRNA is to cause attachment of a specific amino acid to a forming protein chain, it is

Table 3.1 RNA Codons for Amino Acids and for Start and Stop

Amino Acid	RNA Codons					
Alanine	GCU	GCC	GCA	GCG		
Arginine	CGU	CGC	CGA	CGG	AGA	AGG

Threonine	ACU	ACC	ACA	ACG		
Tryptophan	UGG					
Tyrosine	UAU	UAC				
Valine	GUU	GUC	GUA	GUG		
Start (CI)	AUG					
Stop (CT)	UAA	UAG	UGA			

CI, Chain-initiating; *CT*, chain-terminating.

essential that each type of tRNA also have specificity for a particular codon in the mRNA. The specific code in the tRNA that allows it to recognize a specific codon is again a triplet of nucleotide bases and is called an *anticodon*. This anticodon is located approximately in the middle of the tRNA molecule (at the bottom of the cloverleaf configuration shown in **Fig. 3.9**). During formation of the protein molecule, the anticodon bases combine loosely by hydrogen bonding with the codon bases of the mRNA. In this way, the respective amino acids are lined up one after another along the mRNA chain, thus establishing the appropriate sequence of amino acids in the newly forming protein molecule.

RIBOSOMAL RNA

The third type of RNA in the cell is ribosomal RNA, which constitutes about 60% of the *ribosome*. The remainder of the ribosome is protein, including about 75 types of proteins that are both structural proteins and enzymes needed to manufacture proteins.

The ribosome is the physical structure in the cytoplasm on which proteins are synthesized. However, it always functions in association with the other two types of RNA: *tRNA*, which transports amino acids to the ribosome for

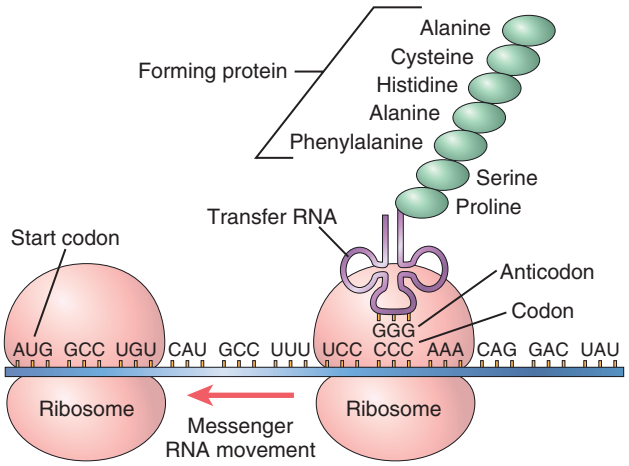

Figure 3.9 A messenger RNA strand is moving through two ribosomes. As each codon passes through, an amino acid is added to the growing protein chain, which is shown in the right-hand ribosome. The transfer RNA molecule transports each specific amino acid to the newly forming protein.

incorporation into the developing protein, and *mRNA*, which provides the information necessary for sequencing the amino acids in proper order for each specific type of protein to be manufactured. Thus, the ribosome acts as a manufacturing plant in which the protein molecules are formed.

Formation of Ribosomes in the Nucleolus. The DNA genes for the formation of ribosomal RNA are located in five pairs of chromosomes in the nucleus. Each of these chromosomes contains many duplicates of these particular genes because of the large amounts of ribosomal RNA required for cellular function.

As the ribosomal RNA forms, it collects in the *nucleolus*, a specialized structure lying adjacent to the chromosomes. When large amounts of ribosomal RNA are being synthesized, as occurs in cells that manufacture large amounts of protein, the nucleolus is a large structure, whereas in cells that synthesize little protein, the nucleolus may not even be seen. Ribosomal RNA is specially processed in the nucleolus, where it binds with ribosomal proteins to form granular condensation products that are primordial subunits of ribosomes. These subunits are then released from the nucleolus and transported through the large pores of the nuclear envelope to almost all parts of the cytoplasm. After the subunits enter the cytoplasm, they are assembled to form mature functional ribosomes. Therefore, proteins are formed in the cytoplasm of the cell, but not in the cell nucleus, because the nucleus does not contain mature ribosomes.

miRNA AND SMALL INTERFERING RNA

A fourth type of RNA in the cell is *microRNA* (miRNA); miRNAs are short (21 to 23 nucleotides) single-stranded RNA fragments that regulate gene expression (**Fig. 3.10**). The miRNAs are encoded from the transcribed DNA of genes, but they are not translated into proteins and are

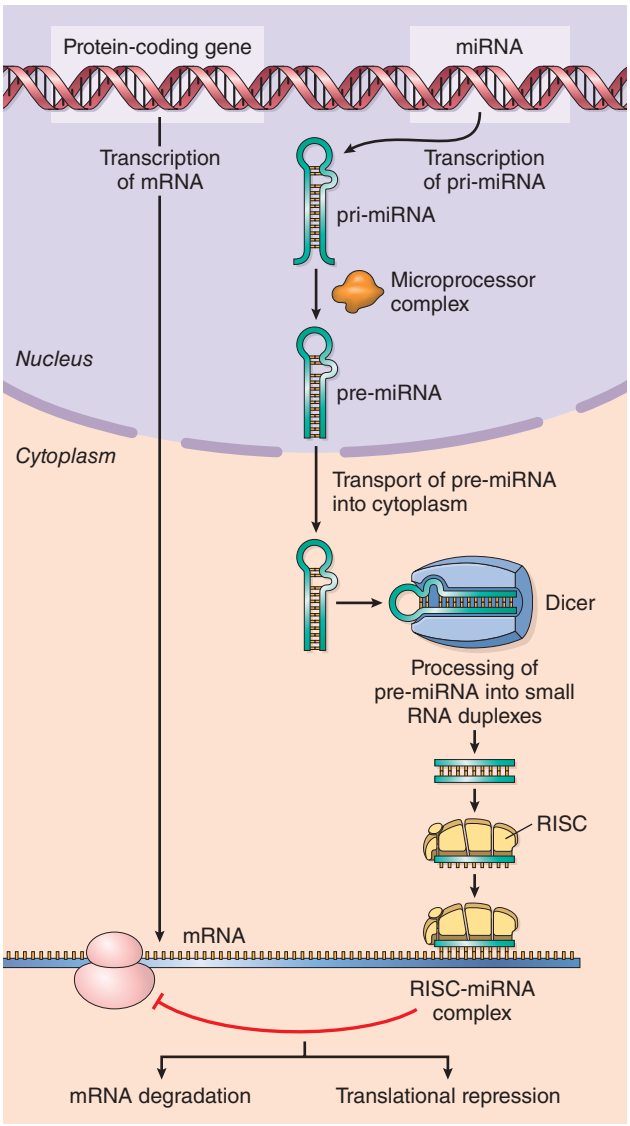

Figure 3.10 Regulation of gene expression by microRNA (miRNA). Primary miRNA (pri-miRNA), the primary transcripts of a gene processed in the cell nucleus by the microprocessor complex, are converted to pre-miRNAs. These pre-miRNAs are then further processed in the cytoplasm by *dicer*, an enzyme that helps assemble an RNA-induced silencing complex (RISC) and generates miRNAs. The miRNAs regulate gene expression by binding to the complementary region of the RNA and repressing translation or promoting degradation of the messenger RNA (mRNA) before it can be translated by the ribosome.

therefore often called *noncoding RNA*. The miRNAs are processed by the cell into molecules that are complementary to mRNA and act to decrease gene expression. The generation of miRNAs involves special processing of longer primary precursor RNAs called *pri-miRNAs*, which are the primary transcripts of the gene. The pri-miRNAs are then processed in the cell nucleus by the *microprocessor complex* to pre-miRNAs, which are 70-nucleotide, stem loop structures. These pre-miRNAs are then further processed in the cytoplasm by a specific *dicer enzyme* that helps assemble an *RNA-induced silencing complex* (RISC) and generates miRNAs.

The miRNAs regulate gene expression by binding to the complementary region of the RNA and promoting repression of translation or degradation of the mRNA before it can be translated by the ribosome. miRNAs are believed to play an important role in normal regulation of cell function, and alterations in miRNA function have been associated with diseases such as cancer and heart disease.

Another type of miRNA is *small interfering RNA* (siRNA), also called *silencing RNA* or *short interfering RNA*. The siRNAs are short, double-stranded RNA molecules, composed of 20 to 25 nucleotides, that interfere with expression of specific genes. siRNAs generally refer to synthetic miRNAs and can be administered to silence expression of specific genes. They are designed to avoid nuclear processing by the microprocessor complex and, after the siRNA enters the cytoplasm, it activates the RISC silencing complex, blocking the translation of mRNA. Because siRNAs can be tailored for any specific sequence in the gene, they can be used to block translation of any mRNA and therefore expression by any gene for which the nucleotide sequence is known. Researchers have proposed that siRNAs may become useful therapeutic tools to silence genes that contribute to the pathophysiology of diseases.

TRANSLATION—FORMATION OF PROTEINS ON THE RIBOSOMES

When a molecule of mRNA comes in contact with a ribosome, it travels through the ribosome, beginning at a predetermined end of the RNA molecule specified by an appropriate sequence of RNA bases called the *chain-initiating codon*. Then, as shown in **Fig. 3.9**, while the mRNA travels through the ribosome, a protein molecule is formed, a process called *translation*. Thus, the ribosome reads the codons of the mRNA in much the same way that a tape is read as it passes through the playback head of a tape recorder. Then, when a "stop" (or "chain-terminating") codon slips past the ribosome, the end of a protein molecule is signaled, and the protein molecule is freed into the cytoplasm.

Polyribosomes—A Cluster of Ribosomes. A single mRNA molecule can form protein molecules in several ribosomes at the same time because the initial end of the RNA strand can pass to a successive ribosome as it leaves the first, as shown at the bottom left in **Fig. 3.9** and **Fig. 3.11**. The protein molecules are in different stages of development in each ribosome. As a result, clusters of ribosomes frequently occur, with 3 to 10 ribosomes being attached to a single mRNA at the same time. These clusters are called *polyribosomes*.

An mRNA can cause formation of a protein molecule in any ribosome; there is no specificity of ribosomes for given types of protein. The ribosome is simply the physical manufacturing plant in which the chemical reactions take place.

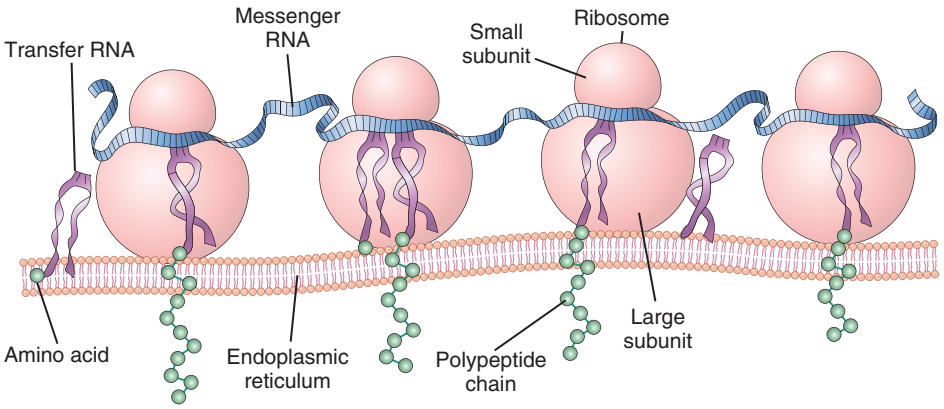

Figure 3.11 The physical structure of the ribosomes, as well as their functional relationship to messenger RNA, transfer RNA, and the endoplasmic reticulum during the formation of protein molecules.

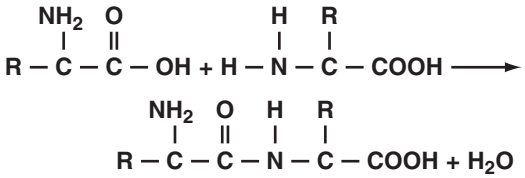
Many Ribosomes Attach to the Endoplasmic Reticulum. In Chapter 2, we noted that many ribosomes become attached to the endoplasmic reticulum. This attachment occurs because the initial ends of many forming protein molecules have amino acid sequences that immediately attach to specific receptor sites on the endoplasmic reticulum, causing these molecules to penetrate the reticulum wall and enter the endoplasmic reticulum matrix. This process gives a granular appearance to the portions of the reticulum where proteins are being formed and are entering the matrix of the reticulum.

Fig. 3.11 shows the functional relationship of mRNA to the ribosomes and the manner in which the ribosomes attach to the membrane of the endoplasmic reticulum. Note the process of translation occurring in several ribosomes at the same time in response to the same strand of mRNA. Note also the newly forming polypeptide (protein) chains passing through the endoplasmic reticulum membrane into the endoplasmic matrix.



Except in glandular cells, in which large amounts of protein-containing secretory vesicles are formed, most proteins synthesized by the ribosomes are released directly into the cytosol instead of into the endoplasmic reticulum. These proteins are enzymes and internal structural proteins of the cell.

Chemical Steps in Protein Synthesis. Some of the chemical events that occur in the synthesis of a protein molecule are shown in **Fig. 3.12**. This figure shows representative reactions for three separate amino acids, AA_1, AA_2, and AA_{20}. The stages of the reactions are as follows:

1. Each amino acid is *activated* by a chemical process in which ATP combines with the amino acid to form an *adenosine monophosphate (AMP) complex with the amino acid*, giving up two high-energy phosphate bonds in the process.
2. The activated amino acid, having an excess of energy, then *combines with its specific tRNA to form an amino acid–tRNA complex* and, at the same time, releases the AMP.
3. The tRNA carrying the amino acid complex then comes in contact with the mRNA molecule in the ribosome, where the anticodon of the tRNA attaches temporarily to its specific codon of the mRNA, thus lining up the amino acid in the appropriate sequence to form a protein molecule.

Then, under the influence of the enzyme *peptidyl transferase* (one of the proteins in the ribosome), *peptide bonds* are formed between the successive amino acids, thus adding progressively to the protein chain. These chemical events require energy from two additional high-energy phosphate bonds, making a total of four high-energy bonds used for each amino acid added to the protein chain. Thus, the synthesis of proteins is one of the most energy-consuming processes of the cell.

Peptide Linkage—Combination of Amino Acids. The successive amino acids in the protein chain combine with one another according to the typical reaction.

In this chemical reaction, a hydroxyl radical (OH^-) is removed from the COOH portion of the first amino acid, and a hydrogen (H^+) of the NH_2 portion of the other amino acid is removed. These combine to form water, and the two reactive sites left on the two successive amino acids bond with each other, resulting in a single molecule. This process is called *peptide linkage*. As each additional amino acid is added, an additional peptide linkage is formed.

PROTEIN ENZYMES CONTROL SYNTHESIS OF OTHER SUBSTANCES IN THE CELL

Many thousand protein enzymes formed in the manner just described control essentially all the other chemical reactions that take place in cells. These enzymes promote synthesis of lipids, glycogen, purines, pyrimidines, and hundreds of other substances. We discuss many of these synthetic processes in relation to carbohydrate, lipid, and

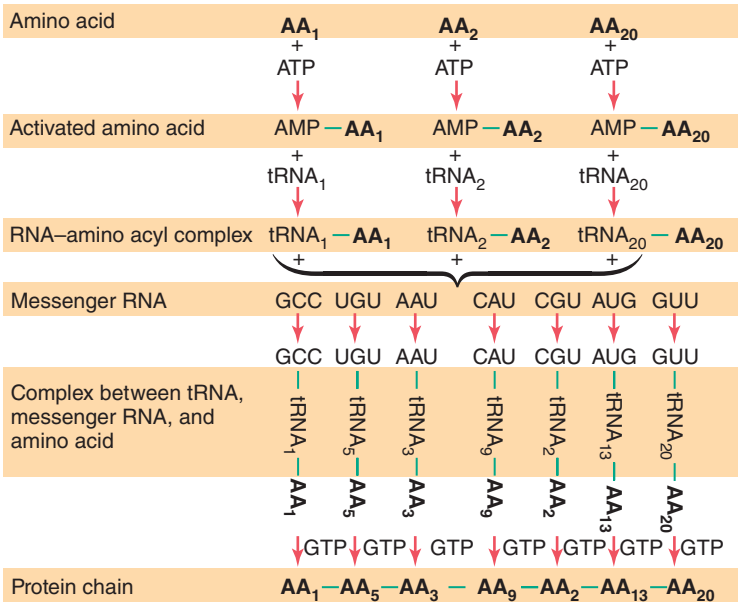


Figure 3.12 Chemical events in the formation of a protein molecule. *AMP*, Adenosine monophosphate; *ATP*, adenosine triphosphate; *GTP*, guanosine triphosphate; *tRNA*, transfer RNA.

protein metabolism in Chapters 68 through 70. These substances each contribute to the various functions of the cells.

REGULATION OF GENE FUNCTION AND BIOCHEMICAL ACTIVITY IN CELLS

Although genes control the physical and chemical functions of the cells, the degree of gene activation must also be controlled; otherwise, some parts of the cell might overgrow or some chemical reactions might overact, causing cell death. Each cell has powerful internal feedback control mechanisms that keep the various functional operations of the cell in step with one another. For each gene (~20,000–25,000 genes in all), at least one such feedback mechanism exists.

There are basically two methods whereby cell biochemical activities are controlled: (1) *genetic regulation*, in which the degrees of gene activation and formation of gene products are controlled, and (2) *enzyme regulation*, in which the activity levels of already formed enzymes in the cell are controlled.

GENETIC REGULATION

Genetic regulation, or regulation of *gene expression*, covers the entire process from transcription of the genetic code in the nucleus to formation of proteins in the cytoplasm. Regulation of gene expression provides all living organisms with the ability to respond to changes in their environment. In animals that have many different types of cells, tissues, and organs, differential regulation of gene expression also permits the various cell types in the body to each perform their specialized functions. Although a cardiac myocyte contains the same genetic code as a renal tubular epithelial cell, many genes are expressed in cardiac cells that are not expressed in renal tubular cells. The

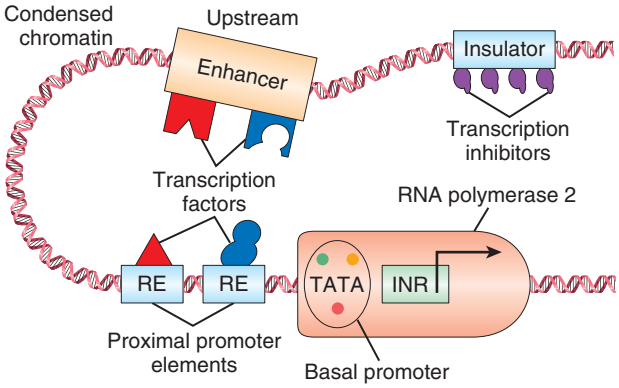

Figure 3.13 Gene transcription in eukaryotic cells. A complex arrangement of multiple clustered enhancer modules is interspersed with insulator elements, which can be located upstream or downstream of a basal promoter containing TATA box (TATA), proximal promoter elements (response elements, RE), and initiator sequences (INR).

ultimate measure of gene "expression" is whether (and how much) of the gene products (proteins) are produced because proteins carry out cell functions specified by the genes. Regulation of gene expression can occur at any point in the pathways of transcription, RNA processing, and translation.

Promoters Control Gene Expression. Synthesis of cellular proteins is a complex process that starts with transcription of DNA into RNA. Transcription of DNA is controlled by regulatory elements found in the promoter of a gene (**Fig. 3.13**). In eukaryotes, which includes all mammals, the basal promoter consists of a sequence of bases (TATAAA) called the *TATA box*, the binding site for the *TATA-binding protein* and several other important *transcription factors* that are collectively referred to as the *transcription factor IID complex*. In addition to the transcription factor IID complex, this region is where transcription factor IIB binds to both the DNA and RNA polymerase 2 to facilitate

transcription of the DNA into RNA. This basal promoter is found in all protein-coding genes, and the polymerase must bind with this basal promoter before it can begin traveling along the DNA strand to synthesize RNA. The *upstream promoter* is located farther upstream from the transcription start site and contains several binding sites for positive or negative transcription factors that can affect transcription through interactions with proteins bound to the basal promoter. The structure and transcription factor binding sites of the upstream promoter vary from gene to gene to give rise to the different expression patterns of genes in different tissues.

Transcription of genes in eukaryotes is also influenced by *enhancers*, which are regions of DNA that can bind transcription factors. Enhancers can be located a great distance from the gene they act on or even on a different chromosome. They can also be located upstream or downstream of the gene that they regulate. Although enhancers may be located far from their target gene, they may be relatively close when DNA is coiled in the nucleus. It is estimated that there are more than 100,000 gene enhancer sequences in the human genome.

In the organization of the chromosome, it is important to separate active genes that are being transcribed from genes that are repressed. This separation can be challenging because multiple genes may be located close together on the chromosome. The separation is achieved by chromosomal *insulators*. These insulators are gene sequences that provide a barrier so that a specific gene is isolated against transcriptional influences from surrounding genes. Insulators can vary greatly in their DNA sequence and the proteins that bind to them. One way an insulator activity can be modulated is by *DNA methylation*, which is the case for the mammalian insulin-like growth factor 2 (IGF-2) gene, for example. The mother's allele has an insulator between the enhancer and promoter of the gene that allows for the binding of a transcriptional repressor. However, the paternal DNA sequence is methylated such that the transcriptional repressor cannot bind to the insulator, and the IGF-2 gene is expressed from the paternal copy of the gene.

Other Mechanisms for Control of Transcription By the Promoter. Variations in the basic mechanism for control of the promoter continue to be discovered. Without giving details, let us list some of them:

1. A promoter is frequently controlled by transcription factors located elsewhere in the genome. That is, the regulatory gene causes the formation of a regulatory protein that in turn acts as an activator or repressor of transcription.
2. Occasionally, many different promoters are controlled at the same time by the same regulatory protein. In some cases, the same regulatory protein functions as an activator for one promoter and as a repressor for another promoter.
3. Some proteins are controlled not at the starting point of transcription on the DNA strand but farther along the strand. Sometimes, the control is not even at the DNA strand but occurs during the processing of the RNA molecules in the nucleus before they are released into the cytoplasm. Control may also occur at the level of protein formation in the cytoplasm during RNA translation by the ribosomes.
4. In nucleated cells, the nuclear DNA is packaged in specific structural units, the *chromosomes*. Within each chromosome, the DNA is wound around small proteins called *histones*, which in turn are held tightly together in a compacted state by additional proteins. As long as the DNA is in this compacted state, it cannot function to form RNA. However, multiple control mechanisms can cause selected areas of chromosomes to become decompacted one part at a time so that partial RNA transcription can occur. Even then, specific *transcriptor factor*s control the actual rate of transcription by the promoter in the chromosome. Thus, still higher orders of control are used to establish proper cell function. In addition, signals from outside the cell, such as some of the body's hormones, can activate specific chromosomal areas and specific transcription factors, therefore controlling the chemical machinery for function of the cell.

Because there are many thousands of different genes in each human cell, the large number of ways in which genetic activity can be controlled is not surprising. The gene control systems are especially important for controlling intracellular concentrations of amino acids, amino acid derivatives, and intermediate substrates and products of carbohydrate, lipid, and protein metabolism.

CONTROL OF INTRACELLULAR FUNCTION BY ENZYME REGULATION

In addition to control of cell function by genetic regulation, cell activities are also controlled by intracellular inhibitors or activators that act directly on specific intracellular enzymes. Thus, enzyme regulation represents a second major category of mechanisms whereby cellular biochemical functions can be controlled.

Enzyme Inhibition. Some chemical substances formed in the cell have direct feedback effects to inhibit the specific enzyme systems that synthesize them. Almost always, the synthesized product acts on the first enzyme in a sequence, rather than on the subsequent enzymes, often binding directly with the enzyme and causing an allosteric conformational change that inactivates it. One can readily recognize the importance of inactivating the first enzyme because this prevents buildup of intermediary products that are not used.

Enzyme inhibition is another example of negative feedback control. It is responsible for controlling intracellular concentrations of multiple amino acids, purines, pyrimidines, vitamins, and other substances.

Enzyme Activation. Enzymes that are normally inactive often can be activated when needed. An example of this phenomenon occurs when most of the ATP has been depleted in a cell. In this case, a considerable amount of cyclic adenosine monophosphate (cAMP) begins to be formed as a breakdown product of ATP. The presence of this cAMP, in turn, immediately activates the glycogen-splitting enzyme phosphorylase, liberating glucose molecules that are rapidly metabolized, with their energy used for replenishment of the ATP stores. Thus, cAMP acts as an enzyme activator for the enzyme phosphorylase and thereby helps control intracellular ATP concentration.

Another interesting example of both enzyme inhibition and enzyme activation occurs in the formation of the purines and pyrimidines. These substances are needed by the cell in approximately equal quantities for the formation of DNA and RNA. When purines are formed, they *inhibit* the enzymes that are required for formation of additional purines. However, they *activate* the enzymes for formation of pyrimidines. Conversely, the pyrimidines inhibit their own enzymes but activate the purine enzymes. In this way, there is continual cross-talk between the synthesizing systems for these two substances, resulting in almost exactly equal amounts of the two substances in the cells at all times.

Summary. There are two principal mechanisms whereby cells control proper proportions and quantities of different cellular constituents: (1) genetic regulation and (2) enzyme regulation. The genes can be activated or inhibited, and likewise, the enzyme systems can be activated or inhibited. These regulatory mechanisms usually function as feedback control systems that continually monitor the cell's biochemical composition and make corrections as needed. Occasionally, substances from outside the cell (especially some of the hormones discussed in this text) also control the intracellular biochemical reactions by activating or inhibiting one or more of the intracellular control systems.

THE DNA–GENETIC SYSTEM CONTROLS CELL REPRODUCTION

Cell reproduction is another example of the ubiquitous role that the DNA–genetic system plays in all life processes. The genes and their regulatory mechanisms determine cell growth characteristics and when, or whether, cells will divide to form new cells. In this way, the all-important genetic system controls each stage in the development of the human, from the single-cell fertilized ovum to the whole functioning body. Thus, if there is any central theme to life, it is the DNA–genetic system.

Life Cycle of the Cell

The life cycle of a cell is the period from cell reproduction to the next cell reproduction. When mammalian cells *are not inhibited and are reproducing as rapidly as they can*, this life cycle may be as little as 10 to 30 hours. It is terminated by a series of distinct physical events called *mitosis* that cause division of the cell into two new daughter cells. The events of mitosis are shown in **Fig. 3.14** and described later. The actual stage of mitosis, however, lasts for only about 30 minutes, and thus more than 95% of the life cycle of even rapidly reproducing cells is represented by the interval between mitosis, called *interphase*.

Except in special conditions of rapid cellular reproduction, inhibitory factors almost always slow or stop the uninhibited life cycle of the cell. Therefore, different cells of the body actually have life cycle periods that vary from as little as 10 hours for highly stimulated bone marrow cells to an entire lifetime of the human body for many nerve cells.

Cell Reproduction Begins With Replication of DNA

The first step of cell reproduction is *replication (duplication) of all DNA in the chromosomes*. It is only after this replication has occurred that mitosis can take place.

The DNA begins to be duplicated 5 to 10 hours before mitosis, and the duplication is completed in 4 to 8 hours. The net result is two exact *replicas* of all DNA. These replicas become the DNA in the two new daughter cells

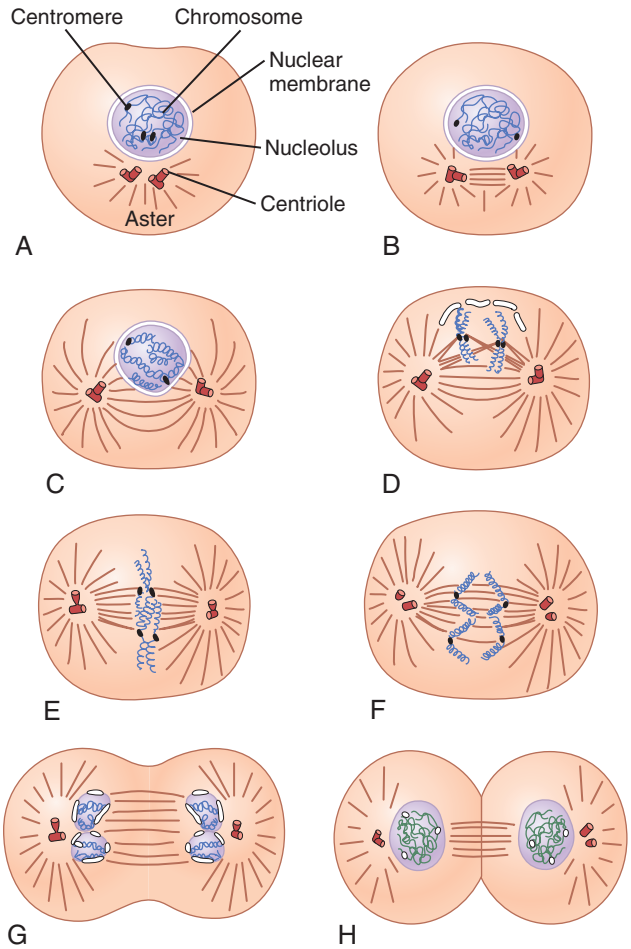

Figure 3.14 Stages of cell reproduction. (A–C) Prophase. (D) Prometaphase. (E) Metaphase. (F) Anaphase. (G–H) Telophase.

that will be formed at mitosis. After replication of the DNA, there is another period of 1 to 2 hours before mitosis begins abruptly. Even during this period, preliminary changes that will lead to the mitotic process are beginning to take place.

DNA Replication. DNA is replicated in much the same way that RNA is transcribed from DNA, except for a few important differences:

1. Both strands of the DNA in each chromosome are replicated, not just one of them.
2. Both entire strands of the DNA helix are replicated from end to end, rather than small portions of them, as occurs in the transcription of RNA.
3. Multiple enzymes called *DNA polymerase*, which is comparable to RNA polymerase, are essential for replicating DNA. The DNA polymerase attaches to and moves along the DNA template strand, adding nucleotides in the 5′ to 3′ direction. Another enzyme, *DNA ligase*, causes bonding of successive DNA nucleotides to one another, using high-energy phosphate bonds to energize these attachments.
4. *Replication fork formation*. Before DNA can be replicated, the double-stranded molecule must be "unzipped" into two single strands (**Fig. 3.15**). Because the DNA helixes in each chromosome are approximately 6 centimeters in length and have millions of helical turns, it would be impossible for the two newly formed DNA helixes to uncoil from each other were it not for some special mechanism. This uncoiling is achieved by *DNA helicase* enzymes that break the hydrogen bonding between the base pairs of the DNA, permitting the two strands to separate into a Y shape known as the *replication fork*, the area that will be the template for replication to begin.

   DNA is directional in both strands, signified by a 5′ and 3′ end (**Fig. 3.15**). Replication progresses only in the 5′ to 3′ direction. At the replication fork one strand, the *leading strand*, is oriented in the 3′ to 5′ direction, toward the replication fork, while the *lagging strand* is oriented 5′ to 3′, away from the replication fork. Because of their different orientations, the two strands are replicated differently.
5. *Primer binding*. Once the DNA strands have been separated, a short piece of RNA called an *RNA primer* binds to the 3′ end of the leading strand. Primers are generated by the enzyme *DNA primase*. Primers always bind as the starting point for DNA replication.
6. *Elongation*. DNA polymerases are responsible for creating the new strand by a process called *elongation*. Because replication proceeds in the 5′ to 3′ direction on the leading strand, the newly formed strand is continuous. The lagging strand begins replication by binding with multiple primers that are only several bases apart. DNA polymerase then adds pieces of DNA, called *Okazaki fragments*, to the strand between primers. This process of replication is discontinuous because the newly created Okazaki fragments are not yet connected. An enzyme, *DNA ligase*, joins the Okazaki fragments to form a single unified strand.
7. *Termination*. After the continuous and discontinuous strands are both formed, the enzyme *exonuclease* removes the RNA primers from the original strands, and the primers are replaced with appropriate bases. Another exonuclease "proofreads" the newly formed DNA, checking and clipping off any mismatched or unpaired residues.

Another enzyme, *topoisomerase*, can transiently break the phosphodiester bond in the backbone of the DNA strand to prevent the DNA in front of the replication fork from being overwound. This reaction is reversible, and the phosphodiester bond reforms as the topoisomerase leaves.

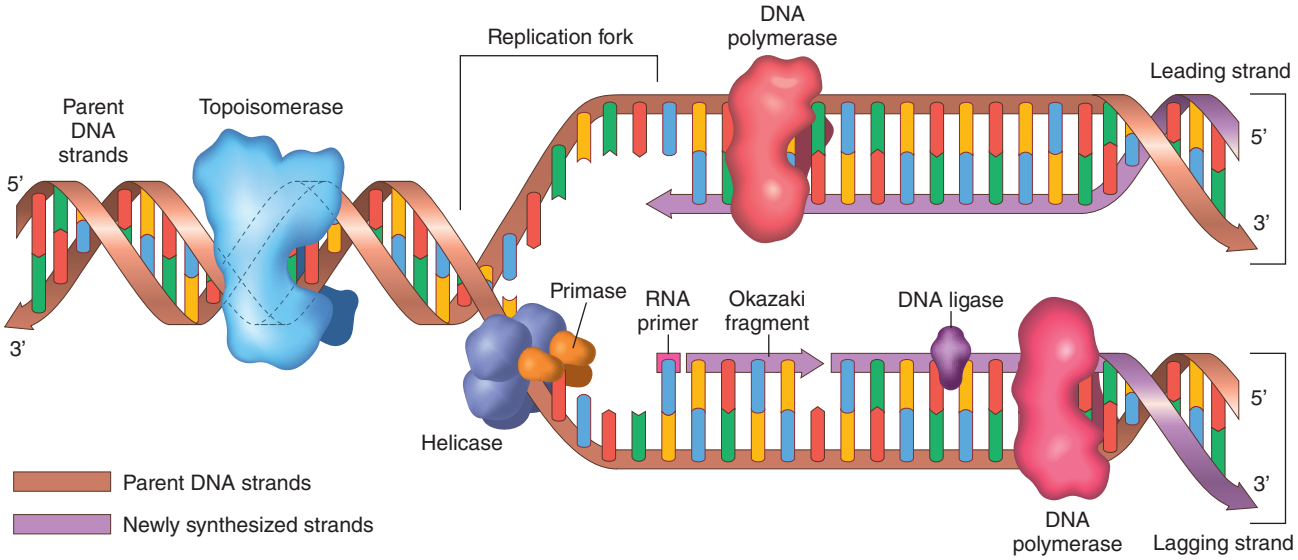

Figure 3.15 DNA replication, showing the replication fork and leading and lagging strands of DNA.

Once completed, the parent strand and its complementary DNA strand coils into the double helix shape. The process of replication therefore produces two DNA molecules, each with one strand from the parent DNA and one new strand. For this reason, DNA replication is often described as *semiconservative*; half of the chain is part of the original DNA molecule and half is brand new.

DNA Repair, DNA "Proofreading," and "Mutations." During the hour or so between DNA replication and the beginning of mitosis, there is a period of active repair and "proofreading" of the DNA strands. Although DNA replication is a highly accurate process, mistakes may occasionally occur, such as a DNA polymerase inserting an incorrect base. Wherever inappropriate DNA nucleotides have been matched up with the nucleotides of the original template strand, special enzymes cut out the defective areas and replace them with appropriate complementary nucleotides. This repair process, which is achieved by the same DNA polymerases and DNA ligases that are used in replication, is referred to as *DNA proofreading*.

Because of repair and proofreading, mistakes are rarely made in the DNA replication process. When a mistake is made, it is called a *mutation*. The mutation may cause formation of some abnormal protein in the cell rather than a needed protein, which may lead to abnormal cellular function and sometimes even cell death. Given that many thousands of genes exist in the human genome and that the period from one human generation to another is about 30 years, one would expect 10 or more mutations in the passage of the genome from parent to offspring. As a further protection, however, each human genome is represented by two separate sets of chromosomes, one derived from each parent, with almost identical genes. Therefore, one functional gene of each pair is almost always available to the child, despite mutations.

CHROMOSOMES AND THEIR REPLICATION

The chromosomes are formed by a mixture of DNA and other proteins, which together are referred to as *chromatin*. The human cell contains 46 chromosomes arranged in 23 pairs. Most of the genes in the two chromosomes of each pair are identical or almost identical to each other, so it is often stated that the different genes also exist in pairs, although occasionally this is not the case.

Organization and Packaging of DNA in Chromosomes. In humans, about 6 feet of DNA (if uncoiled) must be packed into a cell nucleus with a diameter of only about 6 micrometers, or one-tenth the diameter of an average human hair. To accomplish this packaging, DNA is wrapped around many small molecules of electropositively charged *histones* (**Fig. 3.16**). The histones are organized into vast numbers of bobbin-like cores with small segments of each DNA helix coiled sequentially around one core after another. Histones pack the DNA

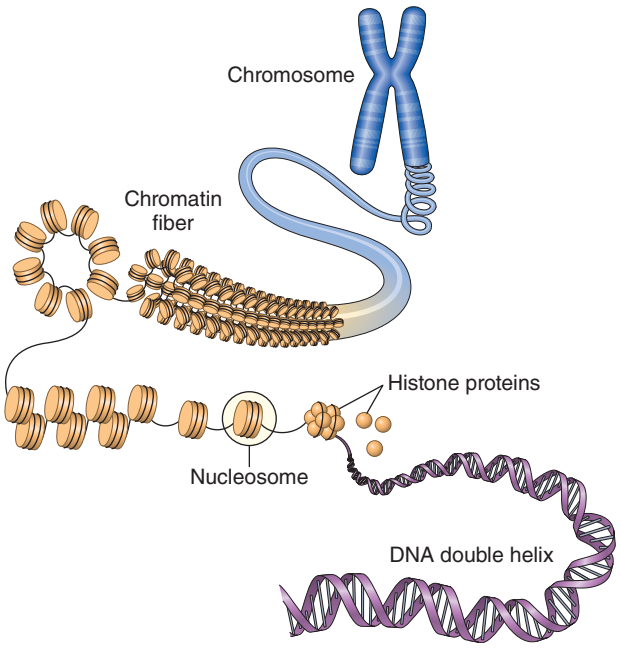

Figure 3.16 Organization and packaging of DNA in chromosomes.

into structural units called *nucleosomes*, the basic repeating subunits of chromatin in the chromosome. When the chromatin is densely packed (*heterochromatin*), transcription of the DNA cannot occur. Open chromatin (*euchromatin*) is loosely packed and transcription can occur.

The histone cores therefore play an important role in regulating DNA activity because as long as the DNA is packaged tightly, it cannot function as a template for RNA formation or replication of new DNA. Furthermore, some of the regulatory proteins *decondense* the histone packaging of the DNA and allow small segments at a time to form RNA. Histones can also undergo posttranslational modifications that influence their interaction with proteins and the DNA and therefore influence gene expression.

Several nonhistone proteins are also major components of chromosomes, functioning as chromosomal structural proteins and, in connection with the genetic regulatory machinery, as activators, inhibitors, and enzymes.

Replication of the chromosomes in their entirety occurs during the next few minutes after replication of the DNA helixes has been completed; the new DNA helixes collect new protein molecules as needed. The two newly formed chromosomes remain attached to each other (until time for mitosis) at a point called the *centromere* located near their center. These duplicated but still attached chromosomes are called *chromatids*.

CELL MITOSIS

The actual process whereby the cell splits into two new cells is called *mitosis*. Once each chromosome has been replicated to form the two chromatids, mitosis follows automatically within 1 or 2 hours in many cells.

Mitotic Apparatus: Function of the Centrioles. One of the first events of mitosis takes place in the cytoplasm in or around the small structures called *centrioles* during the latter part of interphase. As shown in **Fig. 3.14**, two pairs of centrioles lie close to each other near one pole of the nucleus. These centrioles, like the DNA and chromosomes, are also replicated during interphase, usually shortly before DNA replication. Each centriole is a small cylindrical body about 0.4 micrometer long and about 0.15 micrometer in diameter, consisting mainly of nine parallel tubular structures arranged in the form of a cylinder. The two centrioles of each pair lie at right angles to each other. Each pair of centrioles, along with attached *pericentriolar material*, is called a *centrosome*.

Shortly before mitosis takes place, the two pairs of centrioles begin to move apart from each other. This movement is caused by polymerization of protein microtubules growing between the respective centriole pairs and actually pushing them apart. At the same time, other microtubules grow radially away from each of the centriole pairs, forming a spiny star called the *aster*, in each end of the cell. Some of the spines of the aster penetrate the nuclear membrane and help separate the two sets of chromatids during mitosis. The complex of microtubules extending between the two new centriole pairs is called the *spindle*, and the entire set of microtubules plus the two pairs of centrioles is called the *mitotic apparatus*.

Prophase. The first stage of mitosis, called *prophase*, is shown in **Fig. 3.14A–C**. While the spindle is forming, the chromosomes of the nucleus (which in interphase consist of loosely coiled strands) become condensed into well-defined chromosomes.

Prometaphase. During the prometaphase stage (see **Fig. 3.14D**), the growing microtubular spines of the aster fragment the nuclear envelope. At the same time, multiple microtubules from the aster attach to the chromatids at the centromeres, where the paired chromatids are still bound to each other. The tubules then pull one chromatid of each pair toward one cellular pole and its partner toward the opposite pole.

Metaphase. During the metaphase stage (see **Fig. 3.14E**), the two asters of the mitotic apparatus are pushed farther apart. This pushing is believed to occur because the microtubular spines from the two asters, where they interdigitate with each other to form the mitotic spindle, push each other away. Minute contractile protein molecules called "*molecular motors*," which may be composed of the muscle protein *actin*, extend between the respective spines and, using a stepping action as in muscle, actively slide the spines in a reverse direction along each other. Simultaneously, the chromatids are pulled tightly by their attached microtubules to the very center of the cell, lining up to form the *equatorial plate* of the mitotic spindle.

Anaphase. During the anaphase stage (see **Fig. 3.14F**), the two chromatids of each chromosome are pulled apart at the centromere. All 46 pairs of chromatids are separated, forming two separate sets of 46 *daughter chromosomes*. One of these sets is pulled toward one mitotic aster, and the other is pulled toward the other aster, as the two respective poles of the dividing cell are pushed still farther apart.

Telophase. In the telophase stage (see **Fig. 3.14G–H**), the two sets of daughter chromosomes are pushed completely apart. Then, the mitotic apparatus dissipates, and a new nuclear membrane develops around each set of chromosomes. This membrane is formed from portions of the endoplasmic reticulum that are already present in the cytoplasm. Shortly thereafter, the cell pinches in two, midway between the two nuclei. This pinching is caused by the formation of a contractile ring of *microfilaments* composed of *actin* and probably *myosin* (the two contractile proteins of muscle) at the juncture of the newly developing cells that pinches them off from each other.

CONTROL OF CELL GROWTH AND CELL REPRODUCTION

Some cells grow and reproduce all the time, such as the blood-forming cells of the bone marrow, the germinal layers of the skin, and the epithelium of the gut. Many other cells, however, such as smooth muscle cells, may not reproduce for many years. A few cells, such as the neurons and most striated muscle cells, generally do not reproduce during the entire life of a person, except during the original period of fetal life.

In certain tissues, an insufficiency of some types of cells causes them to grow and reproduce rapidly until appropriate numbers of these cells are again available. For example, in some young animals, seven-eighths of the liver can be removed surgically, and the cells of the remaining one-eighth will grow and divide until the liver mass returns to almost normal. The same phenomenon occurs for many glandular cells and most cells of the bone marrow, subcutaneous tissue, intestinal epithelium, and almost any other tissue except highly differentiated cells such as nerve and muscle cells.

The mechanisms that maintain proper numbers of the different types of cells in the body are still poorly understood. However, experiments have shown at least three ways in which growth can be controlled. First, growth often is controlled by *growth factors* that come from other parts of the body. Some of these growth factors circulate in the blood, but others originate in adjacent tissues. For example, epithelial cells of some glands, such as the pancreas, fail to grow without a growth factor from the underlying connective tissue of the gland. Second, most normal cells stop growing when they have run out of space for growth. This phenomenon occurs when cells are grown in tissue culture; the cells grow until they contact a solid object, and then growth stops. Third, cells grown in tissue culture often stop growing when minute amounts of their own secretions are allowed to collect in the culture

medium. This mechanism, too, could provide a means for negative feedback control of growth.

Telomeres Prevent Degradation of Chromosomes. A *telomere* is a region of repetitive nucleotide sequences located at each end of a chromatid (**Fig. 3.17**). Telomeres serve as protective caps that prevent deterioration of the chromosome during cell division. During cell division, a short piece of "primer" RNA attaches to the DNA strand to start the replication. However, because the primer does not attach at the very end of the DNA strand, the copy is missing a small section of the DNA. With each cell division, the copied DNA loses additional nucleotides from the telomere region. The nucleotide sequences provided by the telomeres therefore prevent the degradation of genes near the ends of chromosomes. Without telomeres, the genomes would progressively lose information and be truncated after each cell division. Thus, the telomeres can be considered to be disposable chromosomal buffers that help maintain stability of the genes but are gradually consumed during repeated cell divisions.

Each time a cell divides, an average person loses 30 to 200 base pairs from the ends of that cell's telomeres. In human blood cells, the length of telomeres ranges from 8000 base pairs at birth to as low as 1500 in older people. Eventually, when the telomeres shorten to a critical length, the chromosomes become unstable, and the cells die. This process of telomere shortening is believed to be an important reason for some of the physiological changes associated with aging. Telomere erosion can also occur as a result of diseases, especially those associated with oxidative stress and inflammation.

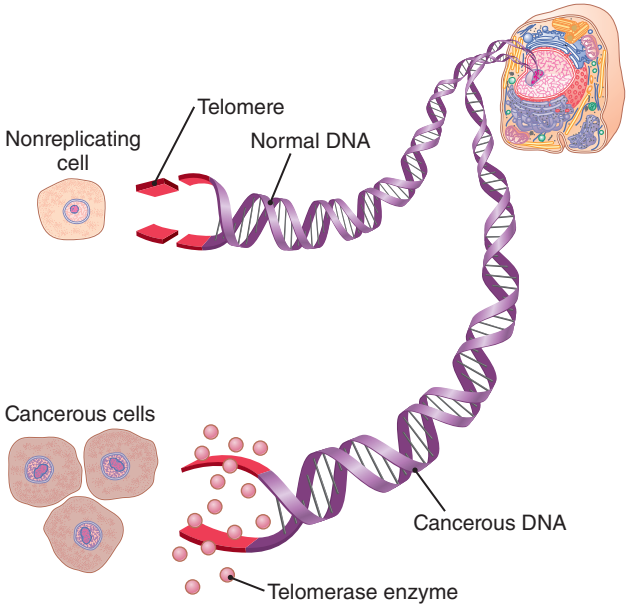

Figure 3.17 Control of cell replication by telomeres and telomerase. The cells' chromosomes are capped by telomeres, which, in the absence of telomerase activity, shorten with each cell division until the cell stops replicating. Therefore, most cells of the body cannot replicate indefinitely. In cancer cells, telomerase is activated, and telomere length is maintained so that the cells continue to replicate themselves uncontrollably.

In some cells, such as stem cells of the bone marrow or skin that must be replenished throughout life, or germ cells in the ovaries and testes, the enzyme *telomerase* adds bases to the ends of the telomeres so that many more generations of cells can be produced. However, telomerase activity is usually low in most cells of the body, and after many generations the descendant cells will inherit defective chromosomes, become *senescent*, and cease dividing. This process of telomere shortening is important in regulating cell proliferation and maintaining gene stability. In cancer cells, telomerase activity is abnormally activated so that telomere length is maintained, making it possible for the cells to replicate over and over again uncontrollably (see **Fig. 3.17**). Some scientists have therefore proposed that telomere shortening protects us from cancer and other proliferative diseases.

CELL DIFFERENTIATION

A special characteristic of cell growth and cell division is *cell differentiation*, which refers to changes in the physical and functional properties of cells as they proliferate in the embryo to form the different body structures and organs. The following description of an interesting experiment helps explain these processes.

When the nucleus from an intestinal mucosal cell of a frog is surgically implanted into a frog ovum from which the original ovum nucleus was removed, the result is often the formation of a normal frog. This experiment demonstrates that even the intestinal mucosal cell, which is a well-differentiated cell, carries all the necessary genetic information for development of all structures of the frog's body.

Therefore, it has become clear that cell differentiation results not from loss of genes but from selective repression of different gene promoters. In fact, electron micrographs suggest that some segments of DNA helixes that are wound around histone cores become so condensed that they no longer uncoil to form RNA molecules. One explanation for this is that the cellular genome begins at a certain stage of cell differentiation to produce a *regulatory protein* that forever after represses a select group of genes. Therefore, the repressed genes never function again. Regardless of the mechanism, mature human cells each produce a maximum of about 8000 to 10,000 proteins rather than the potential 20,000 to 25,000 or more that would be produced if all genes were active.

Embryological experiments have shown that certain cells in an embryo control differentiation of adjacent cells. For example, the *primordial chordamesoderm* is called the *primary organizer* of the embryo because it forms a focus around which the remainder of the embryo develops. It differentiates into a *mesodermal axis* that contains segmentally arranged *somites* and, as a result of *inductions* in the surrounding tissues, causes the formation of essentially all the organs of the body.

Another instance of induction occurs when the developing eye vesicles come into contact with the ectoderm

of the head and cause the ectoderm to thicken into a lens plate that folds inward to form the lens of the eye. Therefore, a large share of the embryo develops as a result of such inductions, with one part of the body affecting another part, and this part affecting still other parts.

Thus, although our understanding of cell differentiation is still hazy, we are aware of many control mechanisms whereby differentiation *could* occur.

APOPTOSIS—PROGRAMMED CELL DEATH

The many trillions of cells in the body are members of a highly organized community in which the total number of cells is regulated not only by controlling the rate of cell division but also by controlling the rate of cell death. When cells are no longer needed or become a threat to the organism, they undergo a suicidal *programmed cell death*, or *apoptosis*. This process involves a specific proteolytic cascade that causes the cell to shrink and condense, disassemble its cytoskeleton, and alter its cell surface so that a neighboring phagocytic cell, such as a macrophage, can attach to the cell membrane and digest the cell.

In contrast to programmed death, cells that die as a result of an acute injury usually swell and burst due to loss of cell membrane integrity, a process called cell *necrosis*. Necrotic cells may spill their contents, causing inflammation and injury to neighboring cells. Apoptosis, however, is an orderly cell death that results in disassembly and phagocytosis of the cell before leakage of its contents occurs, and neighboring cells usually remain healthy.

Apoptosis is initiated by activation of a family of proteases called *caspases*, which are enzymes that are synthesized and stored in the cell as inactive *procaspases*. The mechanisms of activation of caspases are complex but, once activated, the enzymes cleave and activate other procaspases, triggering a cascade that rapidly breaks down proteins within the cell. The cell thus dismantles itself, and its remains are rapidly digested by neighboring phagocytic cells.

A tremendous amount of apoptosis occurs in tissues that are being remodeled during development. Even in adult humans, billions of cells die each hour in tissues such as the intestine and bone marrow and are replaced by new cells. Programmed cell death, however, is normally balanced by formation of new cells in healthy adults. Otherwise, the body's tissues would shrink or grow excessively. Abnormalities of apoptosis may play a key role in neurodegenerative diseases such as Alzheimer disease, as well as in cancer and autoimmune disorders. Some drugs that have been used successfully for chemotherapy appear to induce apoptosis in cancer cells.

CANCER

Cancer may be caused by *mutation* or by some other *abnormal activation* of cellular genes that control cell growth and cell mitosis. *Proto-oncogenes* are normal genes that code for various proteins that control cell adhesion, growth, and division. If mutated or excessively activated, proto-oncogenes can become abnormally functioning *oncogenes* capable of causing cancer. As many as 100 different oncogenes have been discovered in human cancers.

Also present in all cells are *antioncogenes*, also called *tumor suppressor genes*, which suppress the activation of specific oncogenes. Therefore, loss or inactivation of antioncogenes can allow activation of oncogenes that lead to cancer.

For several reasons, only a minute fraction of the cells that mutate in the body ever lead to cancer. First, most mutated cells have less survival capability than normal cells, and they simply die.

Second, only a few of the mutated cells that survive become cancerous because most mutated cells still have normal feedback controls that prevent excessive growth.

Third, cells that are potentially cancerous are often destroyed by the body's immune system before they grow into a cancer. Abnormal proteins from mutated cells activate the body's immune system, causing it to form antibodies or sensitized lymphocytes that destroy the cancerous cells. In people whose immune systems have been suppressed, such as in persons taking immunosuppressant drugs after kidney or heart transplantation, the probability that a cancer will develop is multiplied as much as 5-fold.

Fourth, the simultaneous presence of several different activated oncogenes is usually required to cause a cancer. For example, one such gene might promote rapid reproduction of a cell line, but no cancer occurs because another mutant gene is not present simultaneously to form the needed blood vessels.

What is it that causes the altered genes? Considering that many trillions of new cells are formed each year in humans, a better question might be to ask why all of us do not develop millions or billions of mutant cancerous cells. The answer is the incredible precision with which DNA chromosomal strands are replicated in each cell before mitosis can take place, along with the proofreading process that cuts and repairs any abnormal DNA strand before the mitotic process is allowed to proceed. Yet, despite these inherited cellular precautions, probably one newly formed cell in every few million still has significant mutant characteristics.

Thus, chance alone is all that is required for mutations to take place, so some cancers could occur merely as the result of an unlucky occurrence. However, the probability of mutations can increase substantially when a person is exposed to certain chemical, physical, or biological factors, including the following:

1. *Ionizing radiation*, such as x-rays, gamma rays, particle radiation from radioactive substances, and even exposure to excessive ultraviolet light can predispose individuals to cancer. Ions formed in tissue

cells under the influence of such radiation are highly reactive and can rupture DNA strands, causing many mutations.

2. *Chemical substances* of certain types may also cause mutations. It was discovered long ago that various aniline dye derivatives are likely to cause cancer; thus, workers in chemical plants producing such substances, if unprotected, have a special predisposition to cancer. Chemical substances that cause cancer are called *carcinogens*; those that increase the probability of genetic mutations are called *mutagens*, although not all mutagens are carcinogenic. The carcinogens in cigarette smoke, however, cause at least 85% of lung cancer deaths.
3. *Physical irritants* can also lead to cancer, such as continued abrasion of the linings of the intestinal tract by some types of food. The damage to the tissues leads to rapid mitotic replacement of the cells; the more rapid the mitosis, the greater the chance for mutation.
4. *Hereditary tendency* to cancer occurs in some families. This hereditary tendency results from the fact that most cancers require not one mutation but two or more mutations before cancer occurs. In families that are particularly predisposed to cancer, it is presumed that one or more cancerous genes are already mutated in the inherited genome. Therefore, fewer additional mutations must take place in such family members before a cancer begins to grow. Important gene mutations that can lead to hereditary breast and ovarian cancer, for example, are the *breast cancer 1 (BRCA1)* and *breast cancer 2 (BRCA2) genes*. These genes normally code for proteins that repair damaged DNA and protect against cancer development. However, mutated versions of these genes prevent production of these protective proteins, leading to abnormal cell growth and cancer.
5. *Certain types of oncoviruses* can cause various types of cancer. Some examples of viruses associated with cancers in humans include *human papillomavirus* (HPV), *hepatitis B and hepatitis C virus, Epstein-Barr virus*, *human immunodeficiency virus* (HIV), *human T-cell leukemia virus*, *Kaposi sarcoma–associated herpesvirus* (KSHV), and *Merkel cell polyomavirus*. There are at least two potential ways whereby oncoviruses cause cancer. In the case of DNA viruses, the DNA strand of the virus can insert itself directly into one of the chromosomes, thereby causing a mutation that leads to cancer. In the case of RNA viruses, some of these viruses carry with them an enzyme called *reverse transcriptase* that causes DNA to be transcribed from the RNA. The transcribed DNA then inserts itself into the animal cell genome, leading to cancer.

Invasive Characteristic of Cancer Cells. Major differences between cancer cells and normal cells are as follows:

1. Cancer cells do not respect usual cellular growth limits because they presumably do not require all the same growth factors required for growth of normal cells.
2. Cancer cells are often far less adhesive to one another than are normal cells. Therefore, they tend to wander through the tissues, enter the bloodstream, and be transported all through the body, where they form nidi for numerous new cancerous growths.
3. Some cancers also produce *angiogenic factors* that cause many new blood vessels to grow into the cancer, thus supplying the nutrients required for cancer growth.

Why Do Cancer Cells Kill? Cancer tissue competes with normal tissues for nutrients. Because cancer cells continue to proliferate indefinitely, with their numbers multiplying every day, cancer cells soon demand essentially all the nutrition available to the body or to an essential part of the body. As a result, normal tissues gradually sustain nutritive death.

Some cancers cause disruption of vital organ functions. For example, a lung cancer might replace healthy tissue to the extent that the lungs cannot absorb enough oxygen to maintain tissues in the rest of the body.

Transport of Substances Through Cell Membranes

Fig. 4.1 lists the approximate concentrations of important electrolytes and other substances in the *extracellular fluid* and *intracellular fluid*. Note that extracellular fluid contains a large amount of *sodium* but only a small amount of *potassium*. The opposite is true of intracellular fluid. Also, extracellular fluid contains a large amount of *chloride* ions, whereas intracellular fluid contains very little of these ions. However, the concentrations of *phosphates* and *proteins* in the intracellular fluid are considerably greater than those in the extracellular fluid. These differences are extremely important to the life of the cell. This chapter explains how the differences are achieved by cell membrane transport mechanisms.

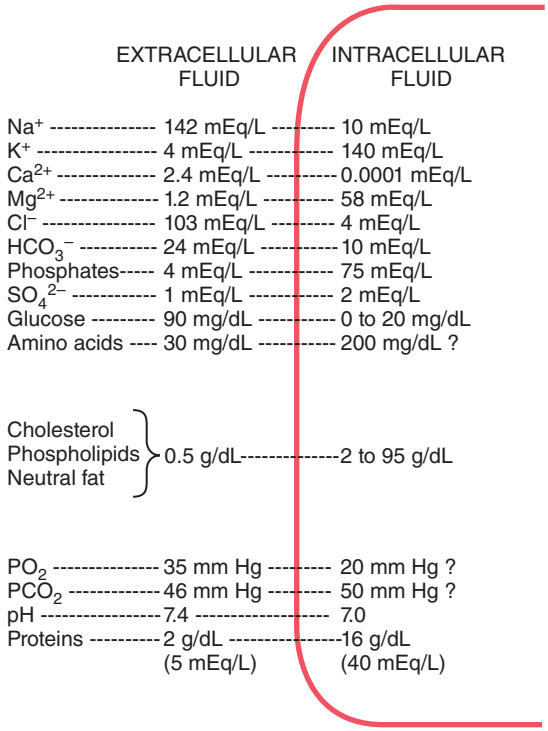

Figure 4.1 Chemical compositions of extracellular and intracellular fluids. The question marks indicate that the precise values for intracellular fluid are unknown. The *red line* indicates the cell membrane.

THE CELL MEMBRANE IS A LIPID BILAYER WITH CELL MEMBRANE TRANSPORT PROTEINS

The structure of the membrane covering the outside of every cell of the body is discussed in Chapter 2 and illustrated in **Fig. 2.3** and **Fig. 4.2**. This membrane consists mainly of a *lipid bilayer* with large numbers of protein molecules in the lipid, many of which penetrate all the way through the membrane.

The lipid bilayer is not miscible with the extracellular fluid or the intracellular fluid. Therefore, it constitutes a barrier against movement of water molecules and water-soluble substances between the extracellular and intracellular fluid compartments. However, as shown in **Fig. 4.2** by the leftmost arrow, lipid-soluble substances can diffuse directly through the lipid substance.

The membrane protein molecules interrupt the continuity of the lipid bilayer, constituting an alternative pathway through the cell membrane. Many of these penetrating proteins can function as *transport proteins*. Some proteins have watery spaces all the way through the molecule and allow nearly free movement of water, as well as selected ions or molecules; these proteins are called *channel proteins*. Other proteins, called *carrier proteins*, bind with molecules or ions that are to be transported, and conformational changes in the protein molecules then move the substances through the interstices of the protein to the other side of the membrane.

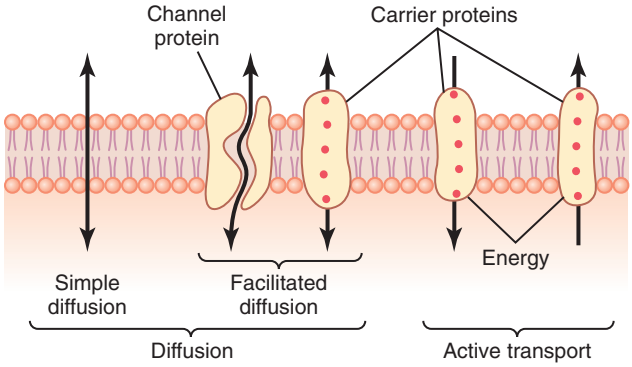

Figure 4.2 Transport pathways through the cell membrane and the basic mechanisms of transport.

Channel proteins and carrier proteins are often selective for the types of molecules or ions that are allowed to cross the membrane.

Diffusion Versus Active Transport. Transport through the cell membrane, either directly through the lipid bilayer or through the proteins, occurs via one of two basic processes, *diffusion* or *active transport*.

Although many variations of these basic mechanisms exist, *diffusion* means random molecular movement of substances molecule by molecule, either through intermolecular spaces in the membrane or in combination with a carrier protein. The energy that causes diffusion is the energy of the normal kinetic motion of matter.

In contrast, *active transport* means movement of ions or other substances across the membrane in combination with a carrier protein in such a way that the carrier protein causes the substance to move against an energy gradient, such as from a low-concentration state to a high-concentration state. This movement requires an additional source of energy besides kinetic energy. A more detailed explanation of the basic physics and physical chemistry of these two processes is provided later in this chapter.

DIFFUSION

All molecules and ions in the body fluids, including water molecules and dissolved substances, are in constant motion. The motion of these particles is what physicists call "heat"—the greater the motion, the higher the temperature—and the motion never ceases, except at absolute zero temperature. When a moving molecule, A, approaches a stationary molecule, B, the electrostatic and other nuclear forces of molecule A repel molecule B, transferring some of the energy of motion of molecule A to molecule B. Consequently, molecule B gains kinetic energy of motion, whereas molecule A slows down, losing some of its kinetic energy. As shown in **Fig. 4.3**, a single molecule in a solution bounces among the other molecules—first in one direction, then another, then another, and so forth—randomly bouncing thousands of times each second. This continual movement of molecules among one another in liquids or gases is called *diffusion*.

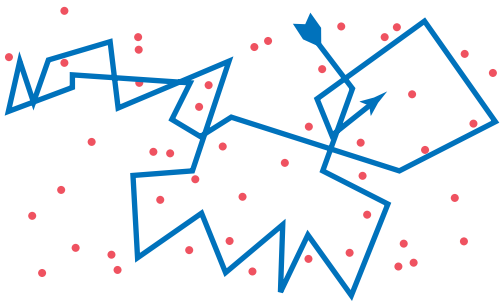

Figure 4.3 Diffusion of a fluid molecule during one thousandth of a second.

Ions diffuse in the same manner as whole molecules, and even suspended colloid particles diffuse in a similar manner, except that the colloids diffuse far less rapidly than molecular substances because of their large size.

DIFFUSION THROUGH THE CELL MEMBRANE

Diffusion through the cell membrane is divided into two subtypes, *simple diffusion* and *facilitated diffusion*. Simple diffusion means that kinetic movement of molecules or ions occurs through a membrane opening or through intermolecular spaces without interaction with carrier proteins in the membrane. The rate of diffusion is determined by the amount of substance available, the velocity of kinetic motion, and the number and sizes of openings in the membrane through which the molecules or ions can move.

Simple diffusion can occur through the interstices of the lipid bilayer if the diffusing substance is lipid-soluble. Facilitated diffusion of a substance can occur through a *channel protein* or by interaction of the substance with a *carrier protein*. Carrier proteins aid passage of molecules or ions through the membrane by binding chemically with them and shuttling them through the membrane in this form (see **Fig. 4.2**).

Diffusion of Lipid-Soluble Substances Through the Lipid Bilayer. The *lipid solubility* of a substance is an important factor for determining how rapidly it diffuses through the lipid bilayer. For example, the lipid solubilities of oxygen, nitrogen, carbon dioxide, and alcohols are high, and all these substances can dissolve directly in the lipid bilayer and diffuse through the cell membrane in the same manner that diffusion of water solutes occurs in a watery solution. The rate of diffusion of each of these substances through the membrane is directly proportional to its lipid solubility. Especially large amounts of oxygen can be transported in this way; therefore, oxygen can be delivered to the interior of the cell almost as though the cell membrane did not exist.

Facilitated Diffusion of Lipid-Insoluble Molecules Through Protein Channels. Even though water is highly insoluble in the membrane lipids, it readily passes through channels in protein molecules that penetrate all the way through the membrane. Many of the body's cell membranes contain protein "pores" called *aquaporins* that selectively permit rapid passage of water through the membrane. The aquaporins are highly specialized, and there are at least 13 different types in various cells of mammals.

The rapidity with which water molecules can diffuse through most cell membranes is astounding. For example, the total amount of water that diffuses in each direction through the red blood cell membrane during each second is about 100 times as great as the volume of the red blood cell.

Other lipid-insoluble molecules can pass through the protein pore channels in the same way as water molecules if they are water-soluble and small enough. However, as they become larger, their penetration falls off rapidly. For example, the diameter of the urea molecule is only 20% greater than that of water, yet its penetration through the cell membrane pores is about 1000 times less than that of water. Even so, given the astonishing rate of water penetration, this amount of urea penetration still allows rapid transport of urea through the membrane within minutes.

DIFFUSION THROUGH PROTEIN PORES AND CHANNELS—SELECTIVE PERMEABILITY AND "GATING" OF CHANNELS

Computerized three-dimensional reconstructions of protein pores and channels have demonstrated tubular pathways all the way from the extracellular to the intracellular fluid. Therefore, substances can move by diffusion directly along these pores and channels from one side of the membrane to the other.

Pores are composed of integral cell membrane proteins that form open tubes through the membrane and are always open. However, the diameter of a pore and its electrical charges provide selectivity that permits only certain molecules to pass through. For example, *aquaporins* permit rapid passage of water through cell membranes but exclude other molecules. Aquaporins have a narrow pore that permits water molecules to diffuse through the membrane in single file. The pore is too narrow to permit passage of any hydrated ions. As discussed in Chapters 28 and 76, the density of some aquaporins (e.g., aquaporin-2) in cell membranes is not static but is altered in different physiological conditions.

The protein channels are distinguished by two important characteristics: (1) they are often *selectively permeable* to certain substances; and (2) many of the channels can be opened or closed by *gates* that are regulated by electrical signals *(voltage-gated channels)* or chemicals that bind to the channel proteins *(ligand-gated channels)*. Thus, ion channels are flexible dynamic structures, and subtle conformational changes influence gating and ion selectivity.

Selective Permeability of Protein Channels. Many protein channels are highly selective for transport of one or more specific ions or molecules. This selectivity results from specific characteristics of the channel, such as its diameter, shape, and the nature of the electrical charges and chemical bonds along its inside surfaces.

Potassium channels, for example, permit passage of potassium ions across the cell membrane at least 100 times more readily than they permit passage of sodium ions. This high degree of selectivity cannot be explained entirely by the molecular diameters of the ions because potassium ions are slightly larger than sodium ions. Potassium channels have a *tetrameric structure* consisting of four identical protein subunits surrounding a central pore (**Fig. 4.4**). At the top of the channel pore are *pore loops* that form a narrow *selectivity filter*. Lining the selectivity filter are *carbonyl oxygens*. When hydrated potassium ions enter the selectivity filter, they interact with the carbonyl oxygens and shed most of their bound water molecules, permitting the dehydrated potassium ions to pass through the channel. The carbonyl oxygens are too far apart, however, to enable them to interact closely with the smaller sodium ions, which are therefore effectively excluded by the selectivity filter from passing through the pore.

Different selectivity filters for the various ion channels are believed to determine, in large part, the specificity of various channels for cations or anions or for particular ions, such as sodium (Na^+), potassium (K^+), and calcium (Ca^{2+}), that gain access to the channels.

One of the most important of the protein channels, the *sodium channel*, is only 0.3 to 0.5 nanometer in diameter, but the ability of sodium channels to discriminate sodium ions among other competing ions in the surrounding fluids is crucial for proper cellular function. The narrowest part of the sodium channel's open pore, the *selectivity filter*, is lined with *strongly negatively charged* amino acid residues, as shown in the top panel of **Fig. 4.5**. These

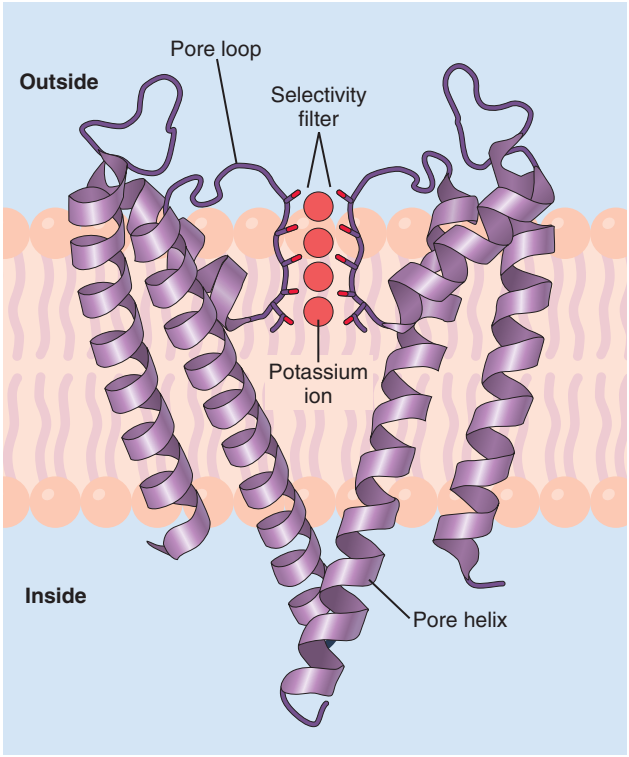

Figure 4.4 The structure of a potassium channel. The channel is composed of four subunits (only two of which are shown), each with two transmembrane helices. A narrow selectivity filter is formed from the pore loops, and carbonyl oxygens line the walls of the selectivity filter, forming sites for transiently binding dehydrated potassium ions. The interaction of the potassium ions with carbonyl oxygens causes the potassium ions to shed their bound water molecules, permitting the dehydrated potassium ions to pass through the pore.

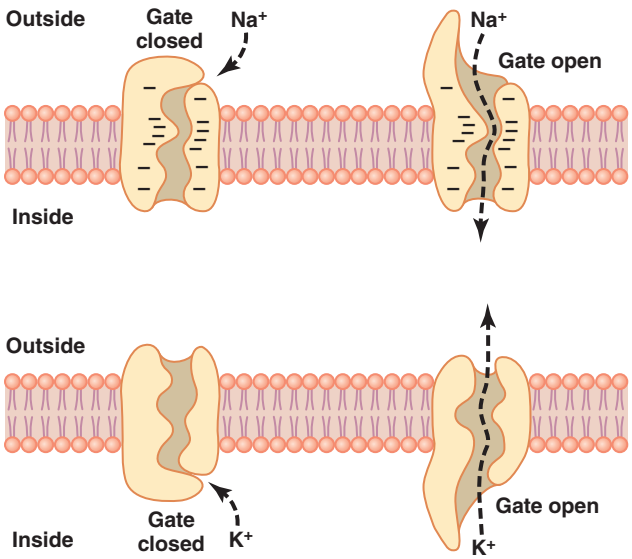

Figure 4.5 Transport of sodium and potassium ions through protein channels. Also shown are conformational changes in the protein molecules to open or close the "gates" guarding the channels.

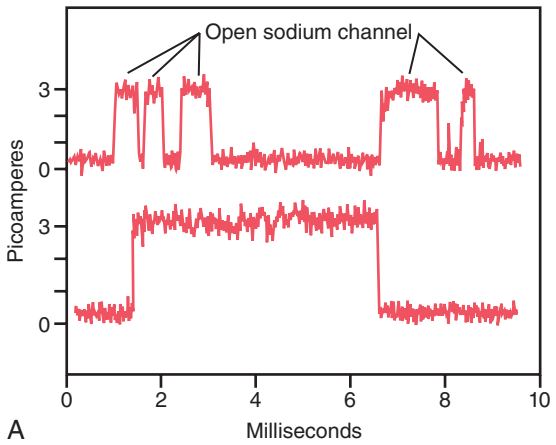
strong negative charges can pull small *dehydrated* sodium ions away from their hydrating water molecules into these channels, although the ions do not need to be fully dehydrated to pass through the channels. Once in the channel, the sodium ions diffuse in either direction according to the usual laws of diffusion. Thus, the sodium channel is highly selective for passage of sodium ions.

Gating of Protein Channels. Gating of protein channels provides a means of controlling ion permeability of the channels. This mechanism is shown in both panels of **Fig. 4.5** for selective gating of sodium and potassium ions. Gate-like extensions of the transport protein molecule can close the opening of the channel or can be lifted away from the opening by a conformational change in the shape of the protein molecule.

The opening and closing of gates are controlled in two principal ways:



1. *Voltage gating*. In the case of voltage gating, the molecular conformation of the gate or its chemical bonds responds to the electrical potential across the cell membrane. For example, in the top panel of **Fig. 4.5**, a strong negative charge on the inside of the cell membrane may cause the outside sodium gates to remain tightly closed. Conversely, when the inside of the membrane loses its negative charge, these gates open suddenly and allow sodium to pass inward through the sodium pores. This process is the basic mechanism for eliciting action potentials in nerves. In the bottom panel of **Fig. 4.5**, the potassium gates are on the intracellular ends of the potassium channels, and they open when the inside of the cell membrane becomes positively charged. The opening of these gates is partly responsible for terminating the action potential, a process discussed in Chapter 5.
2. *Chemical (ligand) gating*. Some protein channel gates are opened by the binding of a chemical substance (a ligand) with the protein, which causes a conformational or chemical bonding change in the protein molecule that opens or closes the gate. One of the most important instances of chemical gating is the effect of the neurotransmitter acetylcholine on the *acetylcholine receptor*, which serves as a ligand-gated ion channel. Acetylcholine opens the gate of this channel, providing a negatively charged pore about 0.65 nanometer in diameter that allows uncharged molecules or positive ions smaller than this diameter to pass through. This gate is exceedingly important for transmission of nerve signals from one nerve cell to another (see Chapter 46) and from nerve cells to muscle cells to cause muscle contraction (see Chapter 7).

Open-State Versus Closed-State of Gated Channels. **Fig. 4.6A** shows two recordings of electrical current flowing through a single sodium channel when there was a 25-millivolt potential gradient across the membrane. Note that the channel conducts current in an all-or-none fashion. That is, the gate of the channel snaps open and then snaps closed, with each open state lasting for only a fraction of a millisecond, up to several milliseconds, demonstrating the rapidity with which changes can occur during the opening and closing of the protein gates. At one voltage potential, the channel may remain closed all the time or almost all the time, whereas at another voltage, it may remain open either all or most of the time. At in-between voltages, as shown in the figure, the gates tend to snap open and closed intermittently, resulting in an average current flow somewhere between the minimum and maximum.

Patch Clamp Method for Recording Ion Current Flow Through Single Channels. The patch clamp method for recording ion current flow through single protein channels is illustrated in **Fig. 4.6B**. A micropipette with a tip diameter of only 1 or 2 micrometers is abutted against the outside of a cell membrane. Suction is then applied inside the pipette to pull the membrane against the tip of the pipette, which creates a seal where the edges of the pipette touch the cell membrane. The result is a minute membrane "patch" at the tip of the pipette through which electrical current flow can be recorded.

Alternatively, as shown at the bottom right in **Fig. 4.6B**, the small cell membrane patch at the end of the pipette can be torn away from the cell. The pipette with its sealed patch is then inserted into a free solution, which allows the concentrations of ions inside the micropipette and in the outside solution to be altered as desired. Also, the voltage between the two sides of the membrane can be set, or "clamped," to a given voltage.

It has been possible to make such patches small enough so that only a single channel protein is found in the membrane patch being studied. By varying the concentrations

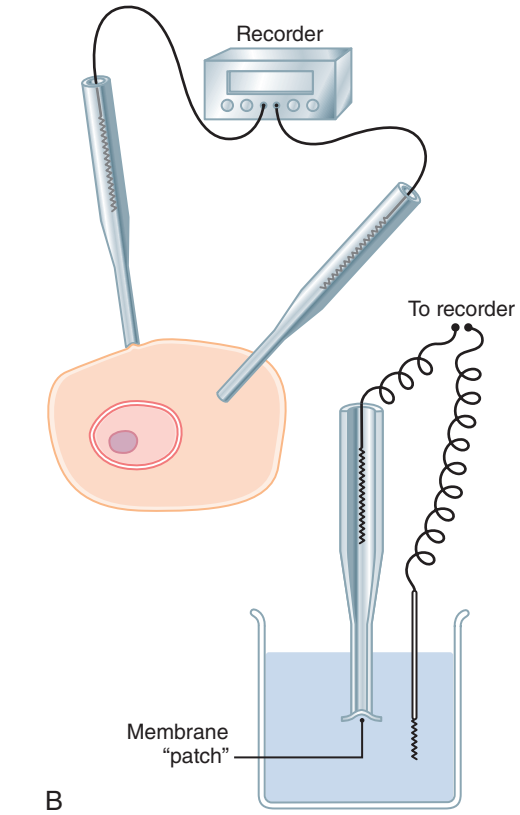


Figure 4.6 (A) Recording of current flow through a single voltage-gated sodium channel, demonstrating the all-or-none principle for opening and closing of the channel. (B) Patch clamp method for recording current flow through a single protein channel. To the left, the recording is performed from a "patch" of a living cell membrane. To the right, the recording is from a membrane patch that has been torn away from the cell.

of different ions, as well as the voltage across the membrane, one can determine the transport characteristics of the single channel, along with its gating properties.

FACILITATED DIFFUSION USING MEMBRANE CARRIER PROTEINS

Another type of facilitated diffusion is called *carrier-mediated diffusion* because a substance transported in this manner diffuses through the membrane with the help

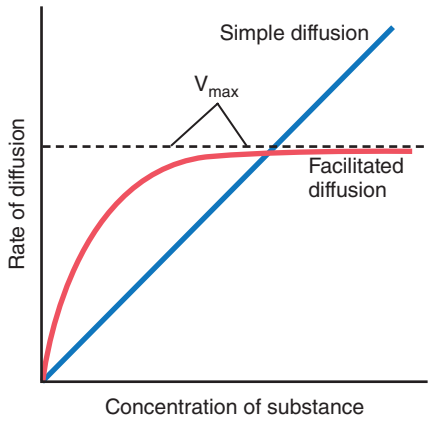

Figure 4.7 Effect of concentration of a substance on the rate of diffusion through a membrane by simple diffusion and facilitated diffusion. This graph shows that facilitated diffusion approaches a maximum rate, called the V_{max}.

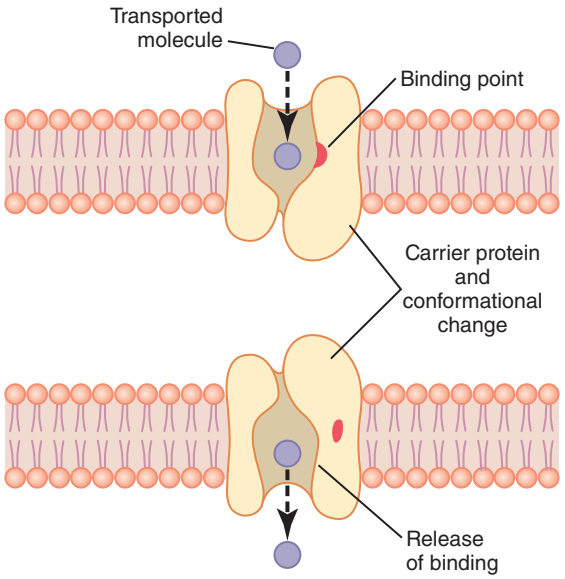

Figure 4.8 Postulated mechanism for facilitated diffusion.

of a specific carrier protein. That is, the carrier *facilitates* diffusion of the substance to the other side.

Facilitated diffusion differs from simple diffusion in the following important way. Although the rate of simple diffusion through the membrane increases proportionately with the concentration of the diffusing substance, in facilitated diffusion the rate of diffusion approaches a maximum, called V_{max}, as the concentration of the diffusing substance increases. This difference between simple diffusion and facilitated diffusion is demonstrated in **Fig. 4.7**. The figure shows that as the concentration of the diffusing substance increases, the rate of simple diffusion continues to increase proportionately but, in the case of facilitated diffusion, the rate of diffusion cannot rise higher than the V_{max} level.

What limits the rate of facilitated diffusion? A probable answer is the mechanism illustrated in **Fig. 4.8**, which shows a carrier protein with a pore large enough

to transport a specific molecule partway through. It also shows a binding receptor on the inside of the protein carrier. The molecule to be transported enters the pore and becomes bound. Then, in a fraction of a second, a conformational or chemical change occurs in the carrier protein so that the pore now opens to the opposite side of the membrane. Because the binding force of the receptor is weak, the thermal motion of the attached molecule causes it to break away and be released on the opposite side of the membrane. The rate at which molecules can be transported by this mechanism can never be greater than the rate at which the carrier protein molecule can undergo change back and forth between its two states. Note specifically, though, that this mechanism allows the transported molecule to move—that is, diffuse—in either direction through the membrane.

Among the many substances that cross cell membranes by carrier-mediated facilitated diffusion are *glucose* and most of the *amino acids*. In the case of glucose, at least 14 members of a family of membrane proteins (called *GLUT*) that transport glucose molecules have been discovered in various tissues. Some of these GLUT proteins transport other monosaccharides that have structures similar to that of glucose, including galactose and fructose. One of these, glucose transporter 4 (GLUT4), can increase the rate of facilitated diffusion of glucose as much as 10- to 20-fold in insulin-sensitive tissues such as skeletal muscle, adipose, and heart. Insulin stimulates translocation of GLUT4 from the cell cytosol to the plasma membrane, thus increasing cell membrane density of the transporter and increasing the maximum rate (V_{max}) of glucose diffusion into cells. This is the principal mechanism whereby insulin controls glucose use in the body, as discussed in Chapter 79.

FACTORS THAT AFFECT THE NET RATE OF DIFFUSION

By now, it is evident that many substances can diffuse through the cell membrane. What is usually important is the *net* rate of diffusion of a substance in the appropriate direction. This net rate is determined by several factors.

Net Diffusion Rate Is Proportional to the Concentration Difference Across a Membrane. **Fig. 4.9A** shows a cell membrane with a high concentration of a substance on the outside and a low concentration of a substance on the inside. The rate at which the substance diffuses *inward* is proportional to the concentration of molecules on the *outside* because this concentration determines how many molecules strike the outside of the membrane each second. Conversely, the rate at which molecules diffuse *outward* is proportional to their concentration *inside* the membrane. Therefore, the rate of net diffusion into the cell is proportional to the concentration on the outside *minus* the concentration on the inside:

$$\text{Net diffusion} \propto (C_o - C_i)$$

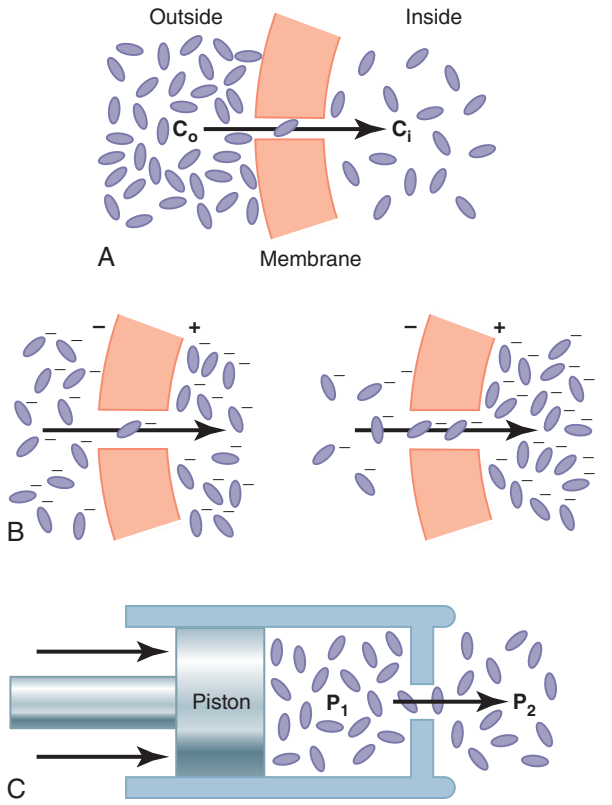

Figure 4.9 Effect of concentration difference (A), electrical potential difference affecting negative ions (B), and pressure difference (C) to cause diffusion of molecules and ions through a cell membrane. C_o, Concentration outside the cell; C_i, concentration inside the cell; P_1, pressure 1; P_2, pressure 2.

in which C_o is the concentration outside and C_i is the concentration inside the cell.

Membrane Electrical Potential and Diffusion of Ions—The "Nernst Potential." If an electrical potential is applied across the membrane, as shown in **Fig. 4.9B**, the electrical charges of the ions drive them to move through the membrane even though no concentration difference exists to cause movement. Thus, in the left panel of **Fig. 4.9B**, the concentration of *negative* ions is the same on both sides of the membrane, but a positive charge has been applied to the right side of the membrane, and a negative charge has been applied to the left, creating an electrical gradient across the membrane. The positive charge attracts the negative ions, whereas the negative charge repels them. Therefore, net diffusion occurs from left to right. After some time, large quantities of negative ions have moved to the right, creating the condition shown in the right panel of **Fig. 4.9B**, in which a concentration difference of the ions has developed in the direction opposite to the electrical potential difference. The concentration difference now tends to move the ions to the left, whereas the electrical difference tends to move them to the right. When the concentration difference rises high enough, the two effects balance each other. At normal body temperature (~98.6°F; 37°C), the electrical difference that will balance a given concentration difference

of *univalent* ions—such as Na^+ ions—can be determined from the following formula, called the *Nernst equation:*

$$\text{EMF (in millivolts)} = \pm 61 \log \frac{C_1}{C_2}$$

in which EMF is the electromotive force (voltage) between side 1 and side 2 of the membrane, C_1 is the concentration on side 1, and C_2 is the concentration on side 2. This equation is extremely important in understanding the transmission of nerve impulses and is discussed in Chapter 5.

Effect of a Pressure Difference Across the Membrane. At times, a considerable pressure difference develops between the two sides of a diffusible membrane. This pressure difference occurs, for example, at the blood capillary membranes where pressure inside many capillaries is about 20 mm Hg greater than outside.

Pressure actually means the sum of all the forces of the different molecules striking a unit surface area at a given instant. Therefore, having a higher pressure on one side of a membrane than on the other side means that the sum of all the forces of the molecules striking the channels on that side of the membrane is greater than on the other side. In most cases, this situation is caused by greater numbers of molecules striking the membrane per second on one side than on the other side. The result is that increased amounts of energy are available to cause a net movement of molecules from the high-pressure side toward the low-pressure side. This effect is demonstrated in **Fig. 4.9C**, which shows a piston developing high pressure on one side of a pore, thereby causing more molecules to strike the pore on this side and, therefore, more molecules to diffuse to the other side.

OSMOSIS ACROSS SELECTIVELY PERMEABLE MEMBRANES—NET DIFFUSION OF WATER

By far, the most abundant substance that diffuses through the cell membrane is water. Enough water ordinarily diffuses in each direction through the red blood cell membrane per second to equal about *100 times the volume of the cell itself.* Yet, the amount that normally diffuses in the two directions is balanced so precisely that zero net movement of water occurs. Therefore, the volume of the cell remains constant. However, under certain conditions, a *concentration difference for water* can develop across a membrane. When this concentration difference for water develops, net movement of water does occur across the cell membrane, causing the cell to swell or shrink, depending on the direction of the water movement. This process of net movement of water caused by a concentration difference of water is called *osmosis.*

To illustrate osmosis, let us assume the conditions shown in **Fig. 4.10**, with pure water on one side of the cell membrane and a solution of sodium chloride on the other side. Water molecules pass through the cell membrane with ease, whereas sodium and chloride ions pass through only with difficulty. Therefore, sodium chloride solution is actually a mixture of permeant water molecules and nonpermeant sodium and chloride ions, and the membrane is said to be *selectively permeable* to water but much less so to sodium and chloride ions. Yet, the presence of the sodium and chloride has displaced some of the water molecules on the right side of the membrane where these ions are present and, therefore, has reduced the concentration of water molecules to less than that of pure water. As a result, in the example shown in **Fig. 4.10**, more water molecules strike the channels on the left side, where there is pure water, than on the right side, where the water concentration has been reduced. Thus, net movement of water occurs from left to right—that is, *osmosis* occurs from the pure water into the sodium chloride solution.

Osmotic Pressure

If in **Fig. 4.10** pressure were applied to the sodium chloride solution, osmosis of water into this solution would be slowed, stopped, or even reversed. The amount of pressure required to stop osmosis is called the *osmotic pressure* of the sodium chloride solution.

The principle of a pressure difference opposing osmosis is demonstrated in **Fig. 4.11**, which shows a selectively permeable membrane separating two columns of fluid, one containing pure water and the other containing a solution of water and any solute that will not penetrate the membrane. Osmosis of water from chamber B into chamber A causes the levels of the fluid columns to become farther and farther apart, until eventually a pressure difference develops between the two sides of the membrane that is great enough to oppose the osmotic effect. The pressure difference across the membrane at this point is equal to the osmotic pressure of the solution that contains the nondiffusible solute.

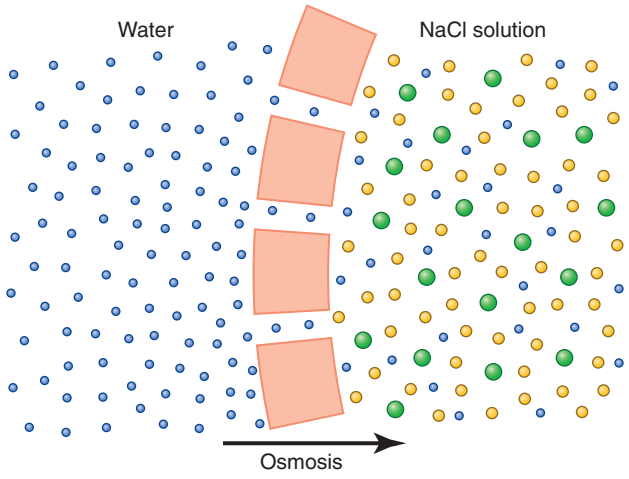

Figure 4.10 Osmosis at a cell membrane when a sodium chloride solution is placed on one side of the membrane and water is placed on the other side.

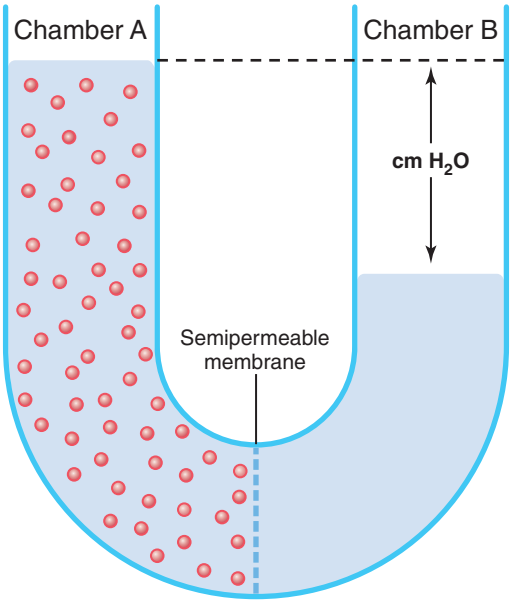

Figure 4.11 Demonstration of osmotic pressure caused by osmosis at a semipermeable membrane.

The Number of Osmotic Particles (Molar Concentration) Determines Osmotic Pressure. The osmotic pressure exerted by particles in a solution, whether they are molecules or ions, is determined by the number of particles per unit volume of fluid, not by the mass of the particles. The reason for this is that each particle in a solution, regardless of its mass, exerts, on average, the same amount of pressure against the membrane. Although large particles have greater mass (m) than small particles, they move at a slower velocity (v). Thus, the average kinetic energies (k), as determined by the following equation, are the same for small and large particles.

$$k = \frac{mv^2}{2}$$

Consequently, the factor that determines the osmotic pressure of a solution is the concentration of the solution in terms of the number of particles (which is the same as its *molar concentration* if it is a nondissociated molecule), not in terms of mass of the solute.

Osmolality—Osmoles per Kilogram of Water. To express the concentration of a solution in terms of numbers of particles, a unit called the *osmole* is used in place of grams.

One osmole is 1 gram molecular weight of osmotically active solute. Thus, 180 grams of glucose, which is 1 gram molecular weight of glucose, is equal to 1 osmole of glucose because glucose does not dissociate into ions. If a solute dissociates into two ions, 1 gram molecular weight of the solute will become 2 osmoles because the number of osmotically active particles is now twice as great as for the nondissociated solute. Therefore, when fully dissociated, 1 gram molecular weight of sodium chloride, 58.5 grams, is equal to 2 osmoles.

Thus, a solution that has *1 osmole of solute dissolved in each kilogram of water* is said to have an *osmolality of 1 osmole per kilogram*, and a solution that has 1/1000 osmole dissolved per kilogram has an osmolality of 1 milliosmole per kilogram. The normal osmolality of the extracellular and intracellular fluids is about *300 milliosmoles per kilogram of water*.

Relationship of Osmolality to Osmotic Pressure. At normal body temperature, 98.6 °F (37°C), a concentration of 1 osmole per liter will cause 19,300 mm Hg osmotic pressure in the solution. Likewise, *1 milliosmole* per liter concentration is equivalent to *19.3 mm Hg* osmotic pressure. Multiplying this value by the 300-milliosmolar concentration of the body fluids gives a total calculated osmotic pressure of the body fluids of 5790 mm Hg. The actual measured value for this, however, averages only about 5500 mm Hg. The reason for this difference is that many ions in the body fluids, such as sodium and chloride ions, are highly attracted to one another; consequently, they cannot move entirely unrestrained in the fluids and create their full osmotic pressure potential. Therefore, on average, the actual osmotic pressure of the body fluids is about 0.93 times the calculated value.

Osmolarity—Osmoles per Liter of Solution. *Osmolarity* is the osmolar concentration expressed as *osmoles per liter of solution* rather than osmoles per kilogram of water. Although, strictly speaking, it is osmoles per kilogram of water (osmolality) that determines osmotic pressure, the quantitative differences between osmolarity and osmolality are less than 1% for dilute solutions such as those in the body. Because it is far more practical to measure osmolarity than osmolality, measuring osmolarity is the usual practice in physiological studies.

ACTIVE TRANSPORT OF SUBSTANCES THROUGH MEMBRANES

At times, a large concentration of a substance is required in the intracellular fluid, even though the extracellular fluid contains only a small concentration. This situation is true, for example, for potassium ions. Conversely, it is important to keep the concentrations of other ions, such as sodium, very low inside the cell even though their concentrations in the extracellular fluid are high. Neither of these two effects could occur by simple diffusion because simple diffusion eventually equilibrates concentrations on the two sides of the membrane. Instead, some energy source must cause excess movement of potassium ions to the inside of cells and excess movement of sodium ions to the outside of cells. When a cell membrane moves molecules or ions uphill against a concentration gradient (or uphill against an electrical or pressure gradient), the process is called *active transport*.

Examples of substances that are actively transported through at least some cell membranes include sodium, potassium, calcium, iron, hydrogen, chloride, iodide,

and urate ions, several different sugars, and most of the amino acids.

Active transport is divided into two types according to the source of the energy used to facilitate the transport, *primary active transport* and *secondary active transport*. In primary active transport, the energy is derived directly from the breakdown of adenosine triphosphate (ATP) or some other high-energy phosphate compound. In secondary active transport, the energy is derived secondarily from energy that has been stored in the form of ionic concentration differences of secondary molecular or ionic substances between the two sides of a cell membrane, created originally by primary active transport.

In both cases, transport depends on *carrier proteins* that penetrate through the cell membrane, as is true for facilitated diffusion. However, in primary active transport, the carrier protein functions differently from the carrier in facilitated diffusion because it is capable of imparting energy to the transported substance to move it against the electrochemical gradient.

PRIMARY ACTIVE TRANSPORT

Sodium-Potassium Pump Transports Sodium Ions Out of Cells and Potassium Ions Into Cells

Among the substances that are transported by primary active transport are sodium, potassium, calcium, hydrogen, chloride, and a few other ions. The active transport mechanism that has been studied in greatest detail is the *sodium-potassium* (Na^+-K^+) pump, a transporter that pumps sodium ions outward through the cell membrane of all cells and, at the same time, pumps potassium ions from the outside to the inside. This pump is responsible for maintaining the sodium and potassium concentration differences across the cell membrane, as well as for establishing a negative electrical voltage inside the cells. Chapter 5 shows that this pump is also the basis of nerve function, transmitting nerve signals throughout the nervous system.

Fig. 4.12 shows the basic physical components of the Na^+-K^+ pump. The *carrier protein* is a complex of two separate globular proteins—a larger one called the α subunit, with a molecular weight of about 100,000, and a smaller one called the β subunit, with a molecular weight of about 55,000. Although the function of the smaller protein is not known (except that it might anchor the protein complex in the lipid membrane), the larger protein has three specific features that are important for the functioning of the pump:

1. It has three *binding sites for sodium ions* on the portion of the protein that protrudes to the inside of the cell.
2. It has two *binding sites for potassium ions* on the outside.
3. The inside portion of this protein near the sodium binding sites has adenosine triphosphatase (ATPase) activity.

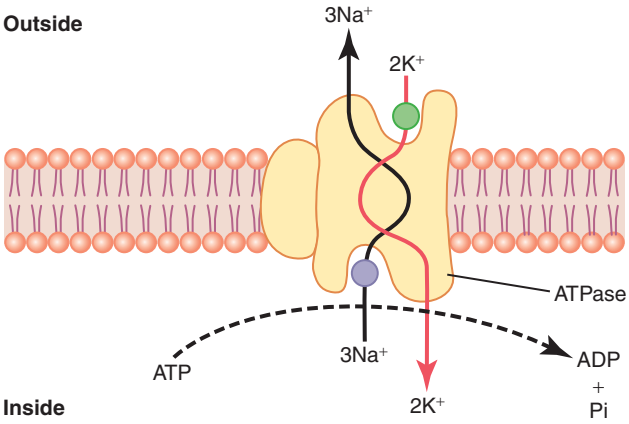

Figure 4.12 Postulated mechanism of the sodium-potassium pump. *ADP*, Adenosine diphosphate; *ATP*, adenosine triphosphate; *Pi*, phosphate ion.

When two potassium ions bind on the outside of the carrier protein and three sodium ions bind on the inside, the ATPase function of the protein becomes activated. Activation of the ATPase function leads to cleavage of one molecule of ATP, splitting it to adenosine diphosphate (ADP) and liberating a high-energy phosphate bond of energy. This liberated energy causes a chemical and conformational change in the protein carrier molecule, extruding three sodium ions to the outside and two potassium ions to the inside.

As with other enzymes, the Na^+-K^+ ATPase pump can run in reverse. If the electrochemical gradients for Na^+ and K^+ are experimentally increased to the degree that the energy stored in their gradients is greater than the chemical energy of ATP hydrolysis, these ions will move down their concentration gradients, and the Na^+-K^+ pump will synthesize ATP from ADP and phosphate. The phosphorylated form of the Na^+-K^+ pump, therefore, can either donate its phosphate to ADP to produce ATP or use the energy to change its conformation and pump Na^+ out of the cell and K^+ into the cell. The relative concentrations of ATP, ADP, and phosphate, as well as the electrochemical gradients for Na^+ and K^+, determine the direction of the enzyme reaction. For some cells, such as electrically active nerve cells, 60% to 70% of the cell's energy requirement may be devoted to pumping Na^+ out of the cell and K^+ into the cell.

The Na^+-K^+ Pump Controls Cell Volume. One of the most important functions of the Na^+-K^+ pump is to control the cell volume. Without function of this pump, most cells of the body would swell and burst.

The mechanism for controlling the volume is as follows. Inside the cell are large numbers of proteins and other organic molecules that cannot escape from the cell. Most of these proteins and other organic molecules are negatively charged and, therefore, attract large numbers of potassium, sodium, and other positive ions. All these molecules and ions then cause osmosis of water to the interior of the cell. Unless this process is checked, the cell

will swell indefinitely until it bursts. The normal mechanism for preventing this outcome is the Na^+-K^+ pump. Note again that this mechanism pumps three Na^+ ions to the outside of the cell for every two K^+ ions pumped to the interior. Also, the membrane is far less permeable to sodium ions than to potassium ions and, once the sodium ions are on the outside, they have a strong tendency to stay there. This process thus represents a net loss of ions out of the cell, which also initiates osmosis of water out of the cell.

If a cell begins to swell for any reason, the Na^+-K^+ pump is automatically activated, moving still more ions to the exterior and carrying water with them. Therefore, the Na^+-K^+ pump performs a continual surveillance role in maintaining normal cell volume.

The Na^+-K^+ Pump Is Electrogenic. Because Na^+-K^+ pump moves three Na^+ ions to the exterior for every two K^+ ions that are moved to the interior, one net positive charge is moved from the interior of the cell to the exterior of the cell for each cycle of the pump. This action creates positivity outside the cell and negativity on the inside. Therefore, the Na^+-K^+ pump is said to be *electrogenic* because it creates an electrical potential across the cell membrane. As discussed in Chapter 5, this electrical potential is a basic requirement in nerve and muscle fibers for transmitting nerve and muscle signals.

Primary Active Transport of Calcium Ions

Another important primary active transport mechanism is the *calcium pump*. Calcium ions are normally maintained at an extremely low concentration in the intracellular cytosol of virtually all cells in the body, at a concentration about 10,000 times less than that in the extracellular fluid. Two primary active transport calcium pumps help maintain this low cytosolic Ca^{2+} concentration. One, which is in the cell membrane, pumps Ca^{2+} to the outside of the cell. The other pumps Ca^{2+} into one or more of the intracellular vesicular organelles of the cell, such as the sarcoplasmic reticulum of muscle cells and the mitochondria in all cells. In each of these cases, the carrier protein penetrates the membrane and functions as an enzyme ATPase, with the same capability to cleave ATP as the ATPase of the sodium carrier protein. The difference is that this protein has a highly specific binding site for calcium instead of for sodium.

Primary Active Transport of Hydrogen Ions

Primary active transport of hydrogen ions is especially important at two places in the body: (1) in the gastric glands of the stomach; and (2) in the kidney tubules, including the late distal tubules, cortical collecting tubules, and outer medullary collecting ducts.

In the gastric glands, the deep-lying *parietal cells* have the most potent primary active mechanism for transporting hydrogen ions of any part of the body. This mechanism is the basis for secreting hydrochloric acid in stomach digestive secretions. At the secretory ends of the gastric gland parietal cells, the hydrogen ion concentration is increased as much as a million-fold and then is released into the stomach, along with chloride ions, to form hydrochloric acid.

In the renal tubules, special *intercalated cells* found in the late distal tubules, cortical collecting tubules, and outer medullary collecting ducts also transport hydrogen ions by primary active transport. In this case, large amounts of hydrogen ions are secreted from the blood into the renal tubular fluid for the purpose of eliminating excess hydrogen ions from the body fluids. The hydrogen ions can be secreted into the renal tubular fluid against a concentration gradient of about 900-fold. Yet, as discussed in Chapter 31, most of these hydrogen ions combine with tubular fluid buffers before they are eliminated in the urine

Energetics of Primary Active Transport

The amount of energy required to transport a substance actively through a membrane is determined by how much the substance is concentrated during transport. Compared with the energy required to concentrate a substance 10-fold, concentrating it 100-fold requires twice as much energy, and concentrating it 1000-fold requires three times as much energy. In other words, the energy required is proportional to the *logarithm* of the degree that the substance is concentrated, as expressed by the following formula:

$$\text{Energy (in calories per osmole)} = 1400 \log \frac{C_1}{C_2}$$

Thus, in terms of calories, the amount of energy required to concentrate 1 osmole of a substance 10-fold is about 1400 calories, whereas to concentrate it 100-fold, 2800 calories are required. One can see that the energy expenditure for concentrating substances in cells or for removing substances from cells against a concentration gradient can be tremendous. Some cells, such as those lining the renal tubules and many glandular cells, expend as much as 90% of their energy for this purpose alone.

SECONDARY ACTIVE TRANSPORT—CO-TRANSPORT AND COUNTER-TRANSPORT

When sodium ions are transported out of cells by primary active transport, a large concentration gradient of sodium ions across the cell membrane usually develops, with a high concentration outside the cell and a low concentration inside. This gradient represents a storehouse of energy, because the excess sodium outside the cell membrane is always attempting to diffuse to the interior. Under appropriate conditions, this diffusion energy of sodium can pull other substances along with the sodium through the cell membrane. This phenomenon, called *co-transport*, is one form of *secondary active transport*.

For sodium to pull another substance along with it, a coupling mechanism is required; this is achieved by means of still another carrier protein in the cell membrane. The carrier in this case serves as an attachment point for both the sodium ion and the substance to be co-transported. Once they are both attached, the energy gradient of the sodium ion causes the sodium ion and the other substance to be transported together to the interior of the cell.

In *counter-transport*, sodium ions again attempt to diffuse to the interior of the cell because of their large concentration gradient. However, this time, the substance to be transported is on the inside of the cell and is transported to the outside. Therefore, the sodium ion binds to the carrier protein, where it projects to the exterior surface of the membrane, and the substance to be counter-transported binds to the interior projection of the carrier protein. Once both have become bound, a conformational change occurs, and energy released by the sodium ion moving to the interior causes the other substance to move to the exterior.

Co-Transport of Glucose and Amino Acids Along With Sodium Ions

Glucose and many amino acids are transported into most cells against large concentration gradients; the mechanism of this action is entirely by co-transport, as shown in **Fig. 4.13**. Note that the transport carrier protein has two binding sites on its exterior side, one for sodium and one for glucose. Also, the concentration of sodium ions is high on the outside and low on the inside, which provides energy for the transport. A special property of the transport protein is that a conformational change to allow sodium movement to the interior will not occur until a glucose molecule also attaches. When they both become attached, the conformational change takes place, and the sodium and glucose are transported to the inside of the cell at the same time. Hence, this is a *sodium-glucose co-transporter*. Sodium-glucose co-transporters (also called *symporters* since sodium and glucose are transported in the same direction) are especially important for transporting glucose across renal and intestinal epithelial cells, as discussed in Chapters 28 and 66.

Sodium co-transport of amino acids occurs in the same manner as for glucose, except that it uses a different set of transport proteins. At least five main types of *amino acid transport proteins* have been identified, each of which is responsible for transporting one subset of amino acids with specific molecular characteristics.

Sodium co-transport of glucose and amino acids occurs especially through the epithelial cells of the intestinal tract and the renal tubules of the kidneys to promote absorption of these substances into the blood. This process will be discussed in later chapters.

Other important co-transport mechanisms in at least some cells include co-transport of potassium, chloride, bicarbonate, phosphate, iodine, iron, and urate ions.

Sodium Counter-Transport of Calcium and Hydrogen Ions

Two especially important counter-transporters (also called *antiporters* because they transport in a direction opposite to the primary ion) are *sodium-calcium counter-transport* and *sodium-hydrogen counter-transport* (**Fig. 4.14**).

Sodium-calcium counter-transport occurs through all or almost all cell membranes, with sodium ions moving to the interior and Ca^{2+} to the exterior; both are bound to the same transport protein in a counter-transport mode. This mechanism is in addition to the primary active transport of Ca^{2+} that occurs in some cells.

Sodium-hydrogen counter-transport occurs in several tissues. An especially important example is in the *proximal tubules* of the kidneys, where sodium ions move from the lumen of the tubule to the interior of the tubular cell and hydrogen ions are counter-transported into the tubule lumen. As a mechanism for concentrating hydrogen ions, counter-transport is not nearly as powerful as the primary active transport of hydrogen ions that occurs in the more distal renal tubules, but it can transport extremely *large numbers of hydrogen ions*, thus making it a key to hydrogen ion control in the body fluids, as discussed in detail in Chapter 31.

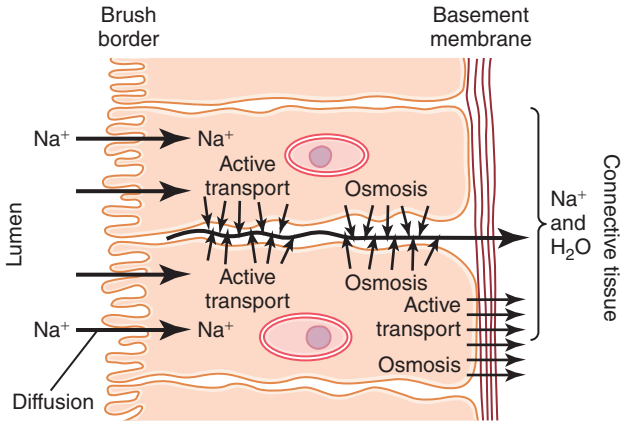

Figure 4.15 Basic mechanism of active transport across a layer of cells.

ACTIVE TRANSPORT THROUGH CELLULAR SHEETS

At many places in the body, substances must be transported all the way through a cellular sheet instead of simply through the cell membrane. Transport of this type occurs through the following: (1) intestinal epithelium; (2) epithelium of the renal tubules; (3) epithelium of all exocrine glands; (4) epithelium of the gallbladder; and (5) membrane of the choroid plexus of the brain, along with other membranes.

The basic mechanism for transport of a substance through a cellular sheet is as follows: (1) *active transport* through the cell membrane *on one side* of the transporting cells in the sheet, and then (2) either *simple diffusion* or *facilitated diffusion* through the membrane *on the opposite side* of the cell.

Fig. 4.15 shows a mechanism for the transport of sodium ions through the epithelial sheet of the intestines, gallbladder, and renal tubules. This figure shows that the epithelial cells are connected together tightly at the luminal pole by means of junctions. The brush border on the luminal surfaces of the cells is permeable to both sodium ions and water. Therefore, sodium and water diffuse readily from the lumen into the interior of the cell. Then, at the basal and lateral membranes of the cells, sodium ions are actively transported into the extracellular fluid of the surrounding connective tissue and blood vessels. This action creates a high sodium ion concentration gradient across these membranes, which in turn causes osmosis of water. Thus, active transport of sodium ions at the basolateral sides of the epithelial cells results in the transport not only of sodium ions but also of water.

It is through these mechanisms that almost all nutrients, ions, and other substances are absorbed into the blood from the intestine. These mechanisms are also how the same substances are reabsorbed from the glomerular filtrate by the renal tubules.

Numerous examples of the different types of transport discussed in this chapter are provided throughout this text.

Membrane Potentials and Action Potentials

Electrical potentials exist across the membranes of virtually all cells of the body. Some cells, such as nerve and muscle cells, generate rapidly changing electrochemical impulses at their membranes, and these impulses are used to transmit signals along the nerve or muscle membranes. In other types of cells, such as glandular cells, macrophages, and ciliated cells, local changes in membrane potentials also activate many of the cell's functions. This chapter reviews the basic mechanisms whereby membrane potentials are generated at rest and during action by nerve and muscle cells. See **Video 5.1**.

BASIC PHYSICS OF MEMBRANE POTENTIALS

Membrane Potentials Caused By Ion Concentration Differences Across a Selectively Permeable Membrane

In **Fig. 5.1A**, the potassium concentration is much higher *inside* a nerve fiber membrane than *outside* the membrane. Let us assume that the membrane in this case is permeable to the potassium ions but not to any other ions. Because of the large potassium concentration gradient from the inside toward the outside, there is a strong tendency for potassium ions to diffuse outward through the membrane. As they do so, they carry positive electrical charges to the outside, thus creating electropositivity outside the membrane and electronegativity inside the membrane because of negative anions that remain behind and do not diffuse outward with the potassium. Within about 1 millisecond, the potential difference between the inside and outside, called the *diffusion potential*, becomes great enough to block further net potassium diffusion to the exterior, despite the high potassium ion concentration gradient. In the normal mammalian nerve fiber, *the potential difference is about 94 millivolts (mV), with negativity inside the fiber membrane.*

Fig. 5.1B shows the same phenomenon as in **Fig. 5.1A**, but this time with a higher concentration of sodium ions *outside* the membrane than on the *inside*. These ions are also positively charged. This time, the membrane is highly permeable to the sodium ions but is impermeable to all other ions. Diffusion of the positively charged sodium ions to the inside creates a membrane potential of opposite polarity to that in **Fig. 5.1A**, with negativity outside and positivity inside. Again, the membrane potential rises high enough within milliseconds to block further net diffusion of sodium ions to the inside; however, this time, in the mammalian nerve fiber, *the potential is about 61 mV positive inside the fiber*.

Thus, in both parts of **Fig. 5.1**, we see that a concentration difference of ions across a selectively permeable membrane can, under appropriate conditions, create a membrane potential. Many of the rapid changes in membrane potentials observed during nerve and muscle impulse transmission result from such rapidly changing diffusion potentials.

The Nernst Equation Describes the Relationship of Diffusion Potential to the Ion Concentration Difference Across a Membrane. The diffusion potential across a membrane that exactly opposes the net diffusion of a particular ion through the membrane is called the *Nernst potential* for that ion, a term that was introduced in Chapter 4. The magnitude of the Nernst potential is determined by the *ratio* of the concentrations of that specific ion on the two sides of the membrane. The greater this ratio, the greater the tendency for the ion to diffuse in one direction and therefore the greater the Nernst

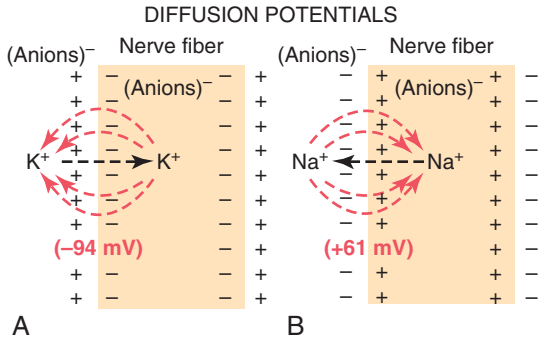

Figure 5.1 (A) Establishment of a diffusion potential across a nerve fiber membrane, caused by diffusion of potassium ions from inside the cell to outside the cell through a membrane that is selectively permeable only to potassium. (B) Establishment of a diffusion potential when the nerve fiber membrane is permeable only to sodium ions. Note that the internal membrane potential is negative when potassium ions diffuse and positive when sodium ions diffuse because of opposite concentration gradients of these two ions.

potential required to prevent additional net diffusion. The following equation, called the *Nernst equation*, can be used to calculate the Nernst potential for any univalent ion at the normal body temperature of 98.6°F (37°C):

$$\text{EMF (millivolts)} = \pm \frac{61}{z} \times \log \frac{\text{Concentration inside}}{\text{Concentration outside}}$$

where EMF is the electromotive force and z is the electrical charge of the ion (e.g., +1 for K^+).

When using this formula, it is usually assumed that the potential in the extracellular fluid outside the membrane remains at zero potential, and the Nernst potential is the potential inside the membrane. Also, the sign of the potential is positive (+) if the ion diffusing from inside to outside is a negative ion, and it is negative (−) if the ion is positive. Thus, if the concentration of positive potassium ions on the inside is 10 times that on the outside, the log of 10 is 1, so the Nernst potential calculates to be −61 mV inside the membrane. In reality, the concentration of potassium ions on the inside is approximately 35 times that on the outside and the Nernst potential calculates to be about −94 mV, as shown in **Fig. 5.1A**.

The Goldman Equation Is Used to Calculate the Diffusion Potential When the Membrane Is Permeable to Several Different Ions. When a membrane is permeable to several different ions, the diffusion potential that develops depends on three factors: (1) the polarity of the electrical charge of each ion; (2) the permeability of the membrane (P) to each ion; and (3) the concentration (C) of the respective ions on the inside (i) and outside (o) of the membrane. Thus, the following formula, called the *Goldman equation* or the *Goldman-Hodgkin-Katz equation*, gives the calculated membrane potential on the *inside* of the membrane when two univalent positive ions, sodium (Na^+) and potassium (K^+), and one univalent negative ion, chloride (Cl^-), are involved:

$$\text{EMF (millivolts)} = -61 \times \log \frac{C_{Na_i^+} P_{Na^+} + C_{K_i^+} P_{K^+} + C_{Cl_o^-} P_{Cl^-}}{C_{Na_o^+} P_{Na^+} + C_{K_o^+} P_{K^+} + C_{Cl_i^-} P_{Cl^-}}$$

Several key points become evident from the Goldman equation. First, sodium, potassium, and chloride ions are the most important ions involved in the development of membrane potentials in nerve and muscle fibers, as well as in the neuronal cells. The concentration gradient of each of these ions across the membrane helps determine the voltage of the membrane potential.

Second, the quantitative importance of each of the ions in determining the voltage is proportional to the membrane permeability for that particular ion. For example, if the membrane has zero permeability to sodium and chloride ions, the membrane potential becomes entirely dominated by the concentration gradient of potassium ions alone, and the resulting potential will be equal to the Nernst potential for potassium. The same holds true for each of the other two ions if the membrane should become selectively permeable for either one of them alone.

Third, a positive ion concentration gradient from *inside* the membrane to the *outside* causes electronegativity inside the membrane. The reason for this phenomenon is that excess positive ions diffuse to the outside when their concentration is higher inside than outside the membrane. This diffusion carries positive charges to the outside but leaves the nondiffusible negative anions on the inside, thus creating electronegativity on the inside. The opposite effect occurs when there is a gradient for a negative ion. That is, a chloride ion gradient from the outside to the inside causes negativity inside the cell because excess negatively charged chloride ions diffuse to the inside while leaving the nondiffusible positive ions on the outside.

Fourth, as explained later, the permeability of the sodium and potassium channels undergoes rapid changes during transmission of a nerve impulse, whereas the permeability of the chloride channels does not change greatly during this process. Therefore, rapid changes in sodium and potassium permeability are primarily responsible for signal transmission in neurons, which is the subject of most of the remainder of this chapter.

Table 5.1 Resting Membrane Potential in Different Cell Types

Cell Type	Resting Potential (mV)
Skeletal muscle	−85 to −95
Cardiac muscle	−80 to −90
Astrocyte	−80 to −90
Neurons	−60 to −70
Smooth muscle	−50 to −60
Hair cell (cochlea)	−45 to −60
Photoreceptor cell	−40 (dark) to −70 (light)
Erythrocyte	−8 to −12

Resting Membrane Potential of Different Cell Types. In some cells, such as the cardiac pacemaker cells discussed in Chapter 10, the membrane potential is continuously changing, and the cells are never "resting." In many other cells, even excitable cells, there is a quiescent period in which a resting membrane potential can be measured. **Table 5.1** shows the approximate resting membrane potentials of different types of cells. The membrane potential is obviously very dynamic in excitable cells such as neurons, in which action potentials occur. However, even in nonexcitable cells, the membrane potential (voltage) also changes in response to various stimuli, which alter activities for the different ion transporters, ion channels, and membrane permeability for sodium, potassium, calcium, and chloride ions. The resting membrane potential is, therefore, only a brief transient state for many cells.

Electrochemical Driving Force. When multiple ions contribute to the membrane potential, the equilibrium

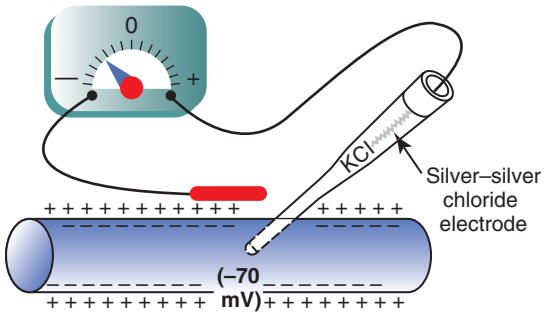

Figure 5.2 Measurement of the membrane potential of the nerve fiber using a microelectrode.

potential for any of the contributing ions will differ from the membrane potential and there will be an *electrochemical driving force* (V_{df}) for each ion that tends to cause net movement of the ion across the membrane. This driving force (V_{df}) is equal to the difference between the membrane potential (V_m) and the equilibrium potential of the ion (V_{eq}). Thus, $V_{df} = V_m - V_{eq}$.

The arithmetic sign of V_{df} (positive or negative) and the valence of the ion (cation or anion) can be used to predict the direction of ion flow across the membrane, into or out of the cell. For cations such as Na^+ and K^+, a positive V_{df} predicts ion movement out of the cell down its electrochemical gradient, and a negative V_{df} predicts ion movement into the cell. For example, the V_{df} for sodium would be equal to ($-70\ V_m - 61\ V_{eq}$), or −131 mV driving force for movement of sodium into the cell. For anions, such as Cl^-, a positive V_{df} predicts ion movement into the cell, and a negative V_{df} predicts ion movement out of the cell. When $V_m = V_{eq}$, there is no net movement of the ion into or out of the cell. Also, the direction of ion flux through the membrane reverses as V_m becomes greater than or less than V_{eq}; hence, the equilibrium potential (V_{eq}) is also called the *reversal potential*.

Measuring the Membrane Potential

The method for measuring the membrane potential is simple in theory but often difficult in practice because most of the cells and fibers are very small. **Fig. 5.2** shows a small micropipette filled with an electrolyte solution. The micropipette is impaled through the cell membrane to the interior of the fiber. Another electrode, called the *indifferent electrode*, is then placed in the extracellular fluid, and the potential difference between the inside and outside of the fiber is measured using an appropriate voltmeter. This special voltmeter is capable of measuring small voltages despite extremely high resistance to electrical flow through the tip of the micropipette, which has a lumen diameter usually less than 1 micrometer and a resistance of more than 1 million ohms. For recording rapid *changes* in the membrane potential during transmission of nerve impulses, the microelectrode is connected to an oscilloscope, as explained later in the chapter.

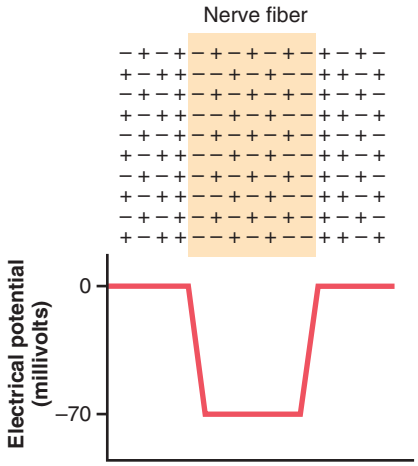

Figure 5.3 Distribution of positively and negatively charged ions in the extracellular fluid surrounding a nerve fiber and in the fluid inside the fiber. Note the alignment of negative charges along the inside surface of the membrane and positive charges along the outside surface. The *lower panel* displays the abrupt changes in membrane potential that occur at the membranes on the two sides of the fiber.

The lower part of **Fig. 5.3** shows the electrical potential that is measured at each point in or near the nerve fiber membrane, beginning at the left side of the figure and passing to the right. As long as the electrode is outside the neuronal membrane, the recorded potential is zero, which is the potential of the extracellular fluid. Then, as the recording electrode passes through the voltage change area at the cell membrane (called the *electrical dipole layer*), the potential decreases abruptly to −70 mV. Moving across the center of the fiber, the potential remains at a steady −70-mV level but reverses back to zero the instant it passes through the membrane on the opposite side of the fiber.

To create a negative potential inside the membrane, only enough positive ions to develop the electrical dipole layer at the membrane itself must be transported outward. The remaining ions inside the nerve fiber can be both positive and negative, as shown in the upper panel of **Fig. 5.3**. Therefore, transfer of an incredibly small number of ions through the membrane can establish the normal resting potential of −70 mV inside the nerve fiber, which means that only about 1/3,000,000 to 1/100,000,000 of the total positive charges inside the fiber must be transferred. Also, an equally small number of positive ions moving from outside to inside the fiber can reverse the potential from −70 mV to as much as +35 mV within as little as 1/10,000 of a second. Rapid shifting of ions in this manner causes the nerve signals discussed in subsequent sections of this chapter.

RESTING MEMBRANE POTENTIAL OF NEURONS

The resting membrane potential of large nerve fibers when they are not transmitting nerve signals is about −70 mV. That is, the potential *inside the fiber* is 70 mV more

negative than the potential in the extracellular fluid on the outside of the fiber. In the next few paragraphs, the transport properties of the resting nerve membrane for sodium and potassium and the factors that determine the level of this resting potential are explained.

Active Transport of Sodium and Potassium Ions Through the Membrane—the Sodium-Potassium (Na^+-K^+) Pump. Recall from Chapter 4 that all cell membranes of the body have a powerful Na^+-K^+ pump that continually transports sodium ions to the outside of the cell and potassium ions to the inside, as illustrated on the left side in **Fig. 5.4**. Note that this is an *electrogenic pump* because three Na^+ ions are pumped to the outside for each two K^+ ions to the inside, leaving a net deficit of positive ions on the inside and causing a negative potential inside the cell membrane.

The Na^+-K^+ pump also causes large concentration gradients for sodium and potassium across the resting nerve membrane. These gradients are as follows:

Na^+ (outside): 142 mEq/L

Na^+ (inside): 14 mEq/L

K^+ (outside): 4 mEq/L

K^+ (inside): 140 mEq/L

The ratios of these two respective ions from the inside to the outside are as follows:

$$Na^+_{inside}/Na^+_{outside} = 0.1$$

$$K^+_{inside}/K^+_{outside} = 35.0$$

Leakage of Potassium Through the Nerve Cell Membrane. The right side of **Fig. 5.4** shows a channel protein (sometimes called a *tandem pore domain, potassium channel*, or *potassium* [K^+] *"leak" channel*) in the nerve membrane through which potassium ions can leak, even in a resting cell. The basic structure of potassium channels was described in Chapter 4 (**Fig. 4.4**). These K^+ leak channels may also leak sodium ions slightly but are far more permeable to potassium than to sodium, normally about 100 times as permeable. As discussed later, this differential in permeability is a key factor in determining the level of the normal resting membrane potential.

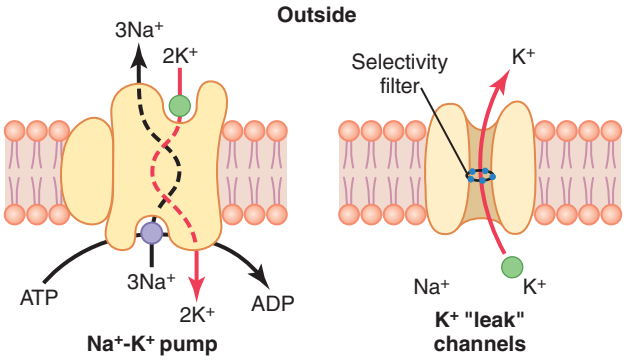

Figure 5.4 Functional characteristics of the Na^+-K^+ pump and the K^+ "leak" channels. The K^+ leak channels also leak Na^+ ions into the cell slightly but are much more permeable to K^+. *ADP*, Adenosine diphosphate; *ATP*, adenosine triphosphate.

Origin of the Normal Resting Membrane Potential

Fig. 5.5 shows the important factors in establishment of the normal resting membrane potential. They are as follows.

Contribution of the Potassium Diffusion Potential. In **Fig. 5.5A**, we assume that the only movement of ions through the membrane is diffusion of potassium ions, as demonstrated by the open channels between the potassium symbol (K^+) inside and outside the membrane. Because of the high ratio of potassium ions inside to outside, 35:1, the Nernst potential corresponding to this ratio is −94 mV because the logarithm of 35 is 1.54, and this,

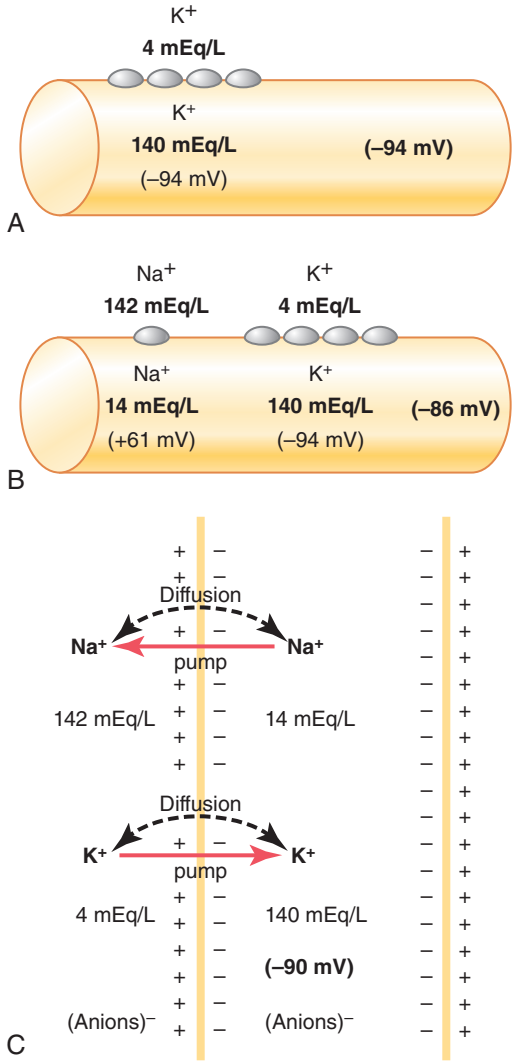

Figure 5.5 Establishment of resting membrane potentials under three conditions. (A) When the membrane potential is caused entirely by potassium diffusion alone. (B) When the membrane potential is caused by diffusion of both sodium and potassium ions. (C) When the membrane potential is caused by diffusion of both sodium and potassium ions plus pumping of both these ions by the Na^+-K^+ pump.

multiplied by −61 mV, is −94 mV. Therefore, if potassium ions were the only factor causing the resting potential, the resting potential *inside the fiber* would be equal to −94 mV, as shown in the figure.

Contribution of Sodium Diffusion Through the Nerve Membrane. **Fig. 5.5B** shows the addition of slight permeability of the nerve membrane to sodium ions, caused by the minute diffusion of sodium ions through the K^+-Na^+ leak channels. The ratio of sodium ions from inside to outside the membrane is 0.1, which gives a calculated Nernst potential for the inside of the membrane of +61 mV. Also shown in **Fig. 5.5B** is the Nernst potential for potassium diffusion of −94 mV. How do these interact with each other, and what will be the summated potential? This question can be answered by using the Goldman equation described previously. Intuitively, one can see that if the membrane is highly permeable to potassium but only slightly permeable to sodium, the diffusion of potassium contributes far more to the membrane potential than the diffusion of sodium. In the normal nerve fiber, the permeability of the membrane to potassium is about 100 times as great as its permeability to sodium. Using this value in the Goldman equation, and considering only sodium and potassium, gives a potential inside the membrane of −86 mV, which is near the potassium potential shown in the figure.

Contribution of the Na^+-K^+ Pump. As shown in **Fig. 5.5C**, the Na^+-K^+ pump provides an additional contribution to the resting potential. This figure shows that continuous pumping of three sodium ions to the outside occurs for each two potassium ions pumped to the inside of the membrane. The pumping of more sodium ions to the outside than the potassium ions being pumped to the inside causes a loss of positive charges from inside the membrane, creating an additional degree of negativity (about −4 mV additional) on the inside, beyond that which can be accounted for by diffusion alone.

Therefore, as shown in **Fig. 5.5C**, the net membrane potential when all these factors are operative at the same time is about −90 mV. However, additional ions, such as chloride, must also be considered in calculating the membrane potential.

In summary, the diffusion potentials alone caused by potassium and sodium diffusion would give a membrane potential of about −86 mV, with almost all of this being determined by potassium diffusion. An additional −4 mV is then contributed to the membrane potential by the continuously acting electrogenic Na^+-K^+ pump, and there is a contribution of chloride ions. As mentioned previously, the resting membrane potential varies in different cells from as low as around −10 mV in erythrocytes to as high as −90 mV in skeletal muscle cells.

NEURON ACTION POTENTIAL

Nerve signals are transmitted by *action potentials*, which are rapid changes in the membrane potential that spread rapidly along the nerve fiber membrane. Each action potential begins with a sudden change from the normal resting negative membrane potential to a positive potential and ends with an almost equally rapid change back to the negative potential. To conduct a nerve signal, the action potential moves along the nerve fiber until it comes to the fiber's end.

The upper panel of **Fig. 5.6** shows the changes that occur at the membrane during the action potential, with the transfer of positive charges to the interior of the fiber at its onset and the return of positive charges to the exterior at its end. The lower panel shows graphically the successive changes in membrane potential over a few milliseconds, illustrating the explosive onset of the action potential and the almost equally rapid recovery.

The successive stages of the action potential are as follows.

Resting Stage. The resting stage is the resting membrane potential before the action potential begins. The membrane is said to be "polarized" during this stage because of the −70 mV negative membrane potential that is present.

Depolarization Stage. An action potential is triggered when a stimulus depolarizes the membrane to a *threshold* level, usually around −55 mV. At this time, the membrane suddenly becomes permeable to sodium ions, allowing rapid diffusion of positively charged sodium ions to the interior of the axon. The normal polarized state of −70 mV is immediately neutralized by the inflowing, positively

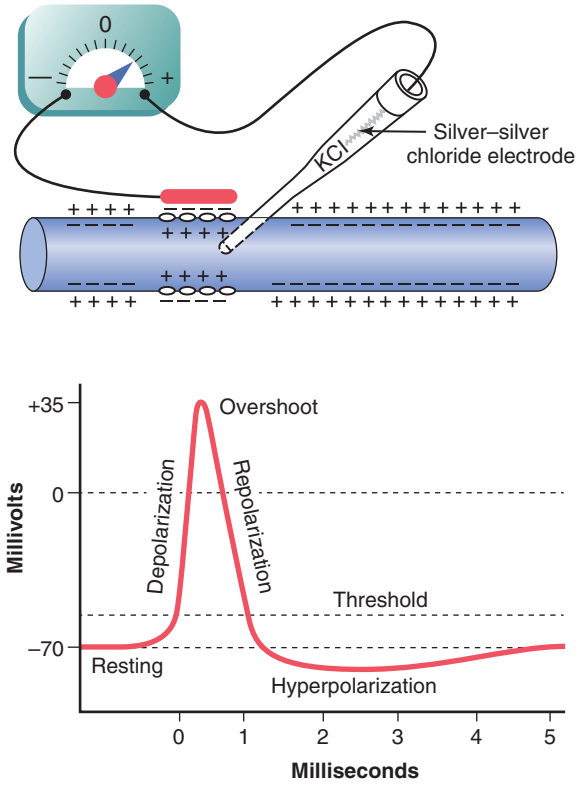

Figure 5.6 Typical action potential recorded by the method shown in the *upper panel*.

charged sodium ions, with the potential rising rapidly in the positive direction—a process called *depolarization*. In large nerve fibers, the great excess of positive sodium ions moving to the inside causes the membrane potential to actually overshoot beyond the zero level and to become somewhat positive. In some smaller fibers, as well as in many central nervous system neurons, the potential merely approaches the zero level and does not overshoot to the positive state.

Repolarization Stage. In less than a millisecond after the membrane becomes highly permeable to sodium ions, the sodium channels begin to close, and the potassium channels open to a greater degree than normal. Then, rapid diffusion of potassium ions to the exterior reestablishes the normal negative resting membrane potential, which is called *repolarization* of the membrane. The potassium channels may remain open longer than needed to return the membrane to its resting potential, resulting in *hyperpolarization* (**Fig. 5.6**), also called *undershoot*. As soon as the potassium channels close, potassium diffusion out of the cell decreases and the membrane potential returns to its normal resting value.

To explain more fully the factors that cause both depolarization and repolarization, we will describe the special characteristics of two other types of transport channels through the nerve membrane, the voltage-gated sodium and potassium channels.

VOLTAGE-GATED SODIUM AND POTASSIUM CHANNELS

An essential factor in causing depolarization and repolarization of the nerve membrane during the action potential is the *voltage-gated sodium channel*. A *voltage-gated potassium channel* also plays an important role in increasing the rapidity of repolarization of the membrane. *These two voltage-gated channels are in addition to the Na^+-K^+ pump and the K^+ leak channels.*

Activation and Inactivation of the Voltage-Gated Sodium Channel

The upper panel of **Fig. 5.7** shows the voltage-gated sodium channel in three separate states. This channel has two *gates*—one near the outside of the channel called the *activation gate*, and another near the inside called the *inactivation gate*. The upper left of the figure depicts the state of these two gates in the normal resting membrane when the membrane potential is −70 mV. In this state, the activation gate is closed, which prevents entry of sodium ions to the interior of the fiber through these sodium channels.

Activation of the Sodium Channel. When the membrane potential becomes less negative than during the resting state, rising from −70 mV toward zero, it finally reaches the threshold voltage, often around 15 mV above the resting membrane potential; this causes a sudden

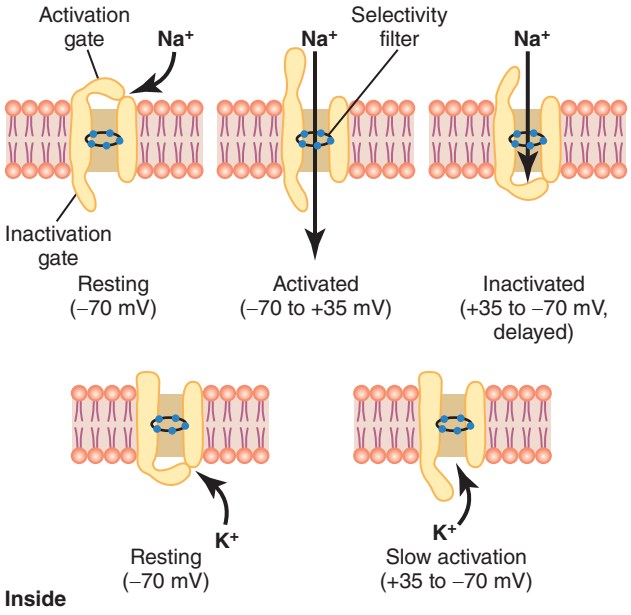

Figure 5.7 Characteristics of the voltage-gated sodium *(top)* and potassium *(bottom)* channels, showing successive activation and inactivation of the sodium channels and delayed activation of the potassium channels when the membrane potential is changed from the normal resting negative value to a positive value.

conformational change in the activation gate, flipping it all the way to the open position. During this *activated state*, sodium ions can flow inward through the channel, increasing the sodium permeability of the membrane as much as 500- to 5000-fold.

Inactivation of the Sodium Channel. The upper right panel of **Fig. 5.7** shows a third state of the sodium channel. The same increase in voltage that opens the activation gate also closes the inactivation gate. The inactivation gate, however, closes a few 10,000ths of a second after the activation gate opens. That is, the conformational change that flips the inactivation gate to the closed state is a slower process than the conformational change that opens the activation gate. Therefore, after the sodium channel has remained open for a few 10,000ths of a second, the inactivation gate closes, and sodium ions no longer can flow to the inside of the membrane. At this point, the membrane potential begins to return toward the resting membrane state, which is the repolarization process.

Another important characteristic of the sodium channel inactivation process is that the inactivation gate will not reopen until the membrane potential returns to or near the original resting membrane potential level. Therefore, it is usually not possible for the sodium channels to open again without first repolarizing the nerve fiber.

Voltage-Gated Potassium Channel and Its Activation

The lower panel of **Fig. 5.7** shows the voltage-gated potassium channel in two states—during the resting state (left) and toward the end of the action potential (right). During the resting state, the gate of the potassium channel

is closed, and potassium ions are prevented from passing through this channel to the exterior. When the membrane potential rises from −70 mV toward zero, this voltage change causes a conformational opening of the gate and allows increased potassium diffusion outward through the channel. However, because of the slight delay in opening of the potassium channels, they generally open at about the same time that the sodium channels begin to close because of inactivation. Thus, the decrease in sodium entry to the cell and the simultaneous increase in potassium exit from the cell combine to speed the repolarization process, leading to recovery of the resting membrane potential within another few 10,000ths of a second.

The Voltage Clamp Method for Measuring the Effect of Voltage on Opening and Closing of Voltage-Gated Channels. The original research that led to quantitative understanding of the sodium and potassium channels was so ingenious that it led to the Nobel Prize in Physiology or Medicine for Alan Hodgkin and Andrew Huxley in 1963. The essence of these studies is shown in **Figs. 5.8 and 5.9**.

Fig. 5.8 shows the *voltage clamp method*, which is used to measure the flow of ions through the different channels. In using this apparatus, two electrodes are inserted into the nerve fiber. One of these electrodes is used to measure the voltage of the membrane potential, and the other is used to conduct electrical current into or out of the nerve fiber.

This apparatus is used in the following way. The investigator decides which voltage to establish inside the nerve fiber. The electronic portion of the apparatus is then adjusted to the desired voltage, automatically injecting either positive or negative electricity through the current electrode at whatever rate is required to hold the voltage, as measured by the voltage electrode, at the level set by the operator. When the membrane potential is suddenly increased by this voltage clamp from −70 mV to zero, the voltage-gated sodium and potassium channels open, and sodium and potassium ions begin to flow through the channels. To counterbalance the effect of these ion movements on the desired setting of the intracellular voltage, electrical current is injected automatically through the current electrode of the voltage clamp to maintain the intracellular voltage at the required steady zero level. To achieve this level, the current injected must be equal to but of opposite polarity to the net current flow through the membrane channels. To measure how much current flow is occurring at each instant, the current electrode is connected to an ampere meter that records the current flow, as demonstrated in **Fig. 5.8**.

Finally, the investigator adjusts the concentrations of the ions to other than normal levels both inside and outside the nerve fiber and repeats the study. This experiment can be performed easily when using large nerve fibers removed from some invertebrates, especially the giant squid axon, which in some cases is as large as 1 millimeter in diameter. When sodium is the only permeant ion in the solutions inside and outside the squid axon, the voltage clamp measures current flow only through the sodium channels. When potassium is the only permeant ion, current flow only through the potassium channels is measured.

Another means for studying the flow of ions through an individual type of channel is to block one type of channel at a time. For example, the sodium channels can be blocked by a toxin called *tetrodotoxin* when it is applied to the outside of the cell membrane where the sodium activation gates are located. Conversely, *tetraethylammonium ion* blocks the potassium channels when it is applied to the interior of the nerve fiber.

Fig. 5.9 shows typical changes in conductance of the voltage-gated sodium and potassium channels when the membrane potential is suddenly changed through use of the voltage clamp, from −70 mV to +10 mV and then, 2 milliseconds later, back to −70 mV. Note the sudden opening of the sodium channels (the activation stage) within a small fraction of a millisecond after the membrane potential is increased to the positive value. However, during the next millisecond or so, the sodium channels automatically close (the inactivation stage).

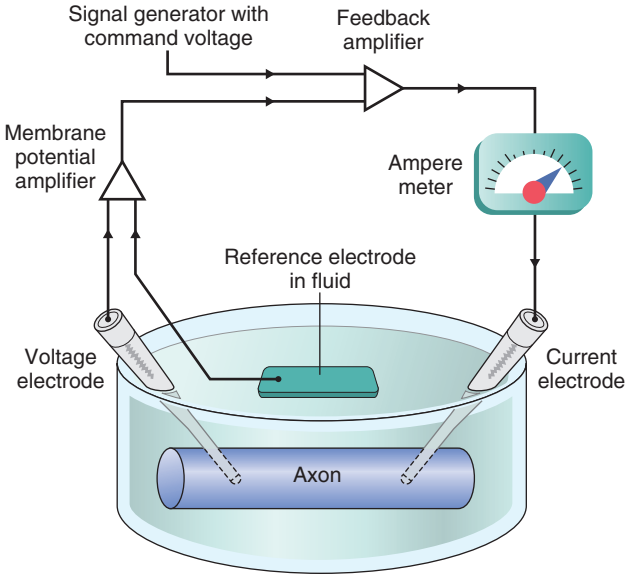

Figure 5.8 Voltage clamp method for studying flow of ions through specific channels.

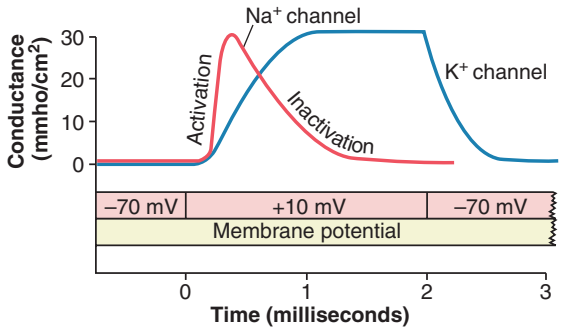

Figure 5.9 Typical changes in conductance of sodium and potassium ion channels when the membrane potential is suddenly increased from the normal resting value of −70 mV to a positive value of +10 mV for 2 milliseconds. This figure shows that the sodium channels open (activate) and then close (inactivate) before the end of the 2 milliseconds, whereas the potassium channels only open (activate), and the rate of opening is much slower than that of the sodium channels.

Note the opening (activation) of the potassium channels, which open less rapidly and reach their full open state only after the sodium channels have almost completely closed. Furthermore, once the potassium channels open, they remain open for the entire duration of the positive membrane potential and do not close again until after the membrane potential is decreased back to a negative value.

SUMMARY OF EVENTS THAT CAUSE THE ACTION POTENTIAL

Fig. 5.10 summarizes the sequential events that occur during and shortly after the action potential. The bottom of the figure shows the changes in membrane conductance for sodium and potassium ions. During the resting state, before the action potential begins, the conductance for potassium ions is 50 to 100 times as great as the conductance for sodium ions. This disparity is caused by much greater leakage of potassium ions than sodium ions through the leak channels. However, at the onset of the action potential, the sodium channels almost instantaneously become activated and allow up to a 5000-fold increase in sodium conductance. The inactivation process then closes the sodium channels within another fraction of a millisecond. The onset of the action potential also initiates voltage gating of the potassium channels, causing them to begin opening more slowly, a fraction of a millisecond after the sodium channels open. At the end of the action potential, the return of the membrane potential to the negative state causes the potassium channels to close back to their original status but only after an additional millisecond or more delay.

The middle portion of **Fig. 5.10** shows the ratio of sodium to potassium conductance at each instant during the action potential, and above this depiction is the action potential itself. During the early portion of the action potential, the ratio of sodium to potassium conductance increases more than 1000-fold. Therefore, far more sodium ions flow to the interior of the fiber than potassium ions to the exterior. This is what causes the membrane potential to become positive at the action potential onset. Then, the sodium channels begin to close, and the potassium channels begin to open; thus, the ratio of conductance shifts far in favor of high potassium conductance but low sodium conductance. This shift allows for rapid loss of potassium ions to the exterior but virtually zero flow of sodium ions to the interior. Consequently, the action potential quickly returns to its baseline level.

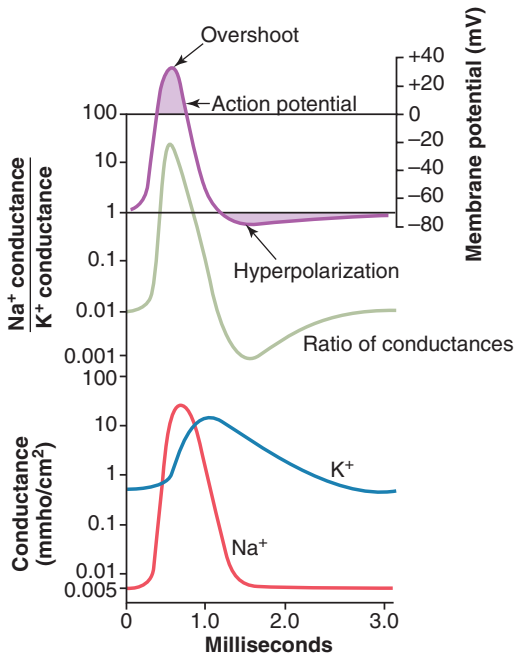

Figure 5.10 Changes in sodium and potassium conductance during the course of the action potential. Sodium conductance increases several thousand–fold during the early stages of the action potential, whereas potassium conductance increases only about 30-fold during the latter stages of the action potential and for a short period thereafter. (These curves were constructed from theory presented in papers by Hodgkin and Huxley but transposed from a squid axon to apply to the membrane potentials of large mammalian nerve fibers.)

Roles of Other Ions During the Action Potential

Thus far, we have considered only the roles of sodium and potassium ions in generating the action potential. At least two other types of ions must be considered, negatively charged ions and calcium ions.

Impermeant Negatively Charged Ions (Anions) Inside the Nerve Axon. Inside the axon are many negatively charged ions that cannot go through the membrane channels. They include the anions of protein molecules and of many organic phosphate compounds and sulfate compounds, among others. Because these ions cannot leave the interior of the axon, any deficit of positive ions inside the membrane leaves an excess of these impermeant negative anions. Therefore, these impermeant negative ions are responsible for the negative charge inside the fiber when there is a net deficit of positively charged potassium ions and other positive ions.

Ca^{2+} Pump and Voltage-Gated Ca^{2+} Channels. The membranes of almost all cells of the body have a Ca^{2+} pump similar to the sodium pump, and Ca^{2+} serves along with (or instead of) sodium in some cells to cause most of the action potential. Like the sodium pump, the Ca^{2+} pump transports Ca^{2+} from the interior to the exterior of the cell membrane (or into the endoplasmic reticulum of the cell), creating a Ca^{2+} gradient of about 10,000-fold. This process leaves an internal cell concentration of Ca^{2+} of about 10^{-7} molar, in contrast to a much higher external concentration of about 10^{-3} molar.

In addition, there are *voltage-gated Ca^{2+} channels*. Because the Ca^{2+}concentration is more than 10,000 times greater in the extracellular fluid than in the intracellular fluid, there is a tremendous diffusion gradient and electrochemical driving force for passive flow of Ca^{2+} into the cells. These channels are slightly permeable to sodium ions and Ca^{2+}, but their permeability to Ca^{2+} is about 1000-fold greater than to sodium under normal physiological conditions. When the channels open in response to a stimulus

that depolarizes the cell membrane, Ca^{2+} ions flow to the interior of the cell.

A major function of the voltage-gated Ca^{2+} channels is to contribute to the depolarizing phase on the action potential in some cells. The gating of Ca^{2+} channels, however, is relatively slow, requiring 10 to 20 times as long for activation as for sodium channels. For this reason, they are often called *slow channels*, in contrast to the sodium channels, which are called *fast channels*. Therefore, opening of Ca^{2+} channels provides a more sustained depolarization, whereas sodium channels play a key role in initiating action potentials.

Calcium channels are numerous in cardiac muscle and smooth muscle. In some types of smooth muscle, the fast sodium channels are hardly present and action potentials are caused almost entirely by activation of slow Ca^{2+} channels.

Decreased Extracellular Fluid Ca^{2+} Concentration Increases Permeability of Sodium Channels. When there is a deficit of Ca^{2+} (*hypocalcemia*), the sodium channels can become activated (opened) by a small increase of the membrane potential from its normal, very negative level. Therefore, the nerve fiber becomes highly excitable, sometimes discharging repetitively without provocation, rather than remaining in the resting state. In fact, when Ca^{2+} concentration falls 50% below normal, spontaneous discharge occurs in some peripheral nerves, often causing *muscle "tetany."* Muscle tetany is sometimes lethal because of tetanic contraction of the respiratory muscles.

Calcium ions affect the sodium channels by binding to the exterior surfaces of the sodium channel protein. The positive charges of Ca^{2+}, in turn, attenuate activity of the sodium channel protein, thus increasing the voltage level required to open the sodium gate. This inhibition of sodium movement through voltage-gated sodium channels is lost with hypocalcemia, and excitable cells, such as neurons, become hyperexcitable.

INITIATION OF THE ACTION POTENTIAL

Thus far, we have explained the changing sodium and potassium permeability of the membrane, as well as the development of the action potential, but we have not explained what initiates the action potential.

A Positive-Feedback Cycle Opens the Sodium Channels. As long as the membrane of the nerve fiber remains undisturbed, no action potential occurs in the normal nerve. However, if any event causes enough initial rise in the membrane potential from −70 mV toward the zero level, the rising voltage will cause many voltage-gated sodium channels to begin opening. This occurrence allows for the rapid inflow of sodium ions, which causes a further rise in the membrane potential, thus opening still more voltage-gated sodium channels and allowing more streaming of sodium ions to the interior of the fiber. This process is a positive-feedback cycle that, once the feedback is strong enough, continues until all the voltage-gated sodium channels have become activated (opened). Then, within another fraction of a millisecond, the rising membrane potential causes closure of the sodium channels and opening of potassium channels, and the action potential soon terminates.

Initiation of the Action Potential Occurs Only After the Threshold Potential Is Reached. An action potential will not occur until the initial rise in membrane potential is great enough to create the positive feedback described in the preceding paragraph. This occurs when the number of sodium ions entering the fiber is greater than the number of potassium ions leaving the fiber. A sudden rise in membrane potential of 15 to 30 mV is usually required. Therefore, a sudden increase in the membrane potential in a large nerve fiber, from −70 mV up to about −55 mV, usually causes the explosive development of an action potential. This level of −55 mV is said to be the *threshold* for stimulation.

PROPAGATION OF THE ACTION POTENTIAL

In the preceding paragraphs, we discussed the action potential as though it occurs at one spot on the membrane. However, an action potential elicited at any one point on an excitable membrane usually excites adjacent portions of the membrane, resulting in propagation of the action potential along the membrane. This mechanism is demonstrated in **Fig. 5.11**.

Fig. 5.11A shows a normal resting nerve fiber, and **Fig. 5.11B** shows a nerve fiber that has been excited in its midportion, which suddenly develops increased

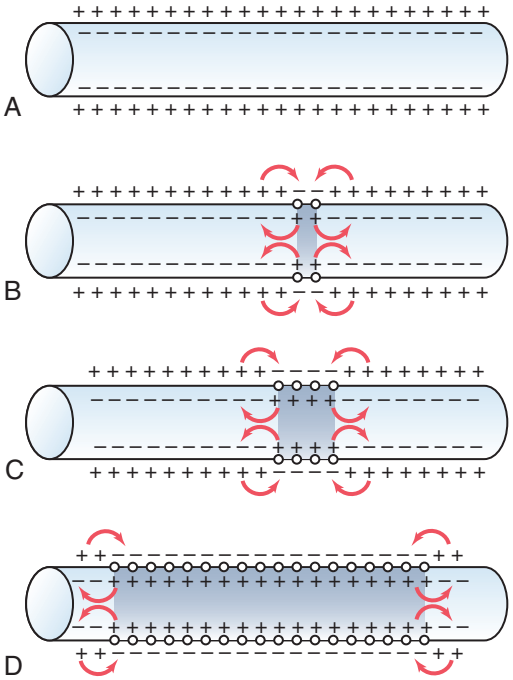

Figure 5.11 (A–D) Propagation of action potentials in both directions along a conductive fiber.

permeability to sodium. The *arrows* show a local circuit of current flow from the depolarized areas of the membrane to the adjacent resting membrane areas. That is, positive electrical charges are carried by the inward-diffusing sodium ions through the depolarized membrane and then for several millimeters in both directions along the core of the axon. These positive charges increase the voltage for a distance of 1 to 3 millimeters inside a large myelinated nerve fiber to above the threshold voltage value for initiating an action potential. Therefore, the sodium channels in these new areas immediately open, as shown in **Fig. 5.11C–D**, and the explosive action potential spreads. These newly depolarized areas produce additional local circuits of current flow farther along the membrane, causing progressively more and more depolarization. Thus, the depolarization process travels along the entire length of the fiber. This transmission of the depolarization process along a nerve or muscle fiber is called a *nerve* or *muscle impulse*.

Direction of Propagation. As demonstrated in **Fig. 5.11**, an excitable membrane has no single direction of propagation, but the action potential travels in all directions away from the stimulus—even along all branches of a nerve fiber—until the entire membrane has become depolarized.

All-or-Nothing Principle. Once an action potential has been elicited at any point on the membrane of a normal fiber, the depolarization process travels over the entire membrane if conditions are right, but it does not travel at all if conditions are not right. This principle is called the *all-or-nothing principle*, and it applies to all normal excitable tissues. Occasionally, the action potential reaches a point on the membrane at which it does not generate sufficient voltage to stimulate the next area of the membrane. When this situation occurs, the spread of depolarization stops. Therefore, for continued propagation of an impulse to occur, the ratio of action potential to threshold for excitation must at all times be greater than 1. This "greater than 1" requirement is called the *safety factor* for propagation.

IMPORTANCE OF ENERGY METABOLISM FOR REESTABLISHING SODIUM AND POTASSIUM IONIC GRADIENTS AFTER ACTION POTENTIALS ARE COMPLETED

Transmission of each action potential along a nerve fiber slightly reduces the concentration differences of sodium and potassium inside and outside the membrane because sodium ions diffuse to the inside during depolarization, and potassium ions diffuse to the outside during repolarization. For a single action potential, this effect is so minute that it cannot be measured. Indeed, 100,000 to 50 million impulses can be transmitted by large nerve fibers before the concentration differences reach the point that action potential conduction ceases. With time, however, it becomes necessary to reestablish the sodium and potassium membrane concentration differences, which is achieved by action of the Na^+-K^+ pump in the same way as described previously for the original establishment of the resting potential. That is, sodium ions that have diffused to the interior of the cell during the action potentials and potassium ions that have diffused to the exterior are returned to their original state by the Na^+-K^+ pump. Because this pump requires energy for operation, this "recharging" of the nerve fiber is an active metabolic process, using energy derived from the adenosine triphosphate (ATP) energy system of the cell. **Fig. 5.12** shows that the nerve fiber produces increased heat during recharging, which is a measure of energy expenditure when the nerve impulse frequency increases.

A special feature of the Na^+-K^+ ATP pump is that its activity is strongly stimulated when excess sodium ions accumulate inside the cell membrane. In fact, the pumping activity increases approximately in proportion to the third power of this intracellular sodium concentration. As the internal sodium concentration rises from 10 to 20 mEq/L, the activity of the pump does not merely double but increases about 8-fold. Therefore, it is easy to understand how recharging of the nerve fiber occurs rapidly whenever the concentration differences of sodium and potassium ions across the membrane begin to run down.

PLATEAU IN SOME ACTION POTENTIALS

In some cases, the excited membrane does not repolarize immediately after depolarization; instead, the potential remains on a plateau near the peak of the spike potential for many milliseconds before repolarization begins. Such a plateau is shown in **Fig. 5.13**; one can readily see that the plateau greatly prolongs the period of depolarization. This type of action potential occurs in heart muscle fibers, where the plateau lasts for as long as 0.2 to 0.3 second and causes contraction of heart muscle to last for this same long period.

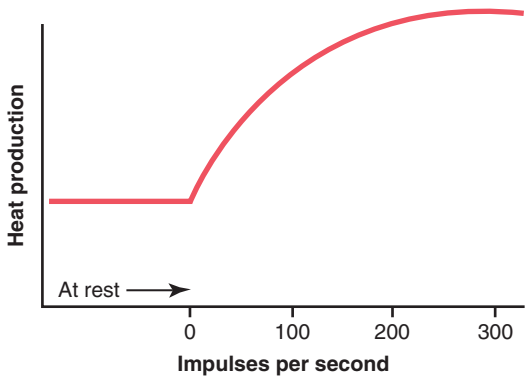

Figure 5.12 Heat production in a nerve fiber at rest and at progressively increasing rates of stimulation.

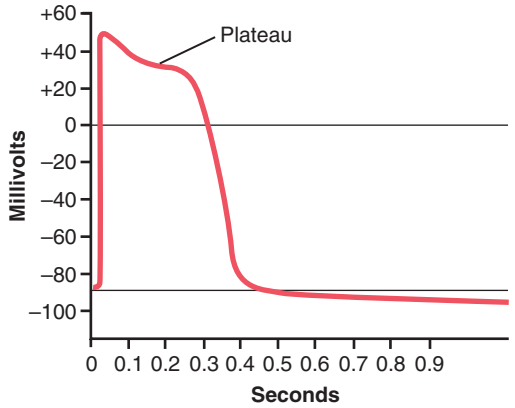

Figure 5.13 Action potential (in millivolts) from a Purkinje fiber of the heart, showing a plateau.

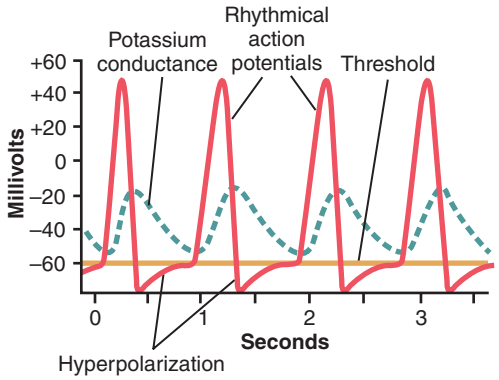

Figure 5.14 Rhythmical action potentials (in millivolts) similar to those recorded in the rhythmical control center of the heart. Note their relationship to potassium conductance and to the state of hyperpolarization.

The cause of the plateau is a combination of several factors. First, in heart muscle, two types of channels contribute to the depolarization process: (1) the usual voltage-activated sodium channels, called *fast channels;* and (2) voltage-activated calcium-sodium channels *(L-type Ca^{2+} channels)*, which are slow to open and therefore are called *slow channels*. Opening of fast channels causes the spike portion of the action potential, whereas the prolonged opening of the slow calcium-sodium channels mainly allows Ca^{2+} to enter the fiber, which is largely responsible for the plateau portion of the action potential.

Another factor that may be partly responsible for the plateau is that the voltage-gated potassium channels are slower to open than usual, often not opening much until the end of the plateau. This factor delays the return of the membrane potential toward its normal negative value of −70 mV. The plateau ends when the calcium-sodium channels close, and permeability to potassium ions increases.

RHYTHMICITY OF SOME EXCITABLE TISSUES—REPETITIVE DISCHARGE

Repetitive self-induced discharges occur normally in the heart, in most smooth muscle, and in many of the neurons of the central nervous system. These rhythmical discharges cause the following: (1) rhythmical beat of the heart; (2) rhythmical peristalsis of the intestines; and (3) other neuronal events such as the rhythmical control of breathing.

In addition, almost all other excitable tissues can discharge repetitively if the threshold for stimulation of the tissue cells is reduced to a low enough level. For example, even large nerve fibers and skeletal muscle fibers, which normally are highly stable, discharge repetitively when they are placed in a solution that contains the drug *veratridine*, which activates sodium ion channels, or when Ca^{2+} concentration decreases below a critical value, which increases the sodium permeability of the membrane.

Re-Excitation Process Necessary for Spontaneous Rhythmicity. For spontaneous rhythmicity to occur, the membrane—even in its natural state—must be permeable enough to sodium ions (or to calcium and sodium ions through the slow calcium-sodium channels) to allow automatic membrane depolarization. Thus, **Fig. 5.14** shows that the resting membrane potential in the rhythmical control center of the heart is only −60 to −70 mV, which is not enough negative voltage to keep the sodium and Ca^{2+} channels totally closed. Therefore, the following sequence occurs: (1) some sodium and calcium ions flow inward; (2) this activity increases the membrane voltage in the positive direction, which further increases membrane permeability; (3) still more ions flow inward; and (4) the permeability increases more, and so on, until an action potential is generated. Then, at the end of the action potential, the membrane repolarizes. After another delay of milliseconds or seconds, spontaneous excitability causes depolarization again, and a new action potential occurs spontaneously. This cycle continues over and over and causes self-induced rhythmical excitation of the excitable tissue.

Why does the membrane of the heart control center not depolarize immediately after it has become repolarized, rather than delaying for nearly 1 second before the onset of the next action potential? The answer can be found by observing the curve labeled "potassium conductance" in **Fig. 5.14**. This curve shows that toward the end of each action potential, and continuing for a short period thereafter, the membrane becomes more permeable to potassium ions. The increased outflow of potassium ions carries tremendous numbers of positive charges to the outside of the membrane, leaving considerably more negativity inside the fiber than would otherwise occur. This continues for nearly 1 second after the preceding action potential is over, thus drawing the membrane potential nearer to the potassium Nernst potential. This state, called *hyperpolarization*, is also shown in **Fig. 5.14**. As long as this state exists, self–re-excitation will not occur. However, the increased potassium conductance (and the state of hyperpolarization) gradually disappears, as shown after each action potential is completed in the figure, thereby

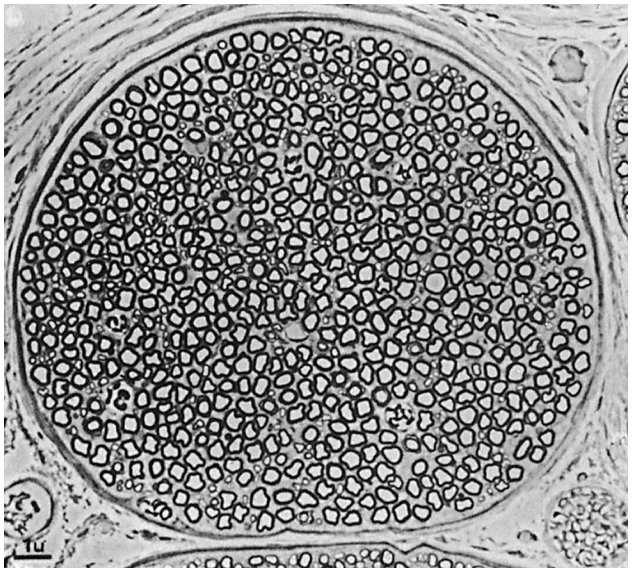

Figure 5.15 Cross section of a small nerve trunk containing both myelinated and unmyelinated fibers.

again allowing the membrane potential to increase up to the *threshold* for excitation. Then, suddenly, a new action potential results and the process occurs again and again.

SPECIAL CHARACTERISTICS OF SIGNAL TRANSMISSION IN NERVE TRUNKS

Myelinated and Unmyelinated Nerve Fibers. Fig. 5.15 shows a cross section of a typical small nerve trunk, revealing many large nerve fibers that constitute most of the cross-sectional area. However, a more careful look reveals many more small fibers lying between the large ones. The large fibers are *myelinated*, and the small ones are *unmyelinated*. The average nerve trunk contains about twice as many unmyelinated fibers as myelinated fibers.

Fig. 5.16 illustrates schematically the features of a typical myelinated fiber. The central core of the fiber is the *axon*, and the membrane of the axon is the membrane that actually conducts the action potential. The axon is filled in its center with *axoplasm*, which is a viscid intracellular fluid. Surrounding the axon is a *myelin sheath* that is often much thicker than the axon itself. About once every 1 to 3 millimeters there is a gap in the myelin sheath called a *node of Ranvier*.

The myelin sheath is deposited around the axon by *Schwann cells* in the following manner. The membrane of a Schwann cell first envelops the axon. The Schwann cell then rotates around the axon many times, laying down multiple layers of Schwann cell membrane containing the lipid substance *sphingomyelin*. This substance is an excellent electrical insulator that decreases ion flow through the membrane about 5000-fold. At the juncture between each two successive Schwann cells along the axon, a small uninsulated area only 2 to 3 micrometers in

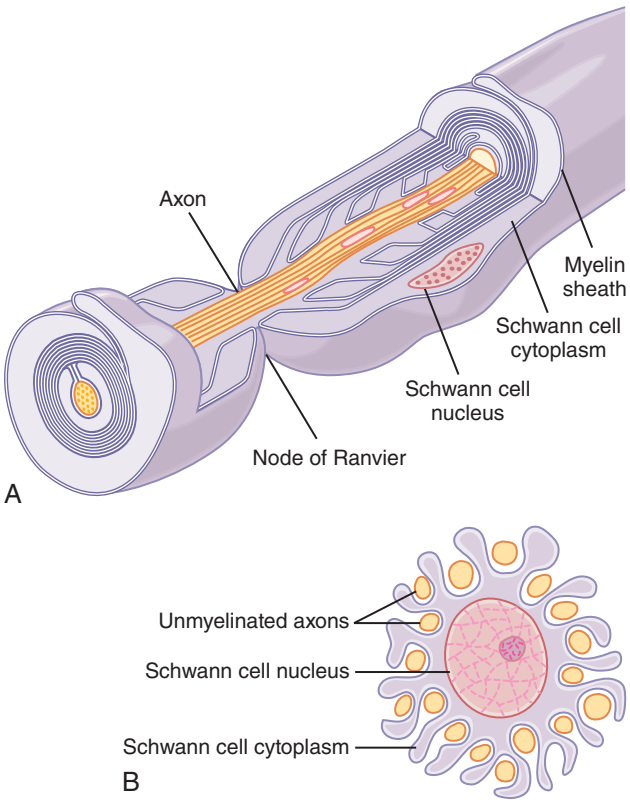

Figure 5.16 Function of the Schwann cell to insulate nerve fibers. (A) Wrapping of a Schwann cell membrane around a large axon to form the myelin sheath of the myelinated nerve fiber. (B) Partial wrapping of the membrane and cytoplasm of a Schwann cell around multiple unmyelinated nerve fibers (shown in cross section). (A, *Modified from Leeson TS, Leeson R:* Histology. *Philadelphia: WB Saunders, 1979.*)

length remains where ions still can flow with ease through the axon membrane between the extracellular fluid and intracellular fluid inside the axon. This area is the *node of Ranvier*.

Saltatory Conduction in Myelinated Fibers From Node to Node. Even though almost no ions can flow through the thick myelin sheaths of myelinated nerves, they can flow with ease through the nodes of Ranvier. Therefore, action potentials occur *only at the nodes*. Yet, the action potentials are conducted from node to node by *saltatory conduction*, as shown in Fig. 5.17. That is, electrical current flows through the surrounding extracellular fluid outside the myelin sheath, as well as through the axoplasm inside the axon from node to node, exciting successive nodes one after another. Thus, the nerve impulse jumps along the fiber, which is the origin of the term *saltatory*.

Saltatory conduction is of value for two reasons:

1. By causing the depolarization process to jump long intervals along the axis of the nerve fiber, this mechanism increases the velocity of nerve transmission in myelinated fibers as much as 5- to 50-fold.
2. Saltatory conduction conserves energy for the axon because only the nodes depolarize, allowing perhaps 100 times less loss of ions than would otherwise be

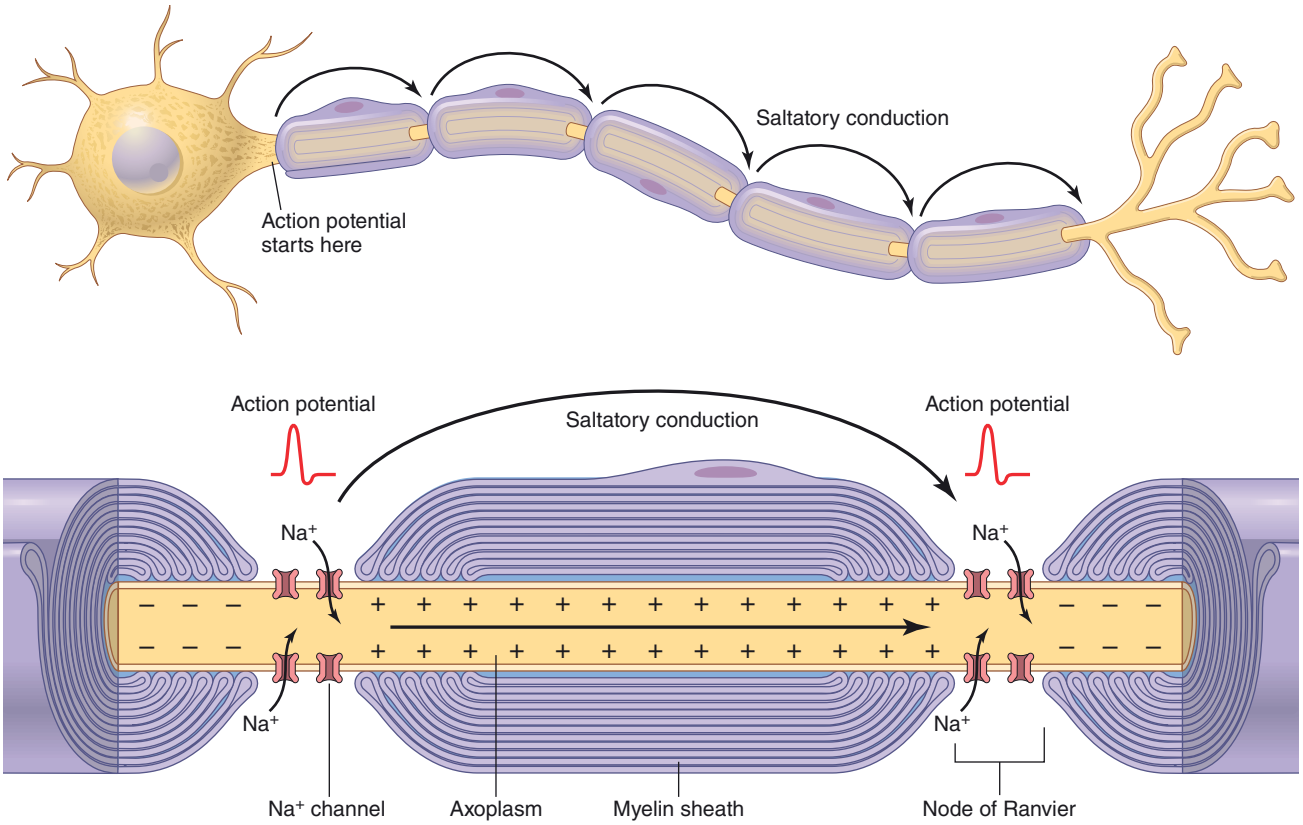

Figure 5.17 Saltatory conduction along a myelinated axon. The flow of electrical current from node to node is illustrated by the *arrows*.

necessary, and therefore requiring much less energy expenditure for reestablishing the sodium and potassium concentration differences across the membrane after a series of nerve impulses.

The excellent insulation afforded by the myelin membrane and the 50-fold decrease in membrane capacitance also allow repolarization to occur with little transfer of ions.

Velocity of Conduction in Nerve Fibers. The velocity of action potential conduction in nerve fibers varies from as little as 0.25 m/sec in small unmyelinated fibers to as much as 100 m/sec—more than the length of a football field in 1 second—in large myelinated fibers.

EXCITATION—THE PROCESS OF ELICITING THE ACTION POTENTIAL

Basically, any factor that causes sodium ions to diffuse inward through the membrane in sufficient numbers can set off automatic regenerative opening of the sodium channels. This automatic regenerative opening can result from *mechanical* disturbance of the membrane, *chemical* effects on the membrane, or passage of *electricity* through the membrane. All these approaches are used at different points in the body to elicit nerve or muscle action potentials: mechanical pressure to excite sensory nerve endings in the skin, chemical neurotransmitters to transmit signals from one neuron to the next in the brain, and electrical current to transmit signals between successive muscle cells in the heart and intestine.

Excitation of a Nerve Fiber By a Negatively Charged Metal Electrode. The usual means for exciting a nerve or muscle in the experimental laboratory is to apply electricity to the nerve or muscle surface through two small electrodes, one of which is negatively charged and the other positively charged. When electricity is applied in this manner, the excitable membrane becomes stimulated at the negative electrode.

Remember that the action potential is initiated by the opening of voltage-gated sodium channels. Furthermore, these channels are opened by a decrease in the normal resting electrical voltage across the membrane—that is, negative current from the electrode decreases the voltage on the outside of the membrane to a negative value nearer to the voltage of the negative potential inside the fiber. This effect decreases the electrical voltage across the membrane and allows the sodium channels to open, resulting in an action potential. Conversely, at the positive electrode, the injection of positive charges on the outside of the nerve membrane heightens the voltage difference across the membrane, rather than lessening it. This effect causes a state of hyperpolarization, which decreases excitability of the fiber rather than causing an action potential.

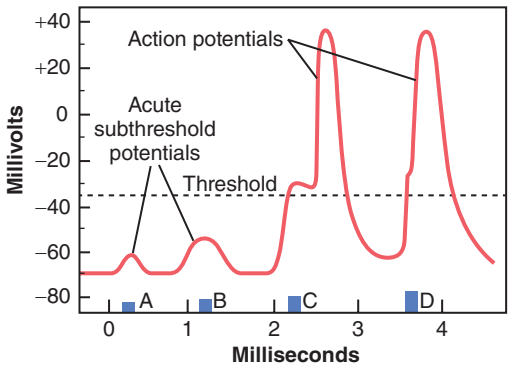

Figure 5.18 Effect of stimuli of increasing voltages to elicit an action potential. Note the development of acute subthreshold potentials when the stimuli are below the threshold value required for eliciting an action potential.

Threshold for Excitation and Acute Local Potentials. A weak negative electrical stimulus may not be able to excite a fiber. However, when the voltage of the stimulus is increased, there comes a point at which excitation takes place. **Fig. 5.18** shows the effects of successively applied stimuli of progressing strength. A weak stimulus at point A causes the membrane potential to change from −70 to −65 mV, but this change is not sufficient for the automatic regenerative processes of the action potential to develop. At point B, the stimulus is greater, but the intensity is still not enough. The stimulus does, however, disturb the membrane potential locally for as long as 1 millisecond or more after both of these weak stimuli. These local potential changes are called *acute local potentials*, and when they fail to elicit an action potential, they are called *acute subthreshold potentials*.

At point C in **Fig. 5.18**, the stimulus is even stronger. Now, the local potential has barely reached the *threshold level* required to elicit an action potential, but this occurs only after a short "latent period." At point D, the stimulus is still stronger, the acute local potential is also stronger, and the action potential occurs after less of a latent period.

Thus, this figure shows that even a weak stimulus causes a local potential change at the membrane, but the intensity of the local potential must rise to a threshold level before the action potential is set off.

DURING THE ABSOLUTE REFRACTORY PERIOD AFTER AN ACTION POTENTIAL A NEW ACTION POTENTIAL CANNOT BE ELICITED

A new action potential cannot occur in an excitable fiber as long as the membrane is still depolarized from the preceding action potential. The reason for this restriction is that shortly after the action potential is initiated, the sodium channels (or calcium channels, or both) become inactivated, and no amount of excitatory signal applied to these channels at this point will open the inactivation gates. The only condition that will allow them to reopen is for the membrane potential to return to or near the original resting membrane potential level. Then, within another small fraction of a second, the inactivation gates of the channels open, and a new action potential can be initiated.

The period during which a second action potential cannot be elicited, even with a strong stimulus, is called the *absolute refractory period*. This period for large myelinated nerve fibers is about 1 millisecond. Therefore, one can readily calculate that such a fiber can transmit a maximum of about 1000 impulses per second. During the *relative refractory period*, which occurs for 2 to 4 milliseconds during the hyperpolarization phase, the neuron can develop another action potential, but a greater stimulus is required compared to the stimulus needed to elicit an action potential in a resting neuron.

Inhibition of Excitability—Stabilizers and Local Anesthetics

In contrast to the factors that increase nerve excitability, *membrane-stabilizing factors* can *decrease excitability*. For example, *a high extracellular fluid Ca^{2+} concentration* decreases membrane permeability to sodium ions and simultaneously reduces excitability. Therefore, Ca^{2+} ions are said to be a membrane *stabilizer*.

Local Anesthetics Act as Membrane Stabilizers. Among the most important stabilizers are the many substances used clinically as local anesthetics, including *procaine* and *tetracaine*. Most of these agents act directly on the activation gates of the sodium channels, making it much more difficult for these gates to open and thereby reducing membrane excitability. When excitability has been reduced so low that the ratio of *action potential strength* to *excitability threshold* (called the *safety factor*) is reduced below 1.0, nerve impulses fail to pass along the anesthetized nerves.

Contraction of Skeletal Muscle

About 40% of the body is skeletal muscle, and perhaps another 10% is smooth muscle and cardiac muscle. Some of the same basic principles of contraction apply to all these muscle types. In this chapter, we mainly consider skeletal muscle function; the specialized functions of smooth muscle are discussed in Chapter 8, and cardiac muscle is discussed in Chapter 9.

PHYSIOLOGICAL ANATOMY OF SKELETAL MUSCLE

Skeletal muscles are composed of numerous fibers ranging from 10 to 80 micrometers in diameter. Each of these fibers is made up of successively smaller subunits, as shown in **Fig. 6.1** and described in subsequent paragraphs.

In most skeletal muscles, each fiber extends the entire length of the muscle. Except for about 2% of the fibers, each fiber is usually innervated by only one nerve ending, located near the middle of the fiber.

The Sarcolemma Is a Thin Membrane Enclosing a Skeletal Muscle Fiber. The sarcolemma consists of a true cell membrane, called the plasma membrane, and an outer coat made up of a thin layer of polysaccharide material that contains numerous thin collagen fibrils. At each end of the muscle fiber, this surface layer of the sarcolemma fuses with a tendon fiber. The tendon fibers, in turn, collect into bundles to form the muscle tendons that then connect the muscles to the bones.

Myofibrils Are Composed of Actin and Myosin Filaments. Each muscle fiber contains several hundred to several thousand *myofibrils*, which are illustrated in **Fig. 6.1C**. Each myofibril (**Fig. 6.1D–E**) is composed of about 1500 adjacent *myosin filaments* and 3000 *actin filaments*, which are large polymerized protein molecules that are responsible for muscle contraction. These filaments are represented diagrammatically in **Fig. 6.1E–L**. The thick filaments in the diagrams are *myosin*, and the thin filaments are *actin*.

Note in **Fig. 6.1E** that the myosin and actin filaments partially interdigitate and thus cause the myofibrils to have alternate light and dark bands. The light bands contain only actin filaments and are called *I bands* because they are *isotropic* to polarized light. The dark bands contain myosin filaments, as well as the ends of the actin filaments, where they overlap the myosin, and are called *A bands* because they are *anisotropic* to polarized light. Note also the small projections from the sides of the myosin filaments in **Fig. 6.1E–L**. These projections are *cross-bridges*, which interact with actin filaments to cause contraction (**Video 6.1**).

Fig. 6.1E also shows that the ends of the actin filaments are attached to a *Z disk*. From this disk, these filaments extend in both directions to interdigitate with the myosin filaments. The Z disk, which is composed of filamentous proteins different from the actin and myosin filaments, passes crosswise across the myofibril and also crosswise from myofibril to myofibril, attaching the myofibrils to one another all the way across the muscle fiber. Therefore, the entire muscle fiber has light and dark bands, as do the individual myofibrils. These bands give skeletal and cardiac muscle their striated appearance.

The portion of the myofibril (or of the whole muscle fiber) that lies between two successive Z disks is called a *sarcomere* (**Fig. 6.1E**). When the muscle fiber is contracted, as shown at the bottom of **Fig. 6.4**, the length of the sarcomere is about 2 micrometers. At this length, the actin filaments completely overlap the myosin filaments, and the tips of the actin filaments are just beginning to overlap one another. As discussed later, the muscle is capable of generating its greatest force of contraction at this length.

Titin Filamentous Molecules Hold the Myosin and Actin Filaments in Place. The side-by-side relationship between the myosin and actin filaments is maintained by a large number of filamentous molecules of a protein called *titin* (also called *connectin*) (**Fig. 6.2**). Each titin molecule has a molecular weight of about 3.9 million, which makes it one of the largest proteins in the body. Also, because it is filamentous, it is very *springy*. These springy titin molecules serve as a framework to hold the myosin and actin filaments in place so that the contractile machinery of the sarcomere will work effectively. One end of the titin molecule is elastic and is attached to the Z disk, acting as a spring and changing length as the sarcomere contracts and relaxes. The other part of the titin molecule tethers it to the myosin thick filament. The titin molecule may also act as a template for the initial formation of portions of

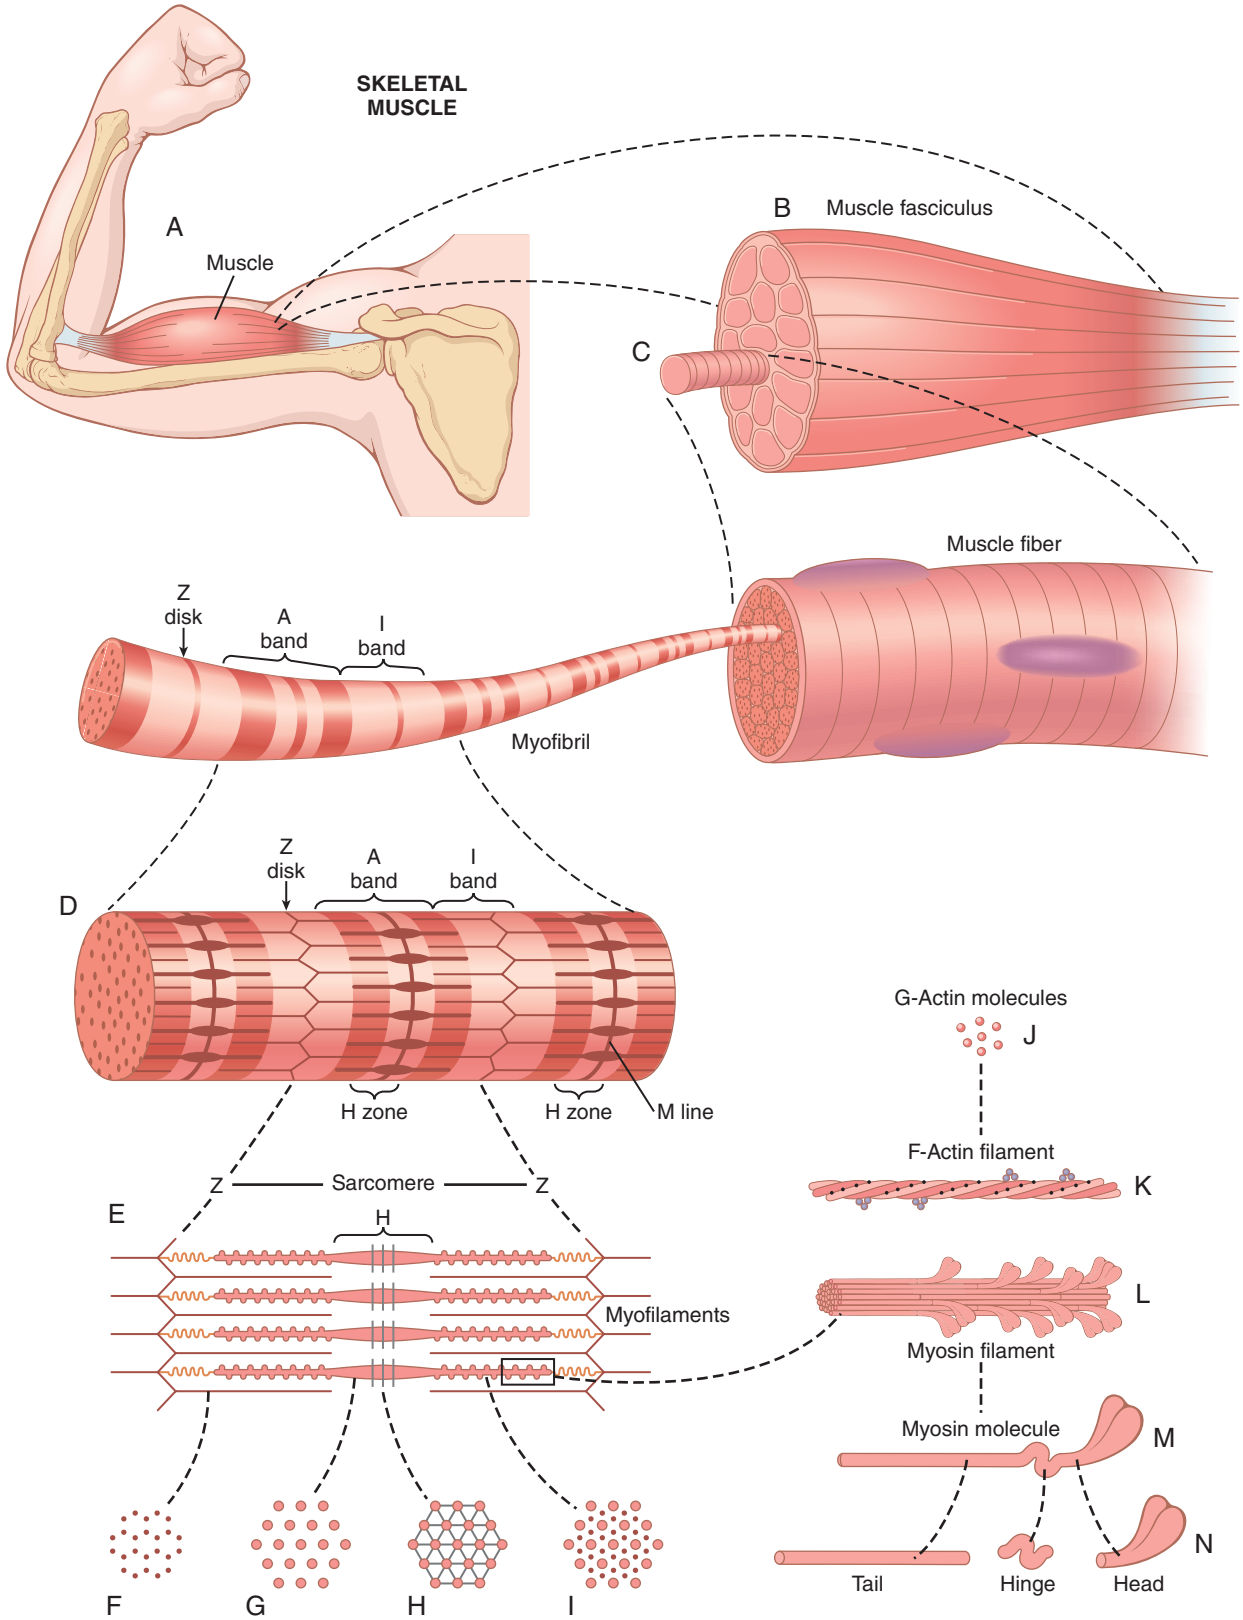

Figure 6.1 (A–E) Organization of skeletal muscle, from the gross to the molecular level. (F–N) Cross sections at the levels indicated.

the contractile filaments of the sarcomere, especially the myosin filaments.

Sarcoplasm Is the Intracellular Fluid Between Myofibrils. Many myofibrils are suspended side by side in each muscle fiber (**Fig. 6.1 and Fig. 6.3**). The spaces between the myofibrils are filled with intracellular fluid called *sarcoplasm*, containing large quantities of potassium, magnesium, and phosphate, plus multiple protein enzymes. Also present are large numbers of *mitochondria* that lie parallel to the myofibrils. These mitochondria supply the contracting myofibrils with energy in the form of adenosine triphosphate (ATP) formed by the mitochondria.

Transverse Tubule–Sarcoplasmic Reticulum System of Skeletal Muscle. In the sarcoplasm surrounding the myofibrils of each muscle fiber is an extensive membranous network called the *sarcoplasmic reticulum* (**Fig. 6.3**). The enlarged ends of the sarcoplasmic reticulum, called the *terminal cisternae*, are closely associated with the *transverse tubules* (*T tubules*), which are actually extensions of the cell membrane, penetrating all of the way through the muscle fiber and surrounding each myofibril. This arrangement permits action potentials to rapidly spread along the T tubules to the deep interior of the muscle fibers.

As discussed further in Chapter 7, the T tubule–sarcoplasmic reticulum system is extremely important in regulating Ca^{2+} storage, release and reuptake, and therefore muscle contraction. The rapidly contracting types of muscle fibers have an especially extensive T tubule–sarcoplasmic reticulum system.

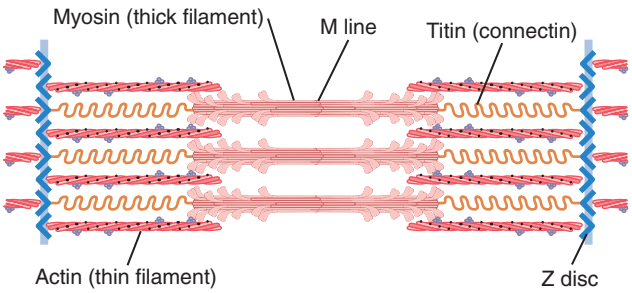

Figure 6.2 Organization of proteins in a sarcomere. Each titin molecule extends from the *Z disk* to the *M line*. Part of the titin (also called connectin) molecule is closely associated with the myosin thick filament, whereas the rest of the molecule is springy and changes length as the sarcomere contracts and relaxes.

GENERAL MECHANISM OF MUSCLE CONTRACTION

The initiation and execution of muscle contraction occur in the following sequential steps.

1. An action potential travels along a motor nerve to its endings on muscle fibers.
2. At each ending, the nerve secretes a small amount of the neurotransmitter *acetylcholine*.
3. Acetylcholine acts on a local area of the muscle fiber membrane to open acetylcholine-gated cation channels through protein molecules floating in the membrane.
4. The opening of acetylcholine-gated channels allows sodium ions to rapidly diffuse to the interior of the muscle fiber membrane. This action causes a local

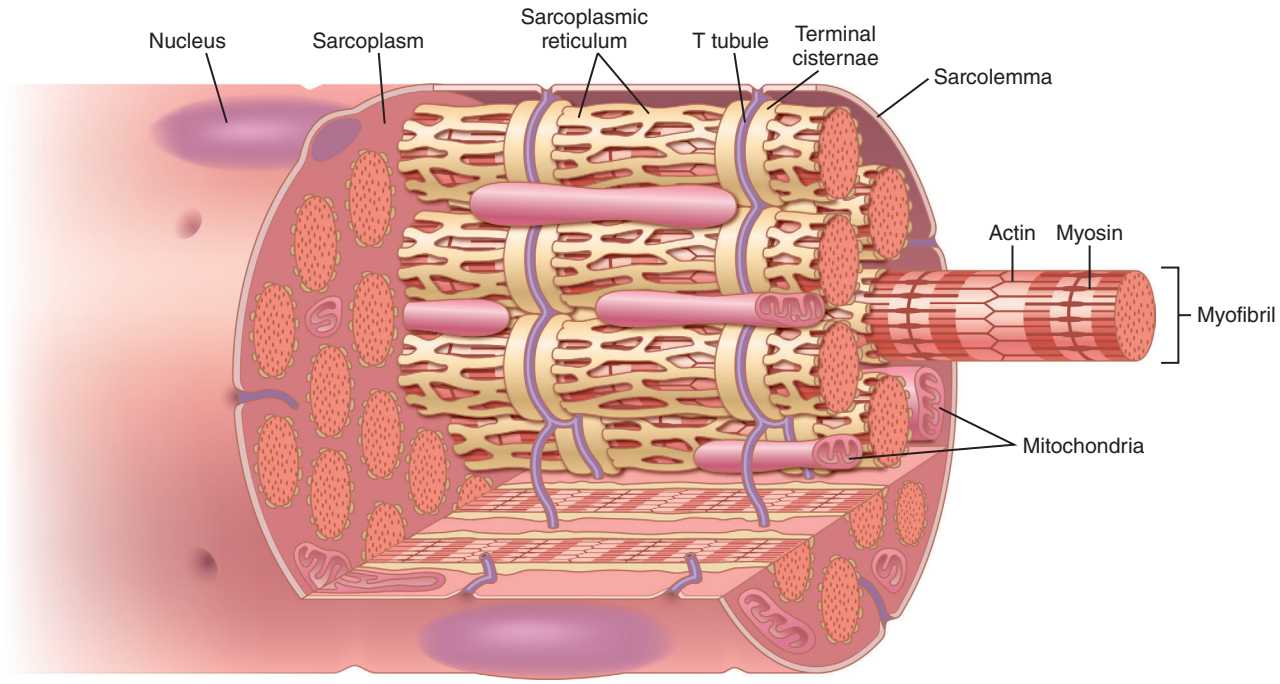

Figure 6.3 Organization of skeletal muscle myofibrils. The extensive sarcoplasmic reticulum network and the transverse tubules (T tubules), which lead to the exterior of the fiber membrane and are important for conducting the electrical signal into the center of the muscle fiber, are also illustrated.

depolarization that in turn leads to the opening of voltage-gated sodium channels, which initiates an action potential at the membrane.

5. The action potential travels along the muscle fiber membrane in the same way that action potentials travel along nerve fiber membranes.
6. The action potential depolarizes the muscle membrane, and much of the action potential electricity flows through the center of the muscle fiber. Here it causes the sarcoplasmic reticulum to release large quantities of Ca^{2+} stored within this reticulum.
7. The Ca^{2+} ions initiate attractive forces between the actin and myosin filaments, causing them to slide alongside each other, which is the basis for muscle contraction.
8. After a fraction of a second, the Ca^{2+} ions are pumped back into the sarcoplasmic reticulum by a Ca^{2+} membrane pump and remain stored in the reticulum until a new muscle action potential comes along; this removal of Ca^{2+} ions from the myofibrils causes the muscle contraction to cease.

MOLECULAR MECHANISMS OF MUSCLE CONTRACTION

Muscle Contraction Occurs By a Sliding Filament Mechanism. **Fig. 6.4** demonstrates the basic mechanism of muscle contraction. It shows the relaxed state of a sarcomere (top) and the contracted state (bottom). In the fully relaxed state, the ends of the actin filaments extending from two successive Z disks do not overlap one another. Conversely, in the contracted state, these actin filaments have been pulled inward among the myosin filaments, so their ends overlap one another to their maximum extent. Also, the Z disks have been pulled by the actin filaments up to the ends of the myosin filaments. Thus, muscle contraction occurs by a *sliding filament mechanism*.

But what causes the actin filaments to slide inward among the myosin filaments? This action is caused by forces generated by interaction of the cross-bridges from the myosin filaments with the actin filaments. Under resting conditions, these forces are inactive, but when an action potential travels along the muscle fiber, this causes the sarcoplasmic reticulum to release large quantities of Ca^{2+} that rapidly surround the myofibrils. The Ca^{2+} ions, in turn, activate the forces between the myosin and actin filaments, and contraction begins. However, energy is needed for the contractile process to proceed. This energy comes from high-energy bonds in the ATP molecule, which is degraded to adenosine diphosphate (ADP) to liberate the energy. In the next few sections, we describe these molecular processes of contraction.

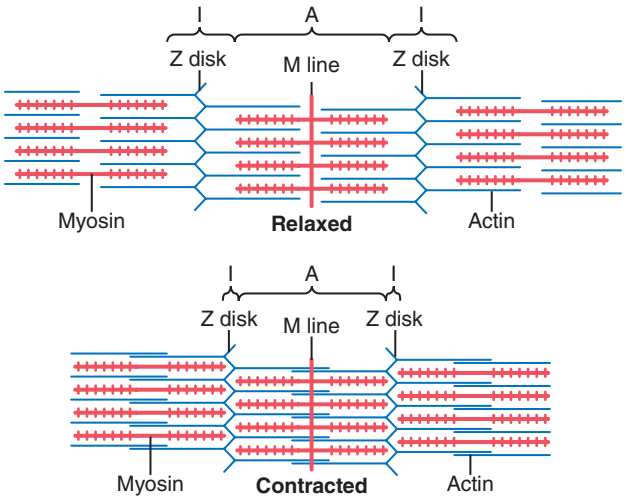

Figure 6.4 Relaxed (top) and contracted (bottom) states of a myofibril, showing sliding of the actin filaments *(blue)* into the spaces between the myosin filaments *(red)* and pulling of the Z membranes toward each other during contraction.

Molecular Characteristics of the Contractile Filaments

Myosin Filaments Are Composed of Multiple Myosin Molecules. Each of the myosin molecules, shown in **Fig. 6.5A**, has a molecular weight of about 480,000. **Fig. 6.5B** shows the organization of many molecules to form a myosin filament, as well as interaction of this filament on one side with the ends of two actin filaments.

The *myosin molecule* (see **Fig. 6.5A**) is composed of six polypeptide chains—two *heavy chains*, each with a molecular weight of about 200,000; and four *light chains*, with molecular weights of about 20,000 each. The two heavy chains wrap spirally around each other to form a double helix, which is called the *tail* of the myosin molecule. One end of each of these chains is folded bilaterally

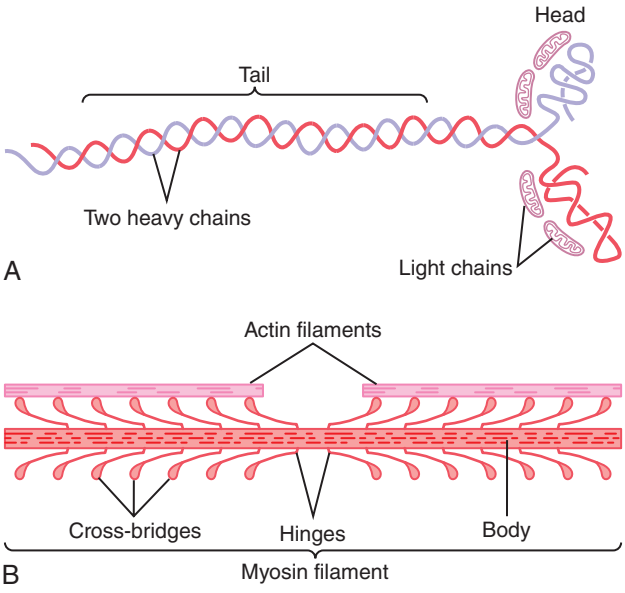

Figure 6.5 (A) Myosin molecule. (B) Combination of many myosin molecules to form a myosin filament. Also shown are thousands of myosin *cross-bridges* and interaction between the *heads* of the cross-bridges with adjacent actin filaments.

into a globular polypeptide structure called a myosin *head*. Thus, there are two free heads at one end of the double-helix myosin molecule. The four light chains are also part of the myosin head, two to each head. These light chains help control the function of the head during muscle contraction.

The *myosin filament* is made up of 200 or more individual myosin molecules. The central portion of one of these filaments is shown in **Fig. 6.5B**, displaying the tails of the myosin molecules bundled together to form the *body* of the filament, while many heads of the molecules hang outward to the sides of the body. Also, part of the body of each myosin molecule hangs to the side along with the head, thus providing an *arm* that extends the head outward from the body, as shown in the figure. The protruding arms and heads together are called *cross-bridges*. Each cross-bridge is flexible at two points called *hinges*—one where the arm leaves the body of the myosin filament and the other where the head attaches to the arm. The hinged arms allow the heads either to be extended far outward from the body of the myosin filament or brought close to the body. The hinged heads, in turn, participate in the contraction process, as discussed in the following sections.

The total length of each myosin filament is uniform, almost exactly 1.6 micrometers. Note, however, that there are no cross-bridge heads in the center of the myosin filament for a distance of about 0.2 micrometer because the hinged arms extend away from the center.

Now, to complete the picture, the myosin filament is twisted so that each successive pair of cross-bridges is axially displaced from the previous pair by 120 degrees. This twisting ensures that the cross-bridges extend in all directions around the filament.

Adenosine Triphosphatase Activity of the Myosin Head. Another feature of the myosin head that is essential for muscle contraction is that it functions as an *adenosine triphosphatase (ATPase) enzyme*. As explained later, this property allows the head to cleave ATP and use the energy derived from the ATP's high-energy phosphate bond to energize the contraction process.

Actin Filaments Are Composed of Actin, Tropomyosin, and Troponin. The backbone of the actin filament is a double-stranded *F-actin protein molecule* (**Fig. 6.6**). The two strands are wound in a helix in the same manner as the myosin molecule.

Each strand of the double F-actin helix is composed of polymerized *G-actin molecules*, each having a molecular weight of about 42,000. Attached to each one of the G-actin molecules is one molecule of ADP. These ADP molecules are believed to be the active sites on the actin filaments with which the cross-bridges of the myosin filaments interact to cause muscle contraction. The active sites on the two F-actin strands of the double helix are staggered, giving one active site on the overall actin filament about every 2.7 nanometers.

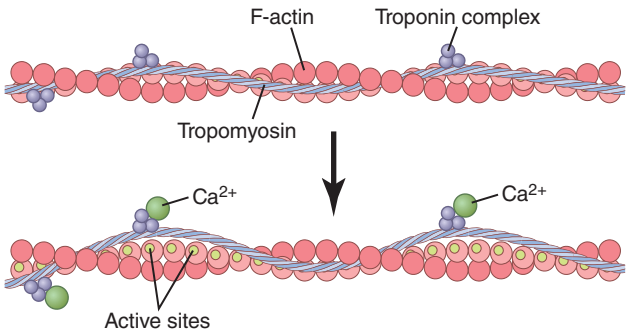

Figure 6.6 Actin filaments are composed of two helical strands of *F-actin* molecules and two strands of *tropomyosin* molecules that fit in the grooves between the actin strands. Attached to each tropomyosin molecule is a *troponin* complex that initiates contraction in the presence of increased Ca^{2+} concentration. When the troponin complex binds Ca^{2+}, a conformation change occurs that tugs on the tropomyosin and exposes myosin binding sites on the actin, permitting myosin to bind to actin and allowing contraction.

Each actin filament is about 1 micrometer long. The bases of the actin filaments are inserted strongly into the Z disks; the ends of the filaments protrude in both directions to lie in the spaces between the myosin molecules, as shown in **Fig. 6.4**.

Tropomyosin Molecules. The actin filament also contains another protein, tropomyosin. Each molecule of tropomyosin has a molecular weight of 70,000 and a length of 40 nanometers. These molecules are wrapped spirally around the sides of the F-actin helix. In the resting state, the tropomyosin molecules lie on top of the active sites of the actin strands so that attraction cannot occur between the actin and myosin filaments to cause contraction. Contraction occurs only when an appropriate signal causes a conformation change in tropomyosin that "uncovers" active sites on the actin molecule and initiates contraction, as explained later.

Troponin and Its Role in Muscle Contraction. Attached intermittently along the sides of the tropomyosin molecules are additional protein molecules called *troponin*. These protein molecules are actually complexes of three loosely bound protein subunits, each of which plays a specific role in controlling muscle contraction. One of the subunits (troponin I) has a strong affinity for actin, another (troponin T) for tropomyosin, and a third (troponin C) for Ca^{2+}. This complex is believed to attach the tropomyosin to the actin. The strong affinity of the troponin for Ca^{2+} is believed to initiate the contraction process, as explained in the next section.

Interaction of One Myosin Filament, Two Actin Filaments, and Ca^{2+} to Cause Contraction

Inhibition of the Actin Filament By the Troponin-Tropomyosin Complex. A pure actin filament, in the absence of the troponin-tropomyosin complex (but in the presence of magnesium ions and ATP), binds instantly

and strongly with the heads of the myosin molecules. If the troponin-tropomyosin complex is added to the actin filament, the binding between myosin and actin does not occur. Therefore, the active sites on the normal actin filament of the relaxed muscle appear to be inhibited or physically covered by the troponin-tropomyosin complex. Consequently, the sites cannot attach to the heads of the myosin filaments to cause contraction. Before contraction can occur, the inhibitory effect of the troponin-tropomyosin complex must itself be inhibited.

Activation of the Actin Filament By Ca^{2+}. In the presence of large amounts of Ca^{2+}, the inhibitory effect of the troponin-tropomyosin on the actin filaments is itself inhibited. When Ca^{2+} combines with troponin C, each molecule of which can bind strongly with up to four Ca^{2+}, the troponin complex appears to undergo a conformational change that in some way tugs on the tropomyosin molecule and moves it deeper into the groove between the two actin strands. This action uncovers the active sites of the actin, allowing these sites to attract the myosin cross-bridge heads and permitting contraction to proceed. Although this mechanism is hypothetical, it emphasizes that the normal relationship between the troponin-tropomyosin complex and actin is altered by Ca^{2+}, producing a new condition that leads to contraction.

Interaction of the Activated Actin Filament and the Myosin Cross-Bridges—The Walk-Along Theory of Contraction. As soon as the actin filament is activated by Ca^{2+}, the heads of the cross-bridges from the myosin filaments become attracted to the active sites of the actin filament and initiate contraction. Although the precise manner in which this interaction between the cross-bridges and the actin causes contraction is still partly theoretical, one hypothesis for which considerable evidence exists is the walk-along (or *ratchet*) theory of contraction.

Fig. 6.7 demonstrates this walk-along mechanism for contraction with the heads of two cross-bridges attaching to and disengaging from active sites of an actin filament. When a head attaches to an active site, this attachment simultaneously causes profound changes in the intramolecular forces between the head and arm of its cross-bridge. The new alignment of forces causes the head to tilt toward the arm and to drag the actin filament along with it. This tilt of the head is called the *power stroke*.

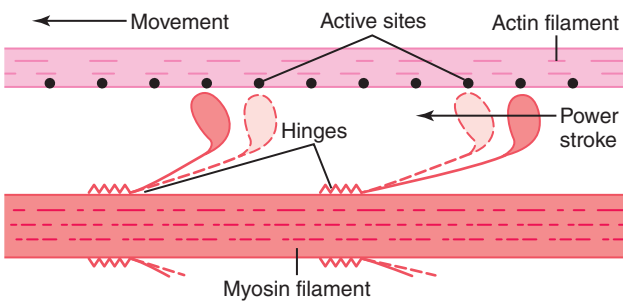

Figure 6.7 The walk-along mechanism for contraction of the muscle.

Immediately after tilting, the head then automatically breaks away from the active site. Next, the head returns to its extended direction. In this position, it combines with a new active site farther down along the actin filament; the head then tilts again to cause a new power stroke, and the actin filament moves another step. Thus, the heads of the cross-bridges bend back and forth and, step by step, walk along the actin filament, pulling the ends of two successive actin filaments toward the center of the myosin filament.

Each of the cross-bridges is believed to operate independently of all the others, with each attaching and pulling in a continuous repeated cycle. Therefore, the greater the number of cross-bridges in contact with the actin filament at any given time, the greater the force of contraction.

ATP Is the Energy Source for Contraction—Chemical Events in the Motion of the Myosin Heads. When a muscle contracts, work is performed, and energy is required. Large amounts of ATP are cleaved to form ADP during the contraction process, and the more work performed by the muscle, the more ATP that is cleaved; this phenomenon is called the *Fenn effect*. The following sequence of events is believed to be the means whereby this effect occurs:

1. Before contraction begins, the heads of the cross-bridges bind with ATP. The ATPase activity of the myosin head immediately cleaves the ATP but leaves the cleavage products, ADP plus phosphate ion, bound to the head. In this state, the conformation of the head is such that it extends perpendicularly toward the actin filament but is not yet attached to the actin.
2. When the troponin-tropomyosin complex binds with Ca^{2+}, active sites on the actin filament are uncovered, and the myosin heads then bind with these sites, as shown in **Fig. 6.7**.
3. The bond between the head of the cross-bridge and the active site of the actin filament causes a conformational change in the head, prompting the head to tilt toward the arm of the cross-bridge and providing the *power stroke* for pulling the actin filament. The energy that activates the power stroke is the energy already stored, like a cocked spring, by the conformational change that occurred in the head when the ATP molecule was cleaved earlier.
4. Once the head of the cross-bridge tilts, release of the ADP and phosphate ion that were previously attached to the head is allowed. At the site of release of the ADP, a new molecule of ATP binds. This binding of new ATP causes detachment of the head from the actin.
5. After the head has detached from the actin, the new molecule of ATP is cleaved to begin the next cycle, leading to a new power stroke. That is, the energy again cocks the head back to its perpendicular condition, ready to begin the new power stroke cycle.
6. When the cocked head (with its stored energy derived from the cleaved ATP) binds with a new

active site on the actin filament, it becomes uncocked and once again provides a new power stroke.

Thus, the process proceeds again and again until the actin filaments pull the Z membrane up against the ends of the myosin filaments or until the load on the muscle becomes too great for further pulling to occur.

Amount of Actin and Myosin Filament Overlap Determines Tension Developed By the Contracting Muscle

Fig. 6.8 shows the effect of sarcomere length and the amount of myosin-actin filament overlap on the active tension developed by a contracting muscle fiber. To the right are different degrees of overlap of the myosin and actin filaments at different sarcomere lengths. At point D on the diagram, the actin filament has pulled all the way out to the end of the myosin filament, with no actin-myosin overlap. At this point, the tension developed by the activated muscle is zero. Then, as the sarcomere shortens, and the actin filament begins to overlap the myosin filament, the tension increases progressively until the sarcomere length decreases to about 2.2 micrometers. At this point, the actin filament has already overlapped all the cross-bridges of the myosin filament but has not yet reached the center of the myosin filament. With further shortening, the sarcomere maintains full tension until point B is reached, at a sarcomere length of about 2 micrometers. At this point, the ends of the two actin filaments begin to overlap each other in addition to overlapping the myosin filaments. As the sarcomere length decreases from 2 micrometers to about 1.65 micrometers at point A, the strength of contraction decreases rapidly. At this point, the two Z disks of the sarcomere abut the ends of the myosin filaments. Then, as contraction proceeds to still shorter sarcomere lengths, the ends of the myosin filaments are crumpled and, as shown in the figure, the strength of contraction approaches zero, but the sarcomere has now contracted to its shortest length.

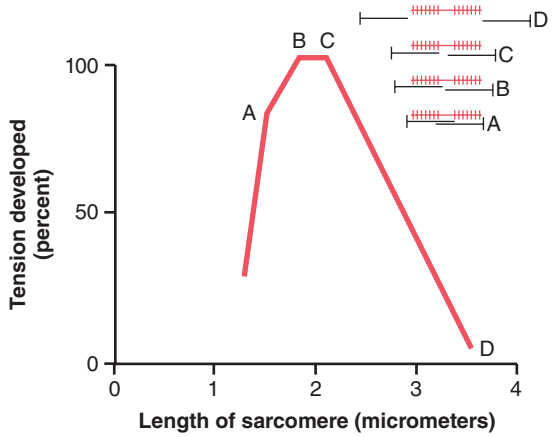

Figure 6.8 Length-tension diagram for a single fully contracted sarcomere, showing the maximum strength of contraction when the sarcomere is 2.0 to 2.2 micrometers in length. At the *upper right* are the relative positions of the actin and myosin filaments at different sarcomere lengths from point A to point D. *(Modified from Gordon AM, Huxley AF, Julian FJ. The length-tension diagram of single vertebrate striated muscle fibers.* J Physiol. *1964;171:28P.)*

Effect of Muscle Length on Force of Contraction in the Whole Intact Muscle. The top curve of **Fig. 6.9** is similar to that in **Fig. 6.8**, but the curve in **Fig. 6.9** depicts tension of the intact whole muscle rather than of a single muscle fiber. The whole muscle has a large amount of connective tissue in it and the sarcomeres in different parts of the muscle do not always contract the same amount. Therefore, the curve has somewhat different dimensions from those shown for the individual muscle fiber, but it exhibits the same general form for the slope *in the normal range of contraction*.

Note in **Fig. 6.9** that when the muscle is at its normal *resting* length, which is at a sarcomere length of about 2 micrometers, it contracts on activation with the approximate maximum force of contraction. However, the *increase* in tension that occurs during contraction, called *active tension*, decreases as the muscle is stretched beyond its normal length—that is, to a sarcomere length greater than about 2.2 micrometers. This phenomenon is demonstrated by the decreased length of the arrow in the figure at greater than normal muscle length.

Relation of Velocity of Contraction to Load

A skeletal muscle contracts rapidly when it contracts against no load to a state of full contraction in about 0.1 second for the average muscle. When loads are applied, the velocity of contraction decreases progressively as the load increases, as shown in **Fig. 6.10**. When the load increases to equal the maximum force that the muscle can exert, the velocity of contraction becomes zero, and no contraction results, despite activation of the muscle fiber.

This decreasing velocity of contraction with load occurs because a load on a contracting muscle is a reverse force that opposes the contractile force caused by muscle contraction. Therefore, the net force that is available to cause the velocity of shortening is correspondingly reduced.

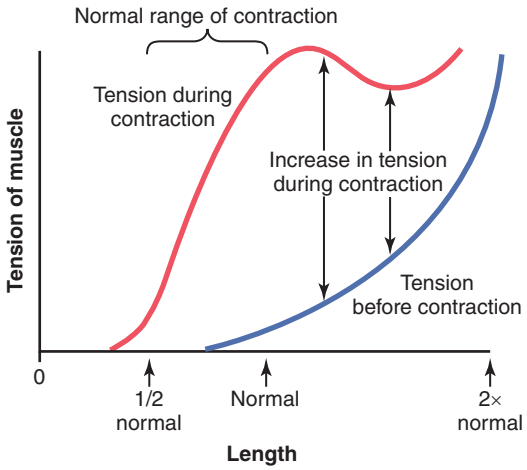

Figure 6.9 Relationship of muscle length to tension in the muscle both before and during muscle contraction.

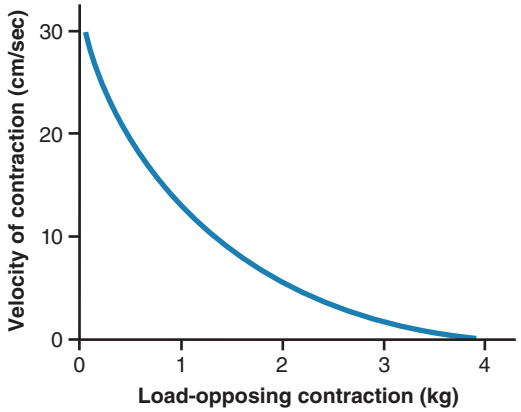

Figure 6.10 Relationship of load to velocity of contraction in a skeletal muscle with a cross section of 1 square centimeter and a length of 8 centimeters.

ENERGETICS OF MUSCLE CONTRACTION

Work Output During Muscle Contraction

When a muscle contracts against a load, it performs *work*. To perform work means that *energy* is transferred from the muscle to the external load to lift an object to a greater height or to overcome resistance to movement.

In mathematical terms, work is defined by the following equation:

$$W = L \times D$$

in which W is the work output, L is the load, and D is the distance of movement against the load. The energy required to perform the work is derived from the chemical reactions in the muscle cells during contraction, as described in the following sections.

Three Sources of Energy for Muscle Contraction

Most of the energy required for muscle contraction is used to trigger the walk-along mechanism whereby the cross-bridges pull the actin filaments, but small amounts are required for the following: (1) pumping Ca^{2+} from the sarcoplasm into the sarcoplasmic reticulum after the contraction is finished; and (2) pumping sodium and potassium ions through the muscle fiber membrane to maintain an appropriate ionic environment for propagation of muscle fiber action potentials.

The concentration of ATP in the muscle fiber, about 4 millimolar, is sufficient to maintain full contraction for only 1 to 2 seconds at most. The ATP is split to form ADP, which transfers energy from the ATP molecule to the contracting machinery of the muscle fiber. Then, as described in Chapter 2, the ADP is rephosphorylated to form new ATP within another fraction of a second, which allows the muscle to continue its contraction. There are three sources of the energy for this rephosphorylation.

The first source of energy used to reconstitute the ATP is *phosphocreatine*, which carries a high-energy phosphate bond similar to the bonds of ATP. The high-energy phosphate bond of phosphocreatine has a slightly higher amount of free energy than that of each ATP bond, as discussed in Chapters 68 and 73. Therefore, phosphocreatine is instantly cleaved, and its released energy causes bonding of a new phosphate ion to ADP to reconstitute the ATP. However, the total amount of phosphocreatine in the muscle fiber is also small, only about 5 times as great as the ATP. Therefore, the combined energy of both the stored ATP and the phosphocreatine in muscle is capable of causing maximal muscle contraction for only 5 to 8 seconds.

The second important source of energy, which is used to reconstitute both ATP and phosphocreatine, is a process called *glycolysis*—the breakdown of *glycogen* previously stored in the muscle cells. Rapid enzymatic breakdown of the glycogen to pyruvic acid and lactic acid liberates energy that is used to convert ADP to ATP; the ATP can then be used directly to energize additional muscle contraction and to re-form the stores of phosphocreatine.

The importance of this glycolysis mechanism is 2-fold. First, glycolytic reactions can occur even in the absence of oxygen, so muscle contraction can be sustained for many seconds and sometimes up to more than 1 minute, even when oxygen delivery from the blood is not available. Second, the rate of ATP formation by glycolysis is about 2.5 times as rapid as ATP formation in response to cellular foodstuffs reacting with oxygen. However, so many end products of glycolysis accumulate in the muscle cells that glycolysis also loses its capability to sustain maximum muscle contraction after about 1 minute.

The third and final source of energy is *oxidative metabolism*, which means combining oxygen with the end products of glycolysis and with various other cellular foodstuffs to liberate ATP. *More than 95% of all energy used by the muscles for sustained long-term contraction is derived from oxidative metabolism*. The foodstuffs that are consumed are carbohydrates, fats, and proteins. For extremely long-term maximal muscle activity—over a period of many hours—the greatest proportion of energy comes from fats but, for periods of 2 to 4 hours, as much as one-half of the energy can come from stored carbohydrates.

The detailed mechanisms of these energetic processes are discussed in Chapters 68 through 73. In addition, the importance of the different mechanisms of energy release during performance of different sports is discussed in Chapter 85.

Efficiency of Muscle Contraction. The efficiency of an engine or a motor is calculated as the percentage of energy input that is converted into work instead of heat. The percentage of the input energy to muscle (the chemical energy in nutrients) that can be converted into work, even under

optimal conditions, is less than 25%, with the remainder becoming heat. The reason for this low efficiency is that about 50% of the energy in foodstuffs is lost during the formation of ATP and, even then, only 40% to 45% of the energy in ATP can later be converted into work.

Maximum efficiency can be realized only when the muscle contracts at a moderate velocity. If the muscle contracts slowly or without any movement, small amounts of *maintenance heat* are released during contraction, even though little or no work is performed, thereby decreasing the conversion efficiency to as little as zero. Conversely, if contraction is too rapid, much of the energy is used to overcome viscous friction within the muscle itself, and this too reduces the efficiency of contraction. Ordinarily, maximum efficiency occurs when the velocity of contraction is about 30% of maximum.

CHARACTERISTICS OF WHOLE MUSCLE CONTRACTION

Many features of muscle contraction can be demonstrated by eliciting single *muscle twitches*. This can be accomplished by electrical excitation of the nerve to a muscle or by passing a short electrical stimulus through the muscle itself, giving rise to a single sudden contraction lasting a fraction of a second.

Isometric Contractions Do Not Shorten Muscle, Whereas Isotonic Contractions Shorten Muscle at a Constant Tension. Muscle contraction is *isometric* when the muscle does not shorten during contraction and *isotonic* when it shortens but the tension on the muscle remains constant throughout the contraction. Systems for recording the two types of muscle contraction are shown in **Fig. 6.11**.

In the isometric system, the muscle contracts against a force transducer without decreasing the muscle length, as shown in the bottom panel of **Fig. 6.11**. In the isotonic system, the muscle shortens against a fixed load, as illustrated in the top panel of the figure, which shows a muscle lifting a weight. The characteristics of isotonic contraction depend on the load against which the muscle contracts, as well as the inertia of the load. However, the isometric system records changes in force of muscle contraction independently of load inertia. Therefore, the isometric system is often used when comparing the functional characteristics of different muscle types.

Characteristics of Isometric Twitches Recorded From Different Muscles. The human body has many sizes of skeletal muscles—from the small stapedius muscle in the middle ear, measuring only a few millimeters long and 1 millimeter or so in diameter, up to the large quadriceps muscle, a half-million times as large as the stapedius. Furthermore, the fibers may be as small as 10 micrometers in diameter or as large as 80 micrometers. Finally, the energetics of muscle contraction vary considerably from

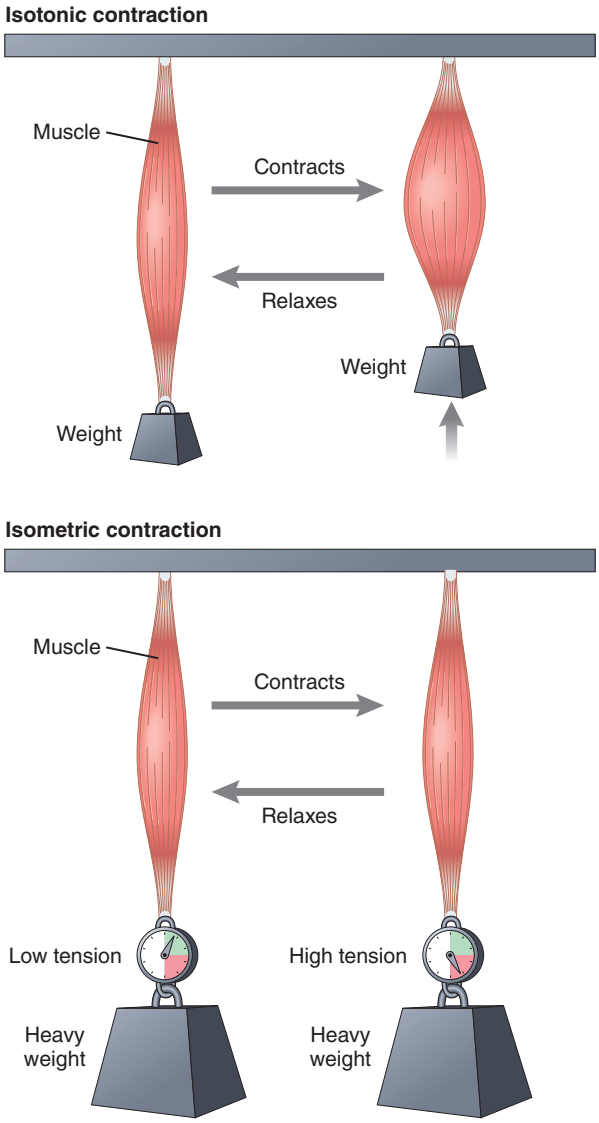

Figure 6.11 Isotonic and isometric systems for recording muscle contractions. Isotonic contraction occurs when the force of the muscle contraction is greater than the load, and the tension on the muscle remains constant during the contraction. When the muscle contracts, it shortens and moves the load. Isometric contraction occurs when the load is greater than the force of the muscle contraction; the muscle creates tension when it contracts, but the overall length of the muscle does not change.

one muscle to another. Therefore, it is no wonder that the mechanical characteristics of muscle contraction differ among muscles.

Fig. 6.12 shows records of isometric contractions of three types of skeletal muscle—an ocular muscle, which has a duration of *isometric* contraction of less than 1/50 second; the gastrocnemius muscle, which has a duration of contraction of about 1/15 second; and the soleus muscle, which has a duration of contraction of about 1/5 second. These durations of contraction are highly adapted to the functions of the respective muscles. Ocular movements must be extremely rapid to maintain fixation of the eyes on specific objects to provide accuracy of vision. The gastrocnemius muscle must contract moderately rapidly

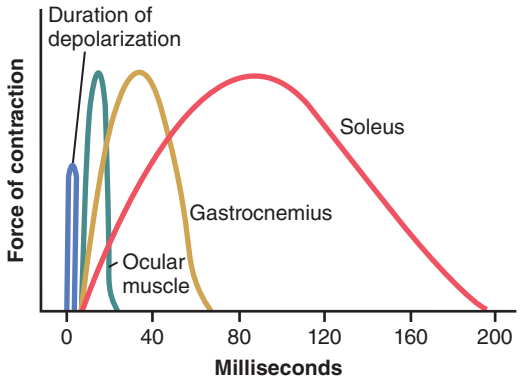

Figure 6.12 Duration of isometric contractions for different types of mammalian skeletal muscles, showing a latent period between the action potential (depolarization) and muscle contraction.

to provide sufficient velocity of limb movement for running and jumping, and the soleus muscle is concerned principally with slow contraction for continual, long-term support of the body against gravity.

Fast Versus Slow Muscle Fibers. As discussed in Chapter 85 on sports physiology, every muscle of the body is composed of a mixture of *fast* and *slow* muscle fibers, with other fibers gradated between these two extremes. Muscles that react rapidly, including the anterior tibialis, are composed mainly of fast fibers, with only small numbers of the slow variety. Conversely, muscles such as soleus that respond slowly but with prolonged contraction are composed mainly of slow fibers. The differences between these two types of fibers are described in the following sections.

Slow Fibers (Type 1, Red Muscle). The following are characteristics of slow fibers:

1. Slow fibers are smaller than fast fibers.
2. Slow fibers are also innervated by smaller nerve fibers.
3. Slow fibers have a more extensive blood vessel system and more capillaries to supply greater amounts of oxygen compared with fast fibers.
4. Slow fibers have greatly increased numbers of mitochondria to support high levels of oxidative metabolism.
5. Slow fibers contain large amounts of myoglobin, an iron-containing protein similar to hemoglobin in red blood cells. Myoglobin combines with oxygen and stores it until needed, which also greatly speeds oxygen transport to the mitochondria. The myoglobin gives the slow muscle a reddish appearance—hence, the name *red muscle*.

Fast Fibers (Type II, White Muscle). The following are characteristics of fast fibers:

1. Fast fibers are large for great strength of contraction.
2. Fast fibers have an extensive sarcoplasmic reticulum for rapid release of Ca^{2+} to initiate contraction.

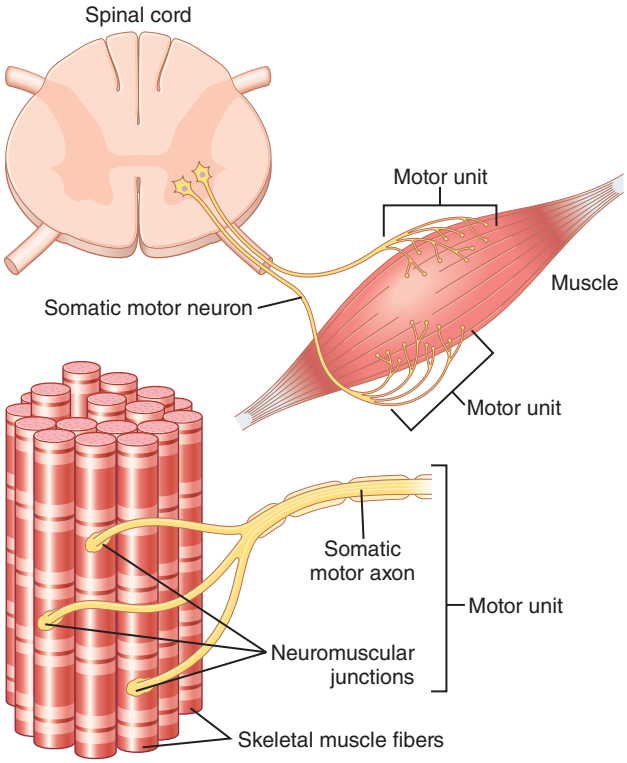

Figure 6.13 A motor unit consists of a motor neuron and the group of skeletal muscle fibers it innervates. A single motor axon may branch to innervate several muscle fibers that function together as a group. Although each muscle fiber is innervated by a single motor neuron, an entire muscle may receive input from hundreds of different motor neurons.

3. Fast fibers have large amounts of glycolytic enzymes for rapid release of energy by glycolysis.
4. Fast fibers have a less extensive blood supply than slow fibers because oxidative metabolism is of secondary importance.
5. Fast fibers have fewer mitochondria than slow fibers, also because oxidative metabolism is secondary. A deficit of red myoglobin in fast muscle gives it the name *white muscle*.

MECHANICS OF SKELETAL MUSCLE CONTRACTION

Motor Unit—All the Muscle Fibers Innervated By a Single Nerve Fiber. Each motoneuron that leaves the spinal cord innervates multiple muscle fibers, with the number of fibers innervated depending on the type of muscle. All the muscle fibers innervated by a single nerve fiber are called a *motor unit* (**Fig. 6.13**). In general, small muscles that react rapidly and require precise control have more nerve fibers for fewer muscle fibers; for example, some of the laryngeal muscles have only two or three muscle fibers per motor unit. In contrast, large muscles that do not require fine control, such as the soleus muscle, may have several hundred muscle fibers in a motor unit. An average figure for all the muscles of the body is

questionable, but a reasonable estimate would be about 80 to 100 muscle fibers to a motor unit.

The muscle fibers in each motor unit are not all bunched together in the muscle but overlap other motor units in microbundles of 3 to 15 fibers. This interdigitation allows the separate motor units to contract in support of one another rather than entirely as individual segments.

Muscle Contractions of Different Force—Force Summation. *Summation* means the adding together of individual twitch contractions to increase the intensity of overall muscle contraction. Summation occurs in two ways: (1) by increasing the number of motor units contracting simultaneously, which is called *multiple fiber summation*; and (2) by increasing the frequency of contraction, which is called *frequency summation* and can lead to *tetanization*, in which individual muscle contractions are fused and cannot be distinguished from one another.

Multiple Fiber Summation. When the central nervous system sends a weak signal to contract a muscle, the smaller motor units of the muscle may be stimulated in preference to the larger motor units. Then, as the strength of the signal increases, larger and larger motor units begin to be excited, with the largest motor units often having as much as 50 times the contractile force of the smallest units. This phenomenon, called the *size principle*, allows gradations of muscle force during weak contraction to occur in small steps, whereas the steps become progressively greater when large amounts of force are required. This size principle occurs because the smaller motor units are driven by small motor nerve fibers, and the small motoneurons in the spinal cord are more excitable than the larger ones, so naturally they are excited first.

Another important feature of multiple fiber summation is that the different motor units are driven asynchronously by the spinal cord; as a result, contraction alternates among motor units one after the other, thus providing smooth contraction, even at low frequencies of nerve signals.

Frequency Summation and Tetanization. Fig. 6.14 shows the principles of frequency summation and tetanization. Individual twitch contractions occurring one after another at low frequency of stimulation are displayed on the left. Then, as the frequency increases, there comes a point when each new contraction occurs before the preceding one is over. As a result, the second contraction is added partially to the first, and the total strength of contraction rises progressively with increasing frequency. When the frequency reaches a critical level, the successive contractions eventually become so rapid that they fuse together, and the whole muscle contraction appears to be completely smooth and continuous, as shown in the figure. At a slightly higher frequency, the strength of contraction reaches its maximum, so any additional increase

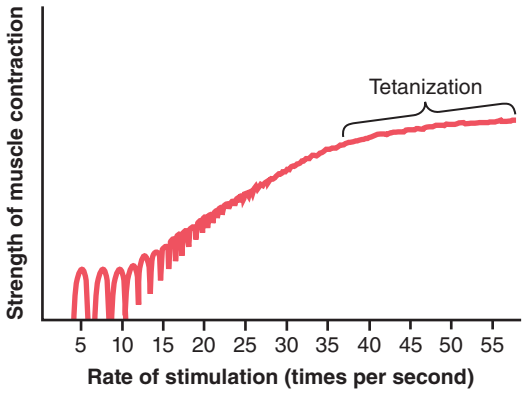

Figure 6.14 Frequency summation and tetanization.

in frequency beyond that point has no further effect in increasing contractile force. Tetany occurs because enough Ca^{2+} ions are maintained in the muscle sarcoplasm, even between action potentials, so that a full contractile state is sustained without allowing any relaxation between the action potentials.

Maximum Strength of Contraction. The maximum strength of tetanic contraction of a muscle operating at a normal muscle length averages between 3 and 4 kg/cm^2 of muscle, or 50 pounds/inch^2. Because a quadriceps muscle can have up to 16 square inches of muscle belly, as much as 800 pounds of tension may be applied to the patellar tendon. Thus, one can readily understand how it is possible for muscles to pull their tendons out of their insertions in bone.

Increases in Muscle Strength After the Onset of Contraction—The Staircase Effect (Treppe). When a muscle begins to contract after a long period of rest, its initial strength of contraction may be as little as one-half its strength 10 to 50 muscle twitches later. That is, the strength of contraction increases to a plateau, a phenomenon called the *staircase effect*, or *treppe*.

Although all the possible causes of the staircase effect are not known, it is believed to be caused primarily by increasing Ca^{2+} in the cytosol because of the release of more and more ions from the sarcoplasmic reticulum with each successive muscle action potential and failure of the sarcoplasmic reticulum to recapture the ions immediately.

Skeletal Muscle Tone. Even when muscles are at rest, a certain amount of tautness usually remains, called *muscle tone*. Because normal skeletal muscle fibers do not contract without an action potential to stimulate the fibers, skeletal muscle tone results entirely from a low rate of nerve impulses coming from the spinal cord. These nerve impulses, in turn, are controlled partly by signals transmitted from the brain to the appropriate spinal cord anterior motoneurons and partly by signals that originate in *muscle spindles*, which are stretch receptors within the muscle. Both these signals are discussed in relationship to muscle spindle and spinal cord function in Chapter 55.

Muscle Fatigue. Prolonged strong contraction of a muscle leads to the well-known state of muscle fatigue. Studies in athletes have shown that muscle fatigue increases in almost direct proportion to the rate of depletion of muscle glycogen. Therefore, fatigue results mainly from the inability of the contractile and metabolic processes of the muscle fibers to continue supplying the same work output. However, experiments have also shown that transmission of the nerve signal through the neuromuscular junction, discussed in Chapter 7, can diminish at least a small amount after intense prolonged muscle activity, thus further diminishing muscle contraction. Interruption of blood flow through a contracting muscle leads to almost complete muscle fatigue within 1 or 2 minutes because of the loss of nutrient supply, especially the loss of oxygen.

Lever Systems of the Body. Muscles operate by applying tension to their points of insertion into bones, and the bones in turn form various types of lever systems. **Fig. 6.15** shows the lever system activated by the biceps muscle to lift the forearm against a load. Assuming that a large biceps muscle has a cross-sectional area of 6 square inches, the maximum force of contraction would be about 300 pounds. When the forearm is at right angles with the upper arm, the tendon attachment of the biceps is about 2 inches anterior to the fulcrum at the elbow, and the total length of the forearm lever is about 14 inches. Therefore, the amount of lifting power of the biceps at the hand would be only one-seventh of the 300 pounds of muscle force, or about 43 pounds. When the arm is fully extended, the attachment of the biceps is much less than 2 inches anterior to the fulcrum, and the force with which the hand can be brought forward is also much less than 43 pounds.

In short, an analysis of the lever systems of the body depends on knowledge of the following: (1) the point of muscle insertion; (2) its distance from the fulcrum of the lever; (3) the length of the lever arm; and (4) the position of the lever. Many types of movement are required in the body, some of which need great strength and others that need large distances of movement. For this reason, there are many different types of muscle; some are long and contract a long distance, and some are short but have large cross-sectional areas and can provide extreme strength of contraction over short distances. The study of different types of muscles, lever systems, and their movements is called *kinesiology* and is an important scientific component of human physiology.

Positioning of a Body Part By Contraction of Agonist and Antagonist Muscles on Opposite Sides of a Joint. Virtually all body movements are caused by simultaneous contraction of agonist and antagonist muscles on opposite sides of joints. This process is called *coactivation of the agonist and antagonist muscles*, and it is controlled by the motor control centers of the brain and spinal cord.

The position of each separate part of the body, such as an arm or a leg, is determined by the relative degrees of contraction of the agonist and antagonist sets of muscles. For example, let us assume that an arm or a leg is to be placed in a midrange position. To achieve this position, agonist and antagonist muscles are excited to about an equal degree. Remember that an elongated muscle contracts with more force than does a shortened muscle, which was illustrated in **Fig. 6.9**, showing maximum strength of contraction at full functional muscle length and almost no strength of contraction at half-normal length. Therefore, the elongated muscle on one side of a joint can contract with far greater force than the shorter muscle on the opposite side. As an arm or leg moves toward its midposition, the strength of the longer muscle decreases, but the strength of the shorter muscle increases until the two strengths equal each other. At this point, movement of the arm or leg stops. Thus, by varying degree of activation of the agonist and antagonist muscles, the nervous system directs the positioning of the arm or leg.

We discuss in Chapter 55 that the motor nervous system has additional important mechanisms to compensate for different muscle loads when directing this positioning process.

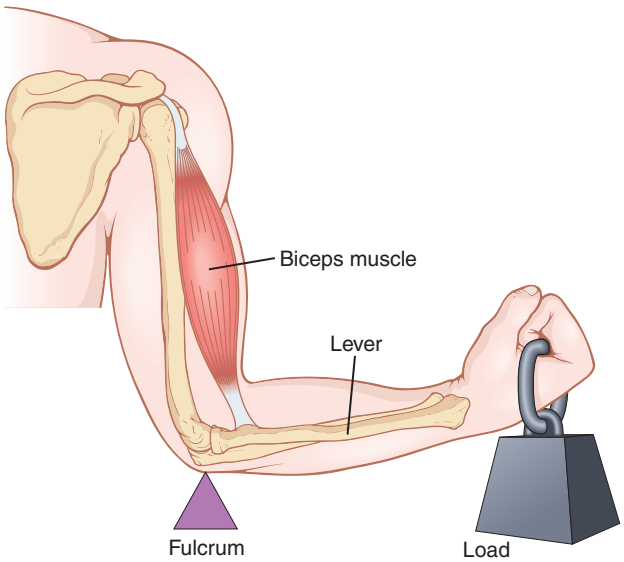

Figure 6.15 Lever system activated by the biceps muscle.

REMODELING OF MUSCLE TO MATCH FUNCTION

The muscles of the body continually remodel to match the functions required of them. Their diameters, lengths, strengths, and vascular supplies are altered, and even the types of muscle fibers are altered, at least slightly. This remodeling process is often quite rapid, occurring within a few weeks. Experiments in animals have shown that muscle contractile proteins in some smaller, more active muscles can be replaced in as little as 2 weeks.

Muscle Hypertrophy and Muscle Atrophy. The increase of the total mass of a muscle is called *muscle hypertrophy*. When the total mass decreases, the process is called *muscle atrophy*.

Virtually all muscle hypertrophy results from an increase in the number of actin and myosin filaments in each muscle fiber, causing enlargement of the individual muscle fibers; this condition is called *fiber hypertrophy*. Hypertrophy occurs to a much greater extent when the muscle is loaded during the contractile process. Only a few strong contractions each day are required to cause significant hypertrophy within 6 to 10 weeks.

The manner in which forceful contraction leads to hypertrophy is not fully understood. It is known that the rate of synthesis of muscle contractile proteins is far greater when hypertrophy is developing, leading also to progressively greater numbers of actin and myosin filaments in the myofibrils, often increasing as much as 50%. Some of the myofibrils have been observed to split within hypertrophying muscle to form new myofibrils, but the importance of this process in the usual enlargement of skeletal muscle is still unclear.

Along with the increasing size of myofibrils, the enzyme systems that provide energy also increase, especially the enzymes for glycolysis, allowing for a rapid supply of energy during short-term forceful muscle contraction.

When a muscle remains unused for many weeks, the rate of degradation of the contractile proteins is more rapid than the rate of replacement. Therefore, muscle atrophy occurs. The pathway that appears to account for much of the protein degradation in a muscle undergoing atrophy is the *ATP-dependent ubiquitin-proteasome pathway*. Proteasomes are large protein complexes that degrade damaged or unneeded proteins by *proteolysis*, a chemical reaction that breaks peptide bonds. Ubiquitin is a regulatory protein that basically labels which cells will be targeted for proteosomal degradation.

Adjustment of Muscle Length. Another type of hypertrophy occurs when muscles are stretched to greater than normal length. This stretching causes new sarcomeres to be added at the ends of the muscle fibers, where they attach to the tendons. In fact, new sarcomeres can be added as rapidly as several per minute in newly developing muscle, illustrating the rapidity of this type of hypertrophy.

Conversely, when a muscle continually remains shortened to less than its normal length, sarcomeres at the ends of the muscle fibers can actually disappear. It is by these processes that muscles are continually remodeled so that they have the appropriate length for proper muscle contraction.

Satellite Cells and Muscle Repair. Skeletal muscle contains a population of adult stem cells called *satellite cells* that are generally quiescent but can be activated to proliferate and repair muscle fibers that are damaged by daily activity or by muscle injury (**Fig. 6.16**). After several cycles of proliferation, these satellite cells differentiate and subsequently fuse at the site of injury to repair the damaged muscle fibers. Satellite cells are essential for normal muscle homeostasis, as well as hypertrophy and regeneration after injury.

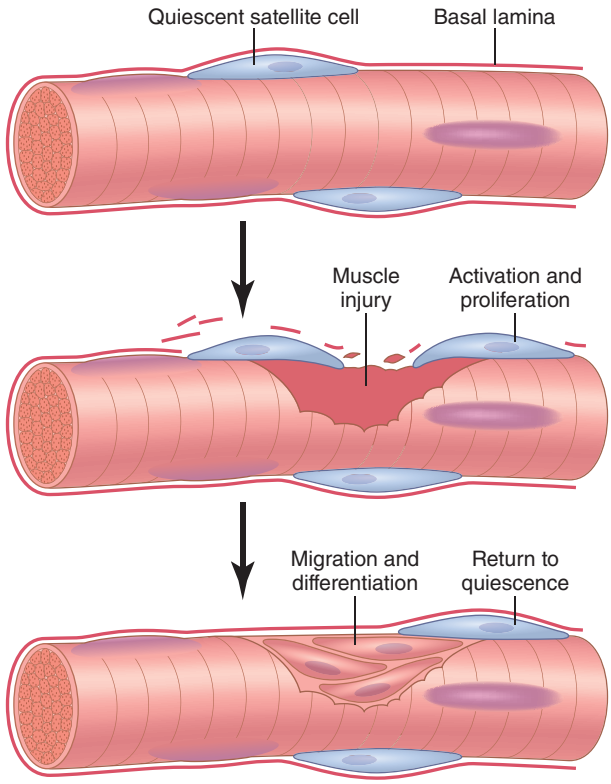

Figure 6.16 Quiescent satellite cells lie beneath the basal lamina and above the sarcolemma of the muscle fiber. After muscle fiber injury, satellite cells are activated and proliferate. Some satellite cells differentiate and migrate through the sarcolemma to the site of injury, where they fuse with the fiber to repair it or contribute to hypertrophy. Other satellite cells self-renew and return to quiescence, ensuring that sufficient satellite cells are available to support future muscle repair.

Reductions in satellite cell populations and their repair capacity may contribute to age-dependent loss of muscle mass, broadly defined as *sarcopenia*. However, exercise activates satellite cells and may prevent or reverse some of the effects of aging on muscle mass.

Hyperplasia of Muscle Fibers. Under rare conditions of extreme muscle force generation, the actual number of muscle fibers has been observed to increase (but only by a few percent), in addition to fiber hypertrophy. This increase in fiber number is called *fiber hyperplasia*. When hyperplasia does occur, the primary mechanism is linear splitting of previously enlarged fibers.

Muscle Denervation Causes Rapid Atrophy. When a muscle loses its nerve supply, it no longer receives the contractile signals that are required to maintain normal muscle size. Therefore, atrophy begins almost immediately. After about 2 months, degenerative changes also begin to appear in the muscle fibers. If the nerve supply to the muscle grows back rapidly, full return of function can occur in as little as 3 months, but from then onward, the capability of functional return becomes less and less, with no further return of function after 1 to 2 years.

In the final stage of denervation atrophy, most of the muscle fibers are destroyed and replaced by fibrous and fatty tissue. The fibers that do remain are composed of a long cell membrane with a lineup of muscle cell nuclei but with few or no contractile properties and little or no capability of regenerating myofibrils if a nerve does regrow.

The fibrous tissue that replaces the muscle fibers during denervation atrophy also has a tendency to continue shortening for many months, a process called *contracture*. Therefore, one of the most important challenges of physical therapy is to keep atrophying muscles from developing debilitating and disfiguring contractures. This goal is achieved by daily stretching of the muscles or use of appliances that keep the muscles stretched during the atrophying process.

Recovery of Muscle Contraction in Poliomyelitis: Development of Macromotor Units. When some but not all nerve fibers to a muscle are destroyed, as occurs in poliomyelitis, the remaining nerve fibers branch off to form new axons that innervate many of the paralyzed muscle fibers. This process results in large motor units called *macromotor units*, which can contain as many as five times the normal number of muscle fibers for each motoneuron coming from the spinal cord. Formation of these large motor units decreases the fineness of muscle control but allows the muscles to regain varying degrees of strength.

Rigor Mortis. Within a few hours after death, all the muscles of the body go into a state of *contracture* called *rigor mortis*; that is, the muscles contract and become rigid, even without action potentials. This rigidity results from loss of all the ATP, which is required to cause separation of the cross-bridges from the actin filaments during the relaxation process. The muscles remain in rigor until the muscle proteins deteriorate about 15 to 25 hours later, which presumably results from autolysis caused by enzymes released from lysosomes. All these events occur more rapidly at higher temperatures.

Muscular Dystrophy. The muscular dystrophies include several inherited disorders that cause progressive weakness and degeneration of muscle fibers, which are replaced by fatty tissue and collagen.

One of the most common forms of muscular dystrophy is *Duchenne muscular dystrophy* (DMD). This disease affects only males because it is transmitted as an X-linked recessive trait and is caused by mutation of the gene that encodes for a protein called *dystrophin*, which links actins to proteins in the muscle cell membrane. Dystrophin and associated proteins form an interface between the intracellular contractile apparatus and extracellular connective matrix.

Lack of dystrophin or mutated forms of the protein cause muscle cell membrane destabilization and activation of multiple pathophysiological processes, including altered intracellular Ca^{2+} handling and impaired membrane repair after injury. One important effect of abnormal dystrophin is an increase in membrane permeability to Ca^{2+}, thus allowing extracellular Ca^{2+} to enter the muscle fiber and initiate changes in intracellular enzymes that ultimately lead to proteolysis and muscle fiber breakdown.

Symptoms of DMD include muscle weakness that begins in early childhood and rapidly progresses, so that the patient is usually in a wheelchair by age 12 years and often dies of respiratory failure before age 30 years. A milder form of this disease, called *Becker muscular dystrophy* (BMD), is also caused by mutations of the gene that encodes for dystrophin but has a later onset and longer survival. It is estimated that DMD and BMD affect 1 of every 5600 to 7700 males between 5 and 24 years of age. Currently, no effective treatment exists for DMD or BMD, although characterization of the genetic basis for these diseases has provided the potential for gene therapy in the future.

CHAPTER 7

Excitation of Skeletal Muscle: Neuromuscular Transmission and Excitation-Contraction Coupling

NEUROMUSCULAR JUNCTION AND TRANSMISSION OF IMPULSES FROM NERVE ENDINGS TO SKELETAL MUSCLE FIBERS

Skeletal muscle fibers are innervated by large myelinated nerve fibers that originate from large motoneurons in the anterior horns of the spinal cord. As discussed in Chapter 6, each nerve fiber, after entering the muscle belly, typically branches and stimulates from three to several hundred skeletal muscle fibers. Each nerve ending makes a junction, called the *neuromuscular junction*, with the muscle fiber near its midpoint. The action potential initiated in the muscle fiber by the nerve signal travels in both directions toward the muscle fiber ends. With the exception of about 2% of the muscle fibers, there is only one such junction per muscle fiber.

THE NEUROMUSCULAR JUNCTION—THE MOTOR END PLATE

Fig. 7.1A–B shows the neuromuscular junction from a large myelinated nerve fiber to a skeletal muscle fiber. The nerve fiber forms a complex of *branching nerve terminals* that invaginate into the surface of the muscle fiber but lie outside the muscle fiber plasma membrane. The entire structure is called the *motor end plate*. It is covered by one or more *Schwann cells* that insulate it from the surrounding fluids.

Fig. 7.1C shows the junction between a single axon terminal and the muscle fiber membrane. The invaginated membrane is called the *synaptic gutter* or *synaptic trough*, and the space between the terminal and the fiber membrane is called the *synaptic space* or *synaptic cleft*, which is 20 to 30 nanometers wide. At the bottom of the gutter are numerous smaller folds of the muscle membrane called *subneural clefts*, which greatly increase the surface area at which the synaptic transmitter can act.

In the axon terminal are many mitochondria that supply adenosine triphosphate (ATP), the energy source used for synthesis of a transmitter, *acetylcholine*, which excites the muscle fiber membrane. Acetylcholine is synthesized in the cytoplasm of the terminal but is absorbed rapidly into many small *synaptic vesicles*, about 300,000 of which are normally in the terminals of a single end plate. In the synaptic space are large quantities of the enzyme *acetylcholinesterase*, which destroys acetylcholine a few milliseconds after it has been released from the synaptic vesicles.

SECRETION OF ACETYLCHOLINE BY THE NERVE TERMINALS

When a nerve impulse reaches the neuromuscular junction, about 125 vesicles of acetylcholine are released from the terminals into the synaptic space. Some of the details of this mechanism can be seen in **Fig. 7.2**, which shows an expanded view of a synaptic space with the neural membrane above and the muscle membrane and its subneural clefts below.

On the inside surface of the neural membrane are linear *dense bars*, shown in cross section in **Fig. 7.2**. To each side of each dense bar are *voltage-gated calcium channels* that penetrate the neural membrane. When an action potential spreads over the terminal, these channels open and allow Ca^{2+} to diffuse from the synaptic space to the interior of the nerve terminal. The Ca^{2+}, in turn, activates *Ca^{2+}-calmodulin–dependent protein kinase*, which, in turn, phosphorylates *synapsin* proteins that anchor the acetylcholine vesicles to the cytoskeleton of the presynaptic terminal. This process frees the acetylcholine vesicles from the cytoskeleton and allows them to move to the *active zone* of the presynaptic neural membrane adjacent to the dense bars. The vesicles then dock at the release sites, fuse with the neural membrane, and empty their acetylcholine into the synaptic space by the process of *exocytosis*.

Acetylcholine Opens Ion Channels on Postsynaptic Membranes. **Fig. 7.2** also shows many small *nicotinic acetylcholine receptors* and *voltage-gated sodium channels* in the muscle fiber membrane. These receptors form *acetylcholine-gated ion channels* that are located almost entirely near the mouths of the subneural clefts lying immediately below the dense bar areas, where acetylcholine is emptied into the synaptic space. The voltage-gated sodium channels also line the subneural clefts.

The nicotinic acetylcholine receptors, found at the neuromuscular junction and on neurons, are distinct from *muscarinic acetylcholine receptors* found in the

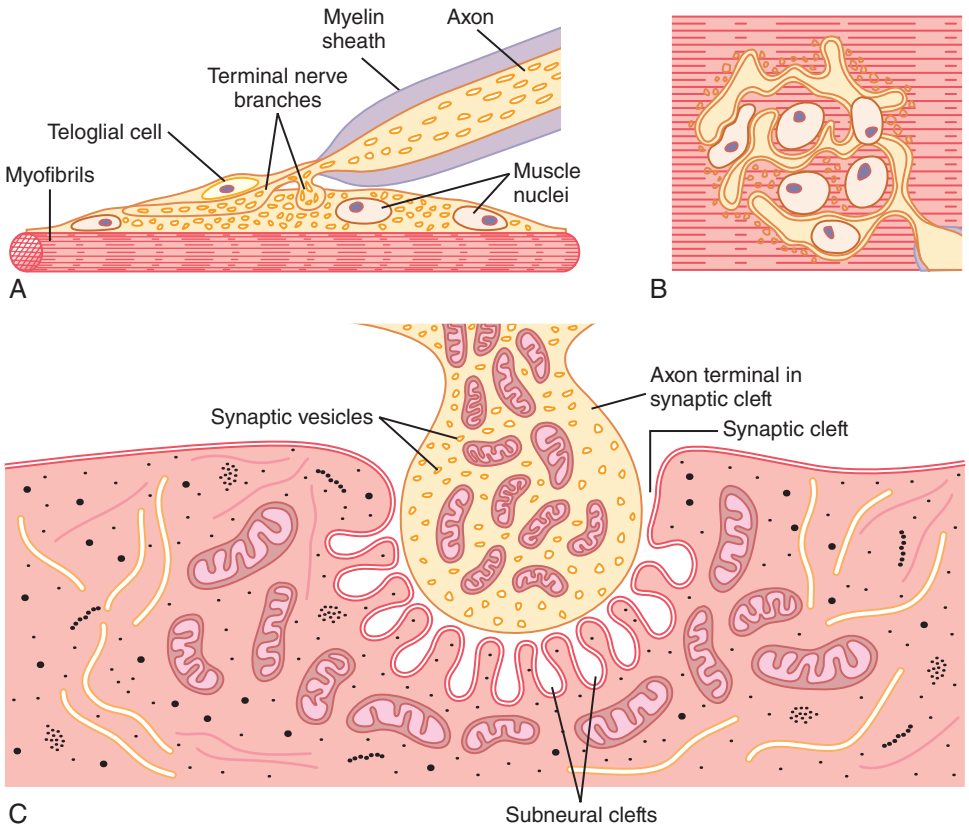

Figure 7.1 Different views of the motor end plate. (A) Longitudinal section through the end plate. (B) Surface view of the end plate. (C) Electron micrographic appearance of the contact point between a single axon terminal and the muscle fiber membrane.

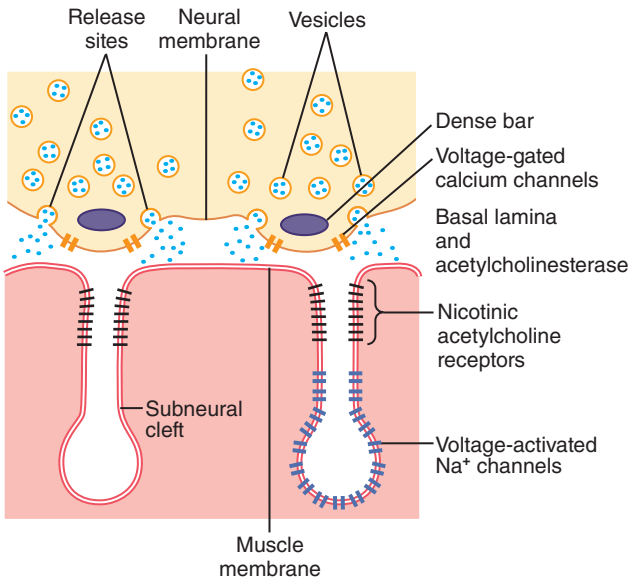

Figure 7.2 Release of acetylcholine from synaptic vesicles at the neural membrane of the neuromuscular junction. Note the proximity of the release sites in the neural membrane to the acetylcholine receptors in the muscle membrane at the mouths of the subneural clefts.

brain, heart, endocrine and exocrine glands, and smooth muscle. The muscarinic cholinergic receptors are a group of *G protein-linked receptors* that signal via second messenger systems (see Chapter 46 for further discussion of G protein-linked receptors).

Each nicotinic acetylcholine receptor in the neuromuscular junction is a protein complex that has a total molecular weight of approximately 275,000. The fetal acetylcholine receptor complex is composed of five subunit proteins, two *alpha* proteins and one each of *beta, delta*, and *gamma* proteins. In the adult, an *epsilon* protein substitutes for the gamma protein in this receptor complex. These protein molecules penetrate all the way through the membrane, lying side by side in a circle to form a channel, illustrated in **Fig. 7.3A**. The channel remains constricted, as shown in part B of the figure, until two acetylcholine molecules attach, respectively, to the two *alpha* subunit proteins. This attachment causes a conformational change that opens the channel, as shown in **Fig. 7.3B**.

The acetylcholine-gated channel has a diameter of about 0.65 nanometer, which is large enough to allow the important positive ions—sodium (Na^+), potassium (K^+), and calcium (Ca^{2+})—to move easily through the opening. Patch clamp studies have shown that one of these channels, when opened by acetylcholine, can transmit 15,000 to 30,000 sodium ions in 1 millisecond. Conversely, negative ions, such as chloride ions, do not pass through because of strong negative charges in the mouth of the channel that repel these negative ions.

Far more sodium ions flow through the acetylcholine-gated channels than any other ions for two reasons. First, there are only two positive ions present in large concentrations—sodium ions in the extracellular fluid

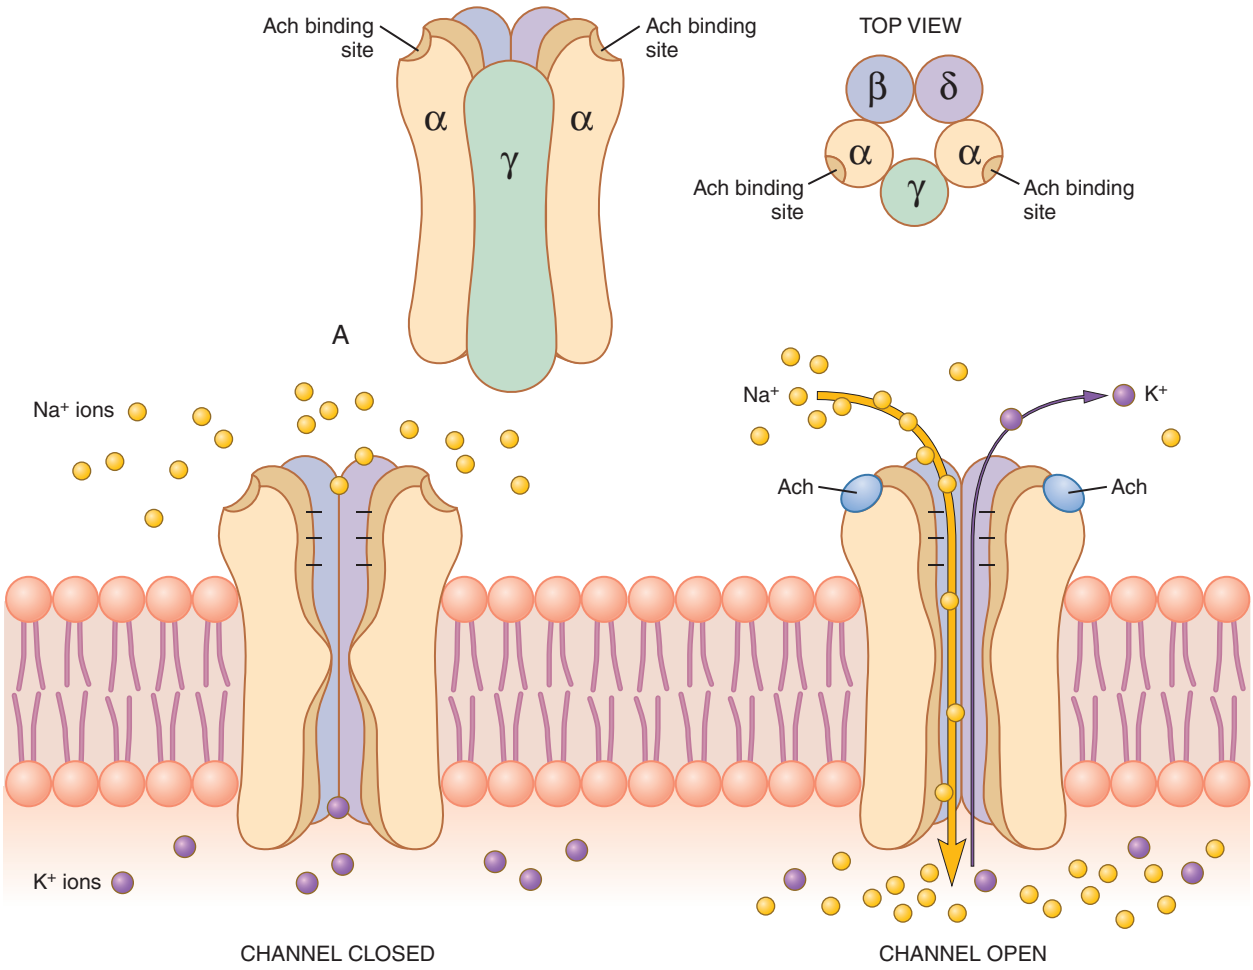

Figure 7.3 Nicotinic acetylcholine (Ach) receptor. (A) Shows the five subunit proteins of the receptor—two alpha (α) proteins and one each of beta (β), delta (δ), and gamma (γ) proteins. (B) Shows the closed state of the receptor-channel and the open state after acetylcholine (Ach) has become attached to the receptor and a conformational change has opened the channel, allowing sodium ions to enter the muscle fiber and excite contraction. When the channel is open, it also permits potassium ions to move out of the muscle fiber, but the inward sodium current is much greater than the outward potassium current, resulting in depolarization. Note the negative charges at the channel mouth that impede passage of negative ions such as chloride ions.

and potassium ions in the intracellular fluid. Second, the electrochemical driving force for sodium is about 160 mV directed inward, and the electrochemical driving force for potassium is about 10 mV directed outward. Thus, sodium and potassium ions move simultaneously in opposite directions through the open acetylcholine-gated channel, but the inward sodium current is much greater compared with the outward potassium current.

As shown in **Fig. 7.3B**, opening the acetylcholine-gated channels allows large numbers of sodium ions to flow to the inside of the fiber, carrying positive charges with them. This action creates a local positive potential change inside the muscle fiber membrane, called the *end plate potential*. This end plate potential normally causes sufficient depolarization to open neighboring voltage-gated sodium channels, allowing even greater sodium ion inflow and initiating an action potential that spreads along the muscle membrane and causes muscle contraction.

Destruction of the Released Acetylcholine By Acetylcholinesterase. The acetylcholine, once released into the synaptic space, continues to activate acetylcholine receptors as long as the acetylcholine persists in the space. However, it is rapidly destroyed by the enzyme *acetylcholinesterase*, which is attached mainly to the spongy layer of fine connective tissue that fills the synaptic space between the presynaptic nerve terminal and the postsynaptic muscle membrane. A small amount of acetylcholine diffuses out of the synaptic space and is then no longer available to act on the muscle fiber membrane.

The short time that the acetylcholine remains in the synaptic space—a few milliseconds at most—normally is sufficient to excite the muscle fiber. Then the rapid removal of the acetylcholine prevents continued muscle re-excitation after the muscle fiber has recovered from its initial action potential.

End Plate Potential and Excitation of the Skeletal Muscle Fiber. The sudden insurgence of sodium ions into the muscle fiber when the acetylcholine-gated channels open causes the electrical potential inside the fiber at the *local area of the end plate* to increase in the positive

direction as much as 50 to 75 millivolts, creating a *local potential* called the *end plate potential*. Recall from Chapter 5 that a sudden increase in nerve membrane potential of more than 20 to 30 millivolts is normally sufficient to initiate more and more sodium channel opening, thus initiating an action potential at the muscle fiber membrane.

Fig. 7.4 illustrates an end plate potential initiating the action potential. This figure shows three separate end plate potentials. End plate potentials A and C are too weak to elicit an action potential, but they do produce weak local end plate voltage changes. By contrast, end plate potential B is much stronger and causes enough sodium channels to open so that the self-regenerative effect of more and more sodium ions flowing to the interior of the fiber initiates an action potential. The weakness of the end plate potential at point A was caused by poisoning of the muscle fiber with *curare*, a drug that blocks the gating action of acetylcholine on the acetylcholine channels by competing for the acetylcholine receptor sites. The weakness of the end plate potential at point C resulted from the effect of *botulinum toxin*, a bacterial poison that decreases the quantity of acetylcholine release by the nerve terminals.

Safety Factor for Transmission at the Neuromuscular Junction—Fatigue of the Junction. Ordinarily, each impulse arriving at the neuromuscular junction causes about three times as much end plate potential as that required to stimulate the muscle fiber. Therefore, the normal neuromuscular junction is said to have a high *safety factor*. However, stimulation of the nerve fiber at rates greater than 100 times per second for several minutes may diminish the number of acetylcholine vesicles so much that impulses fail to pass into the muscle fiber. This *fatigue* of the neuromuscular junction is the same cause of fatigue in central nervous system synapses when they are overexcited. Under normal functioning conditions, measurable fatigue of the neuromuscular junction occurs rarely and, even then, only at the most exhausting levels of muscle activity.

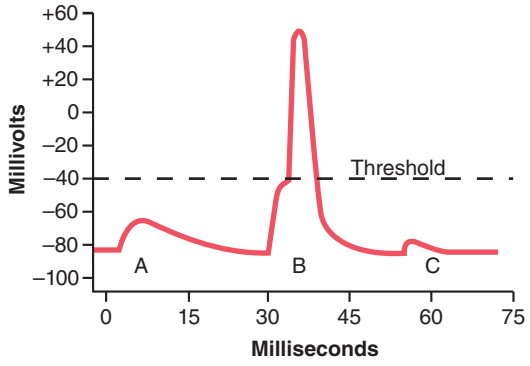

Figure 7.4 End plate potentials (in millivolts). (A) Weakened end plate potential, too weak to elicit an action potential, recorded in a curarized muscle. (B) Normal end plate potential eliciting a muscle action potential. (C) Weakened end plate potential caused by botulinum toxin that decreases end plate release of acetylcholine, again too weak to elicit a muscle action potential.

Acetylcholine Formation and Release

Acetylcholine formation and release at the neuromuscular junction occur in the following stages:

1. Small vesicles, about 40 nanometers in size, are formed by the Golgi apparatus in the cell body of the motoneuron in the spinal cord. These vesicles are then transported by axoplasm that streams through the core of the axon from the central cell body in the spinal cord all the way to the neuromuscular junction at the tips of the peripheral nerve fibers. About 300,000 of these small vesicles collect in the nerve terminals of a single skeletal muscle end plate.
2. Acetylcholine is synthesized in the cytosol of the nerve fiber terminal but is immediately transported through the membranes of the vesicles to their interior, where it is stored in highly concentrated form—about 10,000 molecules of acetylcholine in each vesicle.
3. When an action potential arrives at the nerve terminal, it opens many *calcium channels* in the membrane of the nerve terminal because this terminal has an abundance of voltage-gated calcium channels. As a result, the calcium ion concentration inside the terminal membrane increases about 100-fold, which in turn increases the rate of fusion of the acetylcholine vesicles with the terminal membrane about 10,000-fold. This fusion ruptures many of the vesicles, allowing *exocytosis* of acetylcholine into the synaptic space. About 125 vesicles usually rupture with each action potential. Then, after a few milliseconds, the acetylcholine is split by acetylcholinesterase into acetate ion and choline, and the choline is actively reabsorbed into the neural terminal to be reused to form new acetylcholine. This sequence of events occurs within a period of 5 to 10 milliseconds.
4. The number of vesicles available in the nerve ending is sufficient to allow transmission of only a few thousand nerve to muscle impulses. Therefore, for continued function of the neuromuscular junction, new vesicles need to be re-formed rapidly. Within a few seconds after each action potential, coated pits appear in the terminal nerve membrane, caused by contractile proteins in the nerve ending, especially the protein *clathrin*, which is attached to the membrane in the areas of the original vesicles. Within about 20 seconds, the proteins contract and cause the pits to break away to the interior of the membrane, thus forming new vesicles. Within another few seconds, acetylcholine is transported to the interior of these vesicles, and they are then ready for a new cycle of acetylcholine release.

Drugs That Stimulate the Muscle Fiber by Acetylcholine-Like Action. Several compounds, including *methacholine, carbachol*, and *nicotine*, have nearly the same effect on the muscle fiber as acetylcholine. The main differences between these drugs and acetylcholine are that the drugs are not destroyed by cholinesterase or are destroyed so slowly that their action often persists for many minutes to several hours. These drugs work by causing localized areas of depolarization of the muscle fiber membrane at the motor end plate where the acetylcholine receptors are located. Then, every time the muscle fiber recovers from a

previous contraction, these depolarized areas, by virtue of leaking ions, initiate a new action potential, thereby causing a state of muscle spasm.

Drugs That Stimulate the Neuromuscular Junction By Inactivating Acetylcholinesterase. Three well-known drugs—*neostigmine, physostigmine*, and *diisopropyl fluorophosphate*—inactivate acetylcholinesterase in the synapses so that it no longer hydrolyzes acetylcholine. Therefore, with each successive nerve impulse, additional acetylcholine accumulates and stimulates the muscle fiber repetitively. This activity causes *muscle spasm* when even a few nerve impulses reach the muscle. It can also cause death as a result of laryngeal spasm, which can lead to asphyxiation.

Neostigmine and physostigmine combine with acetylcholinesterase to inactivate the acetylcholinesterase for up to several hours, after which these drugs are displaced from the acetylcholinesterase so that the esterase once again becomes active. Conversely, diisopropyl fluorophosphate, which is a powerful nerve gas poison, inactivates acetylcholinesterase for weeks, which makes this poison particularly lethal.

Drugs That Block Transmission at the Neuromuscular Junction. A group of drugs known as *curariform drugs* can prevent the passage of impulses from the nerve ending into the muscle. For example, D-tubocurarine blocks the action of acetylcholine on the muscle fiber acetylcholine receptors, thus preventing sufficient increase in permeability of the muscle membrane channels to initiate an action potential.

Myasthenia Gravis Causes Muscle Weakness. *Myasthenia gravis*, which occurs in about 1 in every 20,000 persons, causes muscle weakness because of the inability of the neuromuscular junctions to transmit enough signals from the nerve fibers to the muscle fibers. Myasthenia gravis is believed to be an autoimmune disease in which the patients have developed antibodies that block or destroy their own acetylcholine receptors at the postsynaptic neuromuscular junction.

The end plate potentials that occur in the muscle fibers are mostly too weak to initiate opening of the voltage-gated sodium channels, and muscle fiber depolarization does not occur. If the disease is intense enough, the patient may die of respiratory failure as a result of severe weakness of the respiratory muscles. The disease can usually be ameliorated for several hours by administering *neostigmine* or some other anticholinesterase drug, which allows larger than normal amounts of acetylcholine to accumulate in the synaptic space. Within minutes, some of those affected can begin to function almost normally until a new dose of neostigmine is required a few hours later.

MUSCLE ACTION POTENTIAL

Almost everything discussed in Chapter 5 regarding the initiation and conduction of action potentials in nerve fibers applies equally to skeletal muscle fibers, except for quantitative differences. Some of the quantitative aspects of muscle potentials are as follows:

1. The resting membrane potential is about −80 to −90 millivolts in skeletal muscle fibers, about 10 to 20 millivolts more negative than in neurons.
2. The duration of the action potential is 1 to 5 milliseconds in skeletal muscle, about five times as long as in large myelinated nerves.
3. The velocity of conduction is 3 to 5 m/sec, about 1/13 the velocity of conduction in the large myelinated nerve fibers that excite skeletal muscle.

Action Potentials Spread to the Interior of the Muscle Fiber Via Transverse Tubules

The skeletal muscle fiber is so large that action potentials spreading along its surface membrane cause almost no current flow deep within the fiber. Maximum muscle contraction, however, requires the current to penetrate deeply into the muscle fiber to the vicinity of the separate myofibrils. This penetration is achieved by transmission of action potentials along *transverse tubules* (T tubules) that penetrate all the way through the muscle fiber, as illustrated in **Fig. 7.5**. The T tubule action potentials cause release of Ca^{2+} inside the muscle fiber in the immediate vicinity of the myofibrils, and Ca^{2+} then causes contraction. The overall process is called *excitation-contraction* coupling.

EXCITATION-CONTRACTION COUPLING

Transverse Tubule–Sarcoplasmic Reticulum System

Fig. 7.5 shows myofibrils surrounded by the T tubule–sarcoplasmic reticulum system. The T tubules are small and run transverse to the myofibrils. They begin at the cell membrane and penetrate all the way from one side of the muscle fiber to the opposite side. Not shown in the figure is that these tubules branch among themselves and form entire *planes* of T tubules, interlacing among all the separate myofibrils. Also, *where the T tubules originate from the cell membrane, they are open to the exterior of the muscle fiber*. Therefore, they communicate with the extracellular fluid surrounding the muscle fiber and contain extracellular fluid in their lumens. Thus, *the T tubules are actually internal extensions of the cell membrane*. Therefore, when an action potential spreads over a muscle fiber membrane, a potential change also spreads along the T tubules to the deep interior of the muscle fiber. The electrical currents surrounding these T tubules then elicit the muscle contraction.

Fig. 7.5 also shows a sarcoplasmic *reticulum*, in yellow. This sarcoplasmic reticulum is composed of two major parts: (1) large chambers called *terminal cisternae* that abut the T tubules; and (2) long longitudinal tubules that surround all surfaces of the contracting myofibrils.

Release of Ca^{2+} By the Sarcoplasmic Reticulum

One of the special features of the sarcoplasmic reticulum is that within its vesicular tubules is a high concentration of Ca^{2+}. Many of these ions are released from each vesicle when an action potential occurs in the adjacent T tubule.

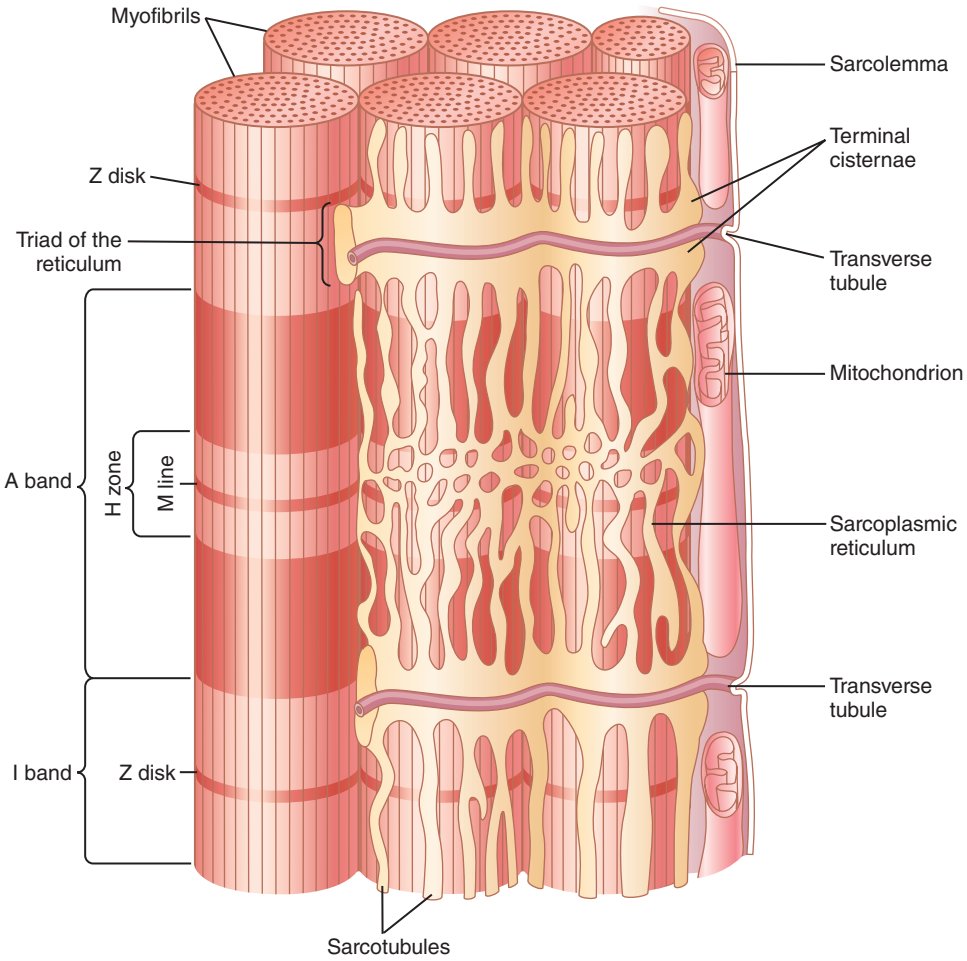

Figure 7.5 Transverse (T) tubule–sarcoplasmic reticulum system. Note that the T tubules communicate with the outside of the cell membrane and, deep in the muscle fiber, each T tubule lies adjacent to the ends of longitudinal sarcoplasmic reticulum tubules that surround all sides of the actual myofibrils that contract. This illustration was drawn from frog muscle, which has one T tubule per sarcomere, located at the Z disk. A similar arrangement is found in mammalian heart muscle, but mammalian skeletal muscle has two T tubules per sarcomere, located at the A-I band junctions.

Figs. 7.6 and 7.7 show that the action potential of the T tubule causes current flow into the sarcoplasmic reticular cisternae where they abut the T tubule. As the action potential reaches the T tubule, the voltage change is sensed by dihydropyridine *receptors* linked to *calcium release channels*, also called *ryanodine receptor channels*, in the adjacent sarcoplasmic reticular cisternae (see **Fig. 7.6**). Activation of dihydropyridine receptors triggers the opening of calcium release channels in the cisternae, as well as in their attached longitudinal tubules. These channels remain open for a few milliseconds, releasing Ca^{2+} into the sarcoplasm surrounding the myofibrils and causing contraction, as discussed in Chapter 6.

Calcium Pump Removes Ca^{2+} From the Myofibrillar Fluid After Contraction Occurs. Once the Ca^{2+} has been released from the sarcoplasmic tubules and diffuses among the myofibrils, muscle contraction continues as long as Ca^{2+} concentration remains high. However, a continually active calcium pump located in the walls of the sarcoplasmic reticulum pumps Ca^{2+} away from the myofibrils back into the sarcoplasmic tubules (see **Fig. 7.6**). This pump, called SERCA (***S***arcoplasmic ***R***eticulum ***C***a^{2+}-***A***TPase), can concentrate Ca^{2+} about 10,000-fold inside the tubules. In addition, inside the reticulum is a *calcium-binding protein* called *calsequestrin*, which can bind up to 40 Ca^{2+} for each molecule of calsequestrin.

Excitatory Pulse of Ca^{2+}. The normal resting state concentration ($<10^{-7}$ molar) of Ca^{2+} in the cytosol that bathes the myofibrils is too little to elicit contraction. Therefore, the troponin-tropomyosin complex keeps the actin filaments inhibited and maintains a relaxed state of the muscle.

Conversely, full excitation of the T tubule and sarcoplasmic reticulum system causes enough release of Ca^{2+} to increase the concentration in the myofibrillar fluid to as high as 2×10^{-4} molar concentration, a 500-fold increase, which is about 10 times the level required to cause maximum muscle contraction. Immediately thereafter, the calcium pump depletes the Ca^{2+} again. The total duration of this calcium pulse in the usual skeletal muscle fiber lasts about 1/20 of a second, although it may last several times as long in some fibers and several times less in others. In heart

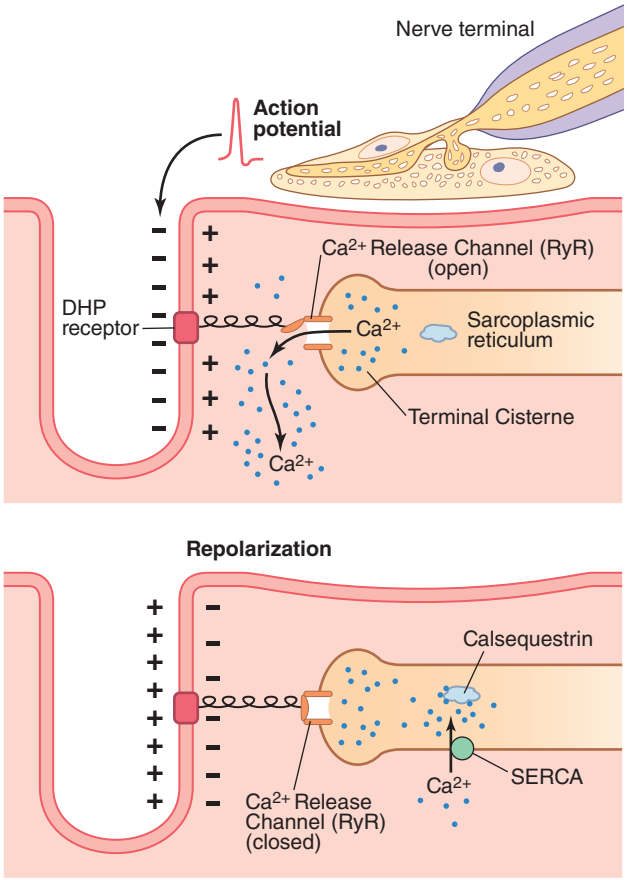

Figure 7.6 Excitation-contraction coupling in skeletal muscle. The *top panel* shows an action potential in the transverse tubule that causes a conformational change in the voltage-sensing dihydropyridine (DHP) receptors, opening the ryanodine (RyR) Ca^{2+} release channels in the terminal cisternae of the sarcoplasmic reticulum and permitting Ca^{2+} to diffuse rapidly into the sarcoplasm and initiate muscle contraction. During repolarization (*bottom panel*), the conformational change in the DHP receptor closes the Ca^{2+} release channels, and Ca^{2+} is transported from the sarcoplasm into the sarcoplasmic reticulum by an adenosine triphosphate–dependent calcium pump, called SERCA (*S*arcoplasmic *R*eticulum Ca^{2+}-*A*TPase).

muscle, the calcium pulse lasts about one-third of a second because of the long duration of the cardiac action potential.

During this calcium pulse, muscle contraction occurs. If the contraction is to continue without interruption for long intervals, a series of calcium pulses must be initiated by a continuous series of repetitive action potentials, as discussed in Chapter 6.

Malignant Hyperthermia

In susceptible individuals, *malignant hyperthermia* and a *hypermetabolic crisis* may be triggered by exposure to certain types of anesthetics, including halothane and isoflurane, or succinylcholine. At least six genetic mutations, especially of the ryanodine receptor or dihydropyridine receptor genes, have been shown to increase susceptibility greatly to developing malignant hyperthermia during anesthesia. The specific mechanisms whereby anesthetics interact with these abnormal receptors to trigger malignant hyperthermia are not fully understood. It is known, however, that these mutations cause unregulated passage of calcium from the sarcoplasmic reticulum into the intracellular spaces, which in turn causes the muscle fibers to contract excessively. These sustained muscled contractions greatly increase metabolic rate, generating large amounts of heat and causing cellular acidosis, as a well as depletion of energy stores.

Symptoms of malignant hyperthermia include muscle rigidity, high fever, and rapid heart rate. Additional complications in severe cases may include rapid breakdown of skeletal muscle (*rhabdomyolysis*) and a high plasma potassium level due to release of large amounts of potassium from damaged muscle cells. Treatment of malignant hyperthermia generally involves rapid cooling and the administration of *dantrolene*, a drug that antagonizes ryanodine receptors, which inhibits calcium ion release for the sarcoplasmic reticulum and attenuates muscle contraction.

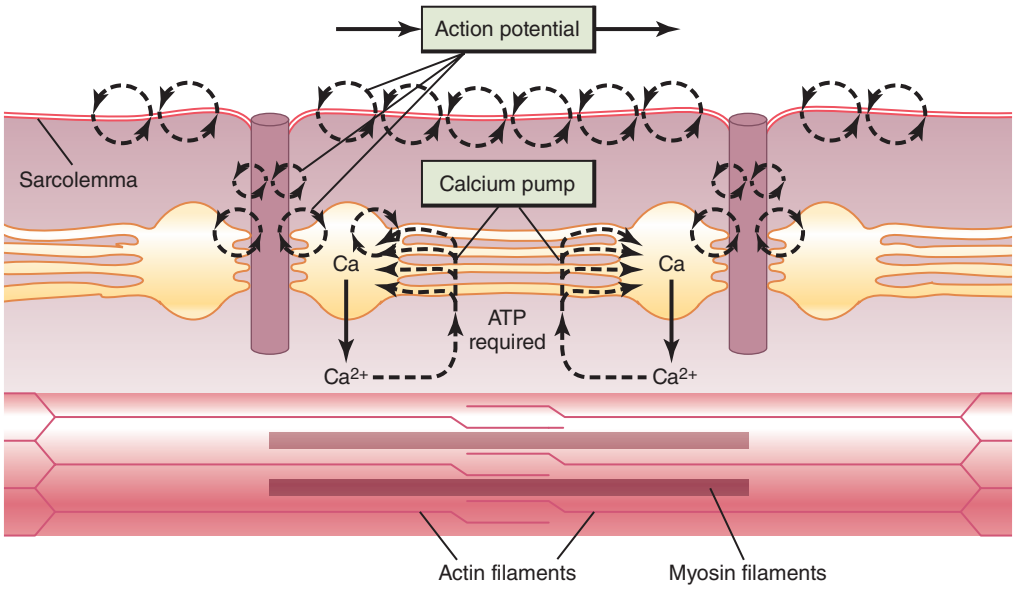

Figure 7.7 Excitation-contraction coupling in the muscle, showing (1) an action potential that causes release of Ca^{2+} from the sarcoplasmic reticulum and then (2) reuptake of Ca^{2+} by a calcium pump. *ATP*, Adenosine triphosphate.

CHAPTER 8

Excitation and Contraction of Smooth Muscle

CONTRACTION OF SMOOTH MUSCLE

Smooth muscle is composed of small fibers that are usually 1 to 5 micrometers in diameter and only 20 to 500 micrometers in length. In contrast, skeletal muscle fibers are as much as 30 times greater in diameter and hundreds of times as long. Despite these differences in size, many of the same principles of contraction apply to smooth muscle as to skeletal muscle. Essentially the same attractive forces between myosin and actin filaments cause contraction in smooth muscle as in skeletal muscle, but the internal physical arrangement of smooth muscle fibers is different.

TYPES OF SMOOTH MUSCLE

The smooth muscle of each organ is distinctive from that of most other organs in several ways: (1) physical dimensions; (2) organization into bundles or sheets; (3) response to different stimuli; (4) characteristics of innervation; and (5) function. Yet, for the sake of simplicity, smooth muscle can generally be divided into two major types, which are shown in **Fig. 8.1**, *multi-unit smooth muscle* and *unitary* (or *single-unit*) *smooth muscle*.

Multi-Unit Smooth Muscle. Multi-unit smooth muscle is composed of discrete, separate smooth muscle fibers. Each fiber operates independently of the others and often is innervated by a single nerve ending, as occurs for skeletal muscle fibers. Furthermore, the outer surfaces of these fibers, like those of skeletal muscle fibers, are covered by a thin layer of basement membrane–like substance, a mixture of fine collagen and glycoprotein that helps insulate the separate fibers from one another.

Each fiber of multi-unit smooth muscle can contract independently of the others, and their control is exerted mainly by nerve signals. In contrast, a major share of control of unitary smooth muscle is exerted by non-nervous stimuli. Some examples of multi-unit smooth muscle are the ciliary muscle of the eye, the iris muscle of the eye, and the piloerector muscles that cause erection of the hairs when stimulated by the sympathetic nervous system.

Unitary Smooth Muscle. Unitary smooth muscle is also called *syncytial smooth muscle* or *visceral smooth muscle*. The term *unitary* does not mean single muscle fibers. Instead, it means a mass of hundreds to thousands of smooth muscle fibers that contract together as a single unit. The fibers usually are arranged in sheets or bundles, and their cell membranes are adherent to one another at multiple points so that force generated in one muscle fiber can be transmitted to the next. In addition, the cell membranes are joined by many *gap junctions* through which ions can flow freely from one muscle cell to the next so that action potentials, or ion flow without action potentials, can travel from one fiber to the next and cause the muscle fibers to contract together. This type of smooth muscle is also known as syncytial smooth muscle because of its syncytial interconnections among fibers. It is also called *visceral smooth muscle* because it is found in the walls of most viscera of the body, including the gastrointestinal tract, bile ducts, ureters, uterus, and many blood vessels.

CONTRACTILE MECHANISM IN SMOOTH MUSCLE

Chemical Basis for Smooth Muscle Contraction

Smooth muscle contains both *actin* and *myosin filaments*, having chemical characteristics similar to those of the actin and myosin filaments in skeletal muscle. Smooth muscle does not contain the troponin complex that is required for skeletal muscle contraction, and thus the mechanism for controlling contraction is different. This topic is discussed in more detail later in this chapter.

Chemical studies have shown that actin and myosin filaments in smooth muscle interact with each other in much the same way that they do in skeletal muscle. Furthermore, the contractile process is activated by Ca^{2+}, and adenosine triphosphate (ATP) is degraded to adenosine diphosphate (ADP) to provide the energy for contraction.

There are, however, major differences between the physical organization of smooth muscle and that of skeletal muscle, as well as differences in excitation-contraction coupling, control of the contractile process by Ca^{2+}, duration of contraction, and the amount of energy required for contraction.

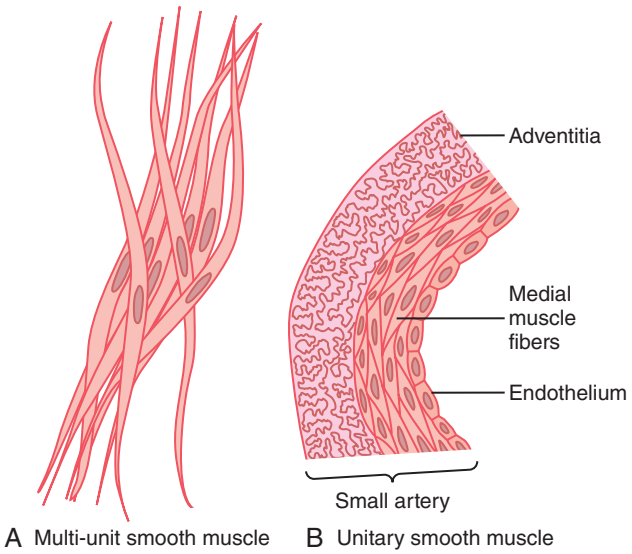

Figure 8.1 Multi-unit (A) and unitary (B) smooth muscle.

Physical Basis for Smooth Muscle Contraction

Smooth muscle does not have the same striated arrangement of actin and myosin filaments as is found in skeletal muscle. Instead, electron micrographic techniques suggest the physical organization shown in **Fig. 8.2A**, which illustrates large numbers of actin filaments attached to *dense bodies*. Some of these bodies are attached to the cell membrane, and others are dispersed inside the cell. Some of the membrane-dense bodies of adjacent cells are bonded together by intercellular protein bridges. It is mainly through these bonds that the force of contraction is transmitted from one cell to the next.

Interspersed among the actin filaments in the smooth muscle fiber are myosin filaments. These filaments have a diameter more than twice that of the actin filaments. In electron micrographs, 5 to 10 times as many actin filaments as myosin filaments are usually found.

Fig. 8.2B is a postulated structure of an individual contractile unit in a smooth muscle cell, showing large numbers of actin filaments radiating from two dense bodies; the ends of these filaments overlap a myosin filament located midway between the dense bodies. This contractile unit is similar to the contractile unit of skeletal muscle, but without the regularity of the skeletal muscle structure. In fact, the dense bodies of smooth muscle serve the same role as the Z disks in skeletal muscle.

Another difference is that most of the myosin filaments have "side polar" cross-bridges arranged so that the bridges on one side hinge in the opposite direction as those on the other side (**Fig. 8.2C**). This configuration allows the myosin to pull an actin filament in one direction on one side while simultaneously pulling another actin filament in the opposite direction on the other side. The value of this organization is that it allows smooth muscle cells to contract as much as 80% of their length instead of being limited to less than 30%, as occurs in skeletal muscle.

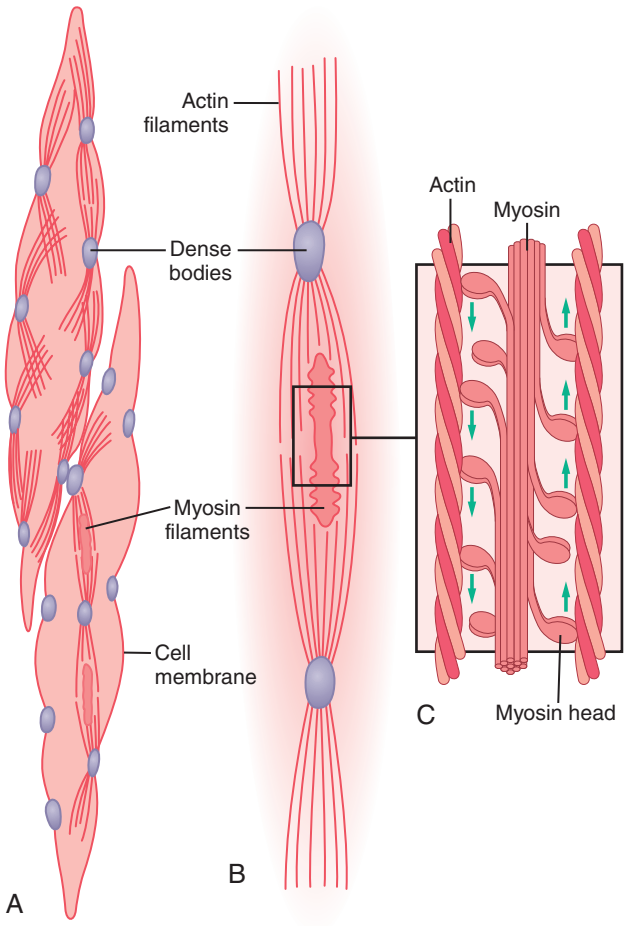

Figure 8.2 Physical structure of smooth muscle fibers. (A) Shows actin filaments radiating from dense bodies. (B) Illustrates the relation of myosin filaments to actin filaments. (C) Shows a smooth muscle myosin filament with cross-bridges on one side hinged in the opposite direction as those on the other side.

Comparison of Smooth Muscle Contraction and Skeletal Muscle Contraction

Although most skeletal muscles contract and relax rapidly, most smooth muscle contraction is prolonged tonic contraction, sometimes lasting hours or even days. Therefore, it is to be expected that both the physical and chemical characteristics of smooth muscle versus skeletal muscle contraction would differ. Some of the differences are noted in the following sections.

Slow Cycling of the Myosin Cross-Bridges. The cycling of the myosin cross-bridges in smooth muscle—that is, their attachment to actin, then release from the actin, and reattachment for the next cycle—is much slower than in skeletal muscle. The frequency is as little as 1/10 to 1/300 that in skeletal muscle. Yet, the *fraction of time* that the cross-bridges remain attached to the actin filaments, which is a major factor that determines the force of contraction, is greatly increased in smooth muscle. A possible reason for the slow cycling is that the cross-bridge heads have far less ATPase activity than in skeletal muscle; thus,

degradation of the ATP that energizes the movements of the cross-bridge heads is greatly reduced, with corresponding slowing of the rate of cycling.

Low Energy Requirement to Sustain Smooth Muscle Contraction. Only 1/10 to 1/300 as much energy is required to sustain the same tension of contraction in smooth muscle as in skeletal muscle. This, too, is believed to result from the slow attachment and detachment cycling of the cross-bridges, and because only one molecule of ATP is required for each cycle, regardless of its duration.

This low energy utilization by smooth muscle is important to the overall energy economy of the body because organs such as the intestines, urinary bladder, gallbladder, and other viscera often maintain tonic muscle contraction almost indefinitely.

Slowness of Onset of Contraction and Relaxation of the Total Smooth Muscle Tissue. A typical smooth muscle tissue begins to contract 50 to 100 milliseconds after it is excited, reaches full contraction about 0.5 second later, and then declines in contractile force in another 1 to 2 seconds, giving a total contraction time of 1 to 3 seconds. This is about 30 times as long as a single contraction of an average skeletal muscle fiber. However, contraction of the many types of smooth muscle can be as short as 0.2 second or as long as 30 seconds.

The smooth muscle's slow onset of contraction, as well as its prolonged contraction, is caused by the slowness of attachment and detachment of the cross-bridges with the actin filaments. In addition, the initiation of contraction in response to Ca^{2+} is much slower than in skeletal muscle, as will be discussed later.

Maximum Force of Contraction Is Often Greater in Smooth Muscle Than in Skeletal Muscle. Despite the relatively few myosin filaments in smooth muscle, and despite the slow cycling time of the cross-bridges, the maximum force of contraction of smooth muscle is often greater than that of skeletal muscle, as much as 4 to 6 kg/cm^2 cross-sectional area for smooth muscle in comparison with 3 to 4 kg/cm^2 for skeletal muscle. This great force of smooth muscle contraction results from the prolonged period of attachment of the myosin cross-bridges to the actin filaments.

Latch Mechanism Facilitates Prolonged Holding of Contractions of Smooth Muscle. Once smooth muscle has developed full contraction, the amount of continuing excitation can usually be reduced to far less than the initial level, even though the muscle maintains its full force of contraction. Furthermore, the energy consumed to maintain contraction is often minuscule, sometimes as little as 1/300 of the energy required for comparable sustained skeletal muscle contraction. This mechanism is called the *latch mechanism*.

The importance of the latch mechanism is that it can maintain prolonged tonic contraction in smooth muscle for hours, with minimal use of energy. Little continued excitatory signal is required from nerve fibers or hormonal sources.

Stress-Relaxation of Smooth Muscle. Another important characteristic of smooth muscle, especially the visceral unitary type of smooth muscle of many hollow organs, is its ability to return to nearly its original *force* of contraction seconds or minutes after it has been elongated or shortened. For example, a sudden increase in fluid volume in the urinary bladder stretches the smooth muscle in the bladder wall and causes an immediate large increase in pressure in the bladder. However, during the next 15 to 60 seconds, despite continued stretch of the bladder wall, the pressure returns almost exactly to the original level. Then, when the volume is increased by another step, the same effect occurs again.

Conversely, when the volume is suddenly decreased, the pressure falls drastically at first but then rises in another few seconds or minutes to or near the original level. These phenomena are called *stress-relaxation* and *reverse stress-relaxation*. Except for short periods, these responses allow a hollow organ to maintain about the same amount of pressure inside its lumen despite sustained large changes in volume.

REGULATION OF CONTRACTION BY CALCIUM IONS

As is true for skeletal muscle, the initiating stimulus for most smooth muscle contraction is an increase in intracellular Ca^{2+}. This increase can be caused in different types of smooth muscle by nerve stimulation of the smooth muscle fiber, hormonal stimulation, stretch of the fiber, or changes in the chemical environment of the fiber.

Smooth muscle does not contain troponin, the regulatory protein that is activated by Ca^{2+} to cause skeletal muscle contraction. Instead, smooth muscle contraction is activated by an entirely different mechanism, as described in the next section.

Ca^{2+} Combines With Calmodulin to Cause Activation of Myosin Kinase and Phosphorylation of the Myosin Head. In place of troponin, smooth muscle cells contain a large amount of another regulatory protein called *calmodulin* (**Fig. 8.3**). Although this protein is similar to troponin in amino acid sequence and in three-dimensional structure, it is different in the manner in which it initiates contraction. Calmodulin initiates contraction by activating the myosin cross-bridges. This activation and subsequent contraction occur in the following sequence:

1. The Ca^{2+} concentration in the cytosolic fluid of smooth muscle increases as a result of the influx of Ca^{2+} from the extracellular fluid through Ca^{2+} channels and/or release of Ca^{2+} from the sarcoplasmic reticulum.
2. The Ca^{2+} ions bind reversibly with calmodulin.

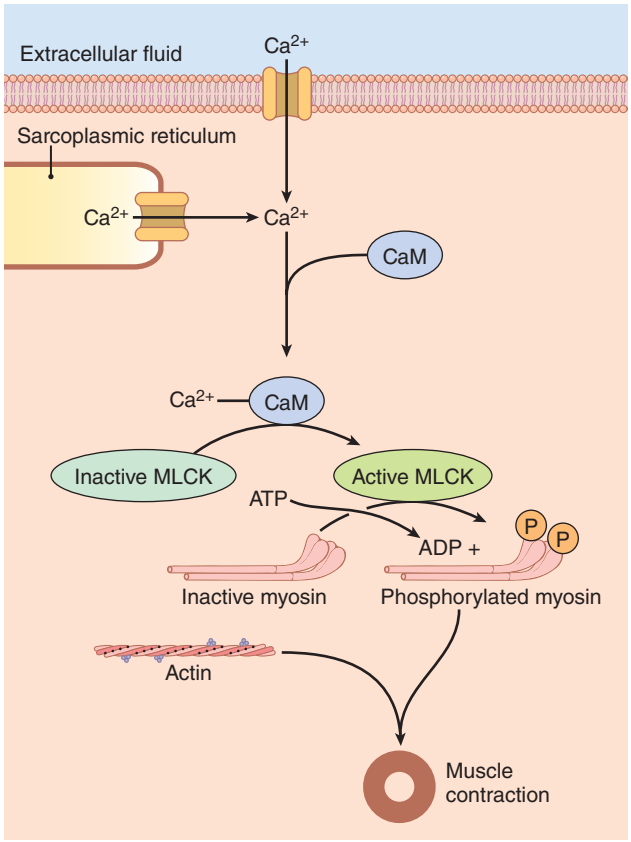

Figure 8.3 Intracellular Ca^{2+} concentration increases when Ca^{2+} enters the cell through Ca^{2+} channels in the cell membrane or is released from the sarcoplasmic reticulum. The Ca^{2+} binds to calmodulin (CaM) to form a Ca^{2+}-CaM complex, which then activates myosin light chain kinase (MLCK). The active MLCK phosphorylates the myosin light chain, leading to attachment of the myosin head with the actin filament and contraction of the smooth muscle. *ADP*, Adenosine diphosphate; *ATP*, adenosine triphosphate; *P*, phosphate.

3. The calmodulin-calcium complex then joins with and activates *myosin light chain kinase*, a phosphorylating enzyme.
4. One of the light chains of each myosin head, called the *regulatory chain*, becomes phosphorylated in response to this myosin kinase. When this chain is not phosphorylated, the attachment-detachment cycling of the myosin head with the actin filament does not occur. However, when the regulatory chain is phosphorylated, the head has the capability of binding repetitively with the actin filament and proceeding through the entire cycling process of intermittent pulls, thus causing muscle contraction.

Most of the Ca^{2+} That Causes Smooth Muscle Contraction Comes From Extracellular Fluid

Although the contractile process in smooth muscle, as in skeletal muscle, is activated by Ca^{2+}, the source of the Ca^{2+} differs. An important difference is that the sarcoplasmic reticulum, which provides virtually all the Ca^{2+} for skeletal muscle contraction, is only slightly developed

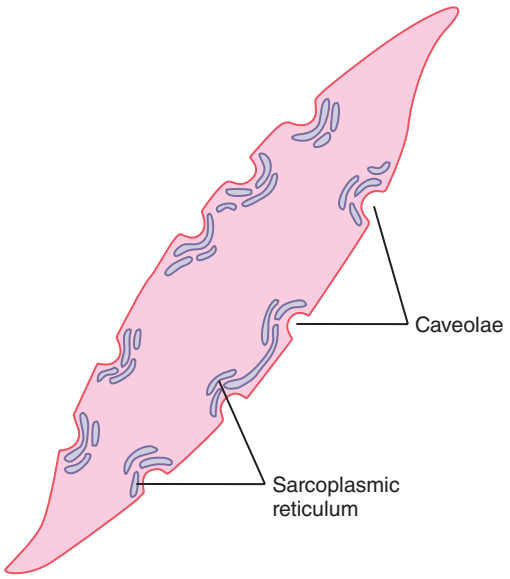

Figure 8.4 Sarcoplasmic tubules in a large smooth muscle fiber showing their relation to invaginations in the cell membrane called *caveolae*.

in most smooth muscle. Instead, most of the Ca^{2+} that causes smooth muscle contraction enters the cell from the extracellular fluid at the time of the action potential or other stimulus. That is, the concentration of Ca^{2+} in the extracellular fluid is greater than 10^{-3} molar, in comparison with less than 10^{-7} molar inside the smooth muscle cell; this causes rapid diffusion of the Ca^{2+} into the cell from the extracellular fluid when the Ca^{2+} channels open. The time required for this diffusion to occur averages 200 to 300 milliseconds and is called the *latent period* before contraction begins. This latent period is about 50 times as great for smooth muscle as for skeletal muscle contraction.

Role of Sarcoplasmic Tubules and Caveolae in Smooth Muscle Contraction. Fig. 8.4 shows a few slightly developed sarcoplasmic tubules that lie near the cell membrane in some larger smooth muscle cells. Small invaginations of the cell membrane, called *caveolae*, abut the surfaces of these tubules. The caveolae suggest a rudimentary analog of the transverse tubule system of skeletal muscle. When an action potential is transmitted into the caveolae, this is believed to excite Ca^{2+} release from the abutting sarcoplasmic tubules in the same way that action potentials in skeletal muscle transverse tubules cause release of Ca^{2+} from the skeletal muscle longitudinal sarcoplasmic tubules. In general, the more extensive the sarcoplasmic reticulum in the smooth muscle fiber, the more rapidly it contracts.

Smooth Muscle Contraction Depends on Extracellular Ca^{2+} Concentration. Whereas changing the extracellular fluid Ca^{2+} concentration from normal has little effect on the force of contraction of skeletal muscle, this is not true for most smooth muscle. When the extracellular fluid Ca^{2+} concentration decreases to about 1/3 to

1/10 normal, smooth muscle contraction usually ceases. Therefore, the force of smooth muscle contraction is usually highly dependent on extracellular fluid Ca^{2+} concentration.

A Ca^{2+} Pump Is Required to Cause Smooth Muscle Relaxation. To cause relaxation of smooth muscle after it has contracted, the Ca^{2+} must be removed from the intracellular fluids. This removal is achieved by a *Ca^{2+} pump* that transports Ca^{2+} out of the smooth muscle fiber back into the extracellular fluid or into a sarcoplasmic reticulum if it is present (**Fig. 8.5**). This pump requires ATP and is slow acting in comparison with the fast-acting sarcoplasmic reticulum pump in skeletal muscle. Therefore, a single smooth muscle contraction often lasts for seconds rather than hundredths to tenths of a second, as occurs for skeletal muscle.

Myosin Phosphatase Is Important in Cessation of Contraction. Relaxation of the smooth muscle occurs when the *calcium* channels close and the Ca^{2+} pump transports Ca^{2+} out of the cytosolic fluid of the cell. When the Ca^{2+} concentration falls below a critical level, the aforementioned processes automatically reverse, except for phosphorylation of the myosin head, which requires another enzyme, *myosin phosphatase* (see **Fig. 8.5**). This enzyme is located in the cytosol of the smooth muscle cell and splits the phosphate from the regulatory light chain. Then the cycling stops, and contraction ceases. The time required for the relaxation of muscle contraction, therefore, is determined to a great extent by the amount of active myosin phosphatase in the cell.

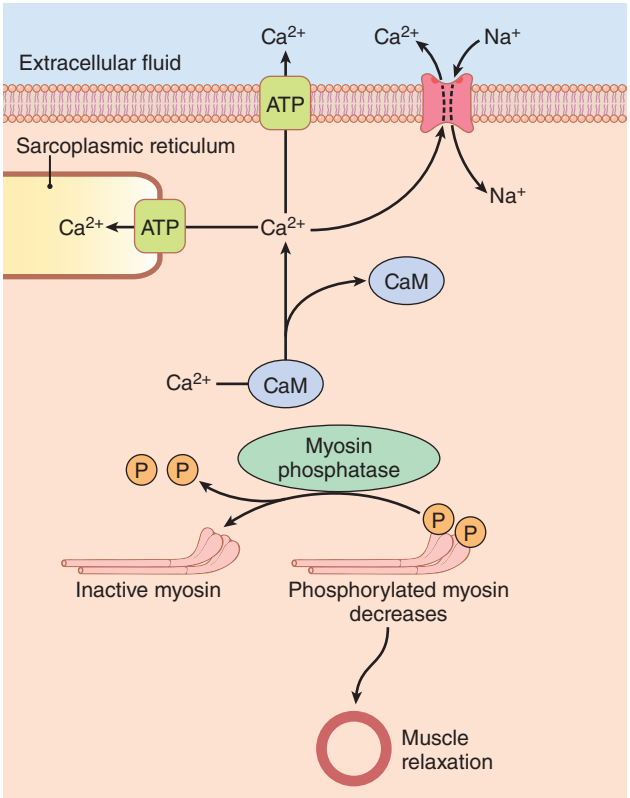

Figure 8.5 Relaxation of smooth muscle occurs when the Ca^{2+} concentration decreases below a critical level as Ca^{2+} is pumped out of the cell or into the sarcoplasmic reticulum. Ca^{2+} is then released from calmodulin (CaM), and myosin phosphatase removes phosphate from the myosin light chain, causing detachment of the myosin head from the actin filament and relaxation of the smooth muscle. *ADP*, Adenosine diphosphate; *ATP*, adenosine triphosphate; *Na^+*, sodium; *P*, phosphate.

Possible Mechanism for Regulating the Latch Phenomenon. Because of the importance of the latch phenomenon in smooth muscle, and because this phenomenon allows for the long-term maintenance of tone in many smooth muscle organs without much expenditure of energy, many attempts have been made to explain it. Among the many mechanisms that have been postulated, one of the simplest is the following.

When the myosin kinase and myosin phosphatase enzymes are both strongly activated, the cycling frequency of the myosin heads and the velocity of contraction are great. Then, as activation of the enzymes decreases, the cycling frequency decreases, but at the same time the deactivation of these enzymes allows the myosin heads to remain attached to the actin filament for a longer and longer proportion of the cycling period. Therefore, the number of heads attached to the actin filament at any given time remains large. Because the number of heads attached to the actin determines the static force of contraction, tension is maintained, or latched, yet little energy is used by the muscle because ATP is not degraded to ADP, except on the rare occasion when a head detaches.

NERVOUS AND HORMONAL CONTROL OF SMOOTH MUSCLE CONTRACTION

Although skeletal muscle fibers are stimulated exclusively by the nervous system, smooth muscle can be stimulated to contract by nervous signals, hormonal stimulation, stretch of the muscle, and several other ways. The principal reason for the difference is that the smooth muscle membrane contains many types of receptor proteins that can initiate the contractile process. Additional receptor proteins inhibit smooth muscle contraction, which is another difference from skeletal muscle. Therefore, in this section, we discuss nervous control of smooth muscle contraction, followed by hormonal control and other means of control.

NEUROMUSCULAR JUNCTIONS OF SMOOTH MUSCLE

Physiologic Anatomy of Smooth Muscle Neuromuscular Junctions. Neuromuscular junctions of the highly structured type found on skeletal muscle fibers do not occur in smooth muscle. Instead, the *autonomic nerve fibers* that innervate smooth muscle generally branch diffusely on top of a sheet of muscle fibers, as shown in **Fig. 8.6**. In most cases, these fibers do not make direct

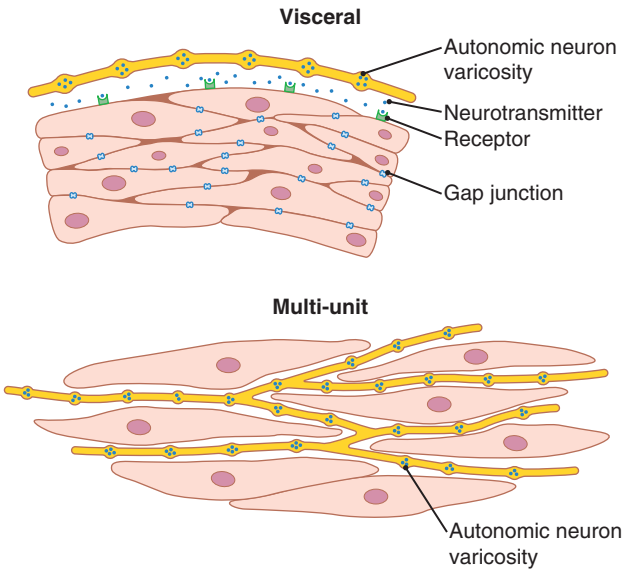

Figure 8.6 Innervation of smooth muscle by autonomic nerve fibers that branch diffusely and secrete neurotransmitter from multiple varicosities. Unitary (visceral) smooth muscle cells are connected by gap junctions so that depolarization can rapidly spread from one cell to another, permitting the muscle cells to contract as a single unit. In multi-unit smooth muscle, each cell is stimulated independently by a neurotransmitter released from closely associated autonomic nerve varicosities.

contact with the smooth muscle fiber cell membranes but instead form *diffuse junctions* that secrete their transmitter substance into the matrix coating of the smooth muscle, often a few nanometers to a few micrometers away from the muscle cells. The transmitter substance then diffuses to the cells. Furthermore, where there are many layers of muscle cells, the nerve fibers often innervate only the outer layer. Muscle excitation travels from this outer layer to the inner layers by action potential conduction in the muscle mass or by additional diffusion of the transmitter substance.

The axons that innervate smooth muscle fibers do not have the typical branching end feet of the type found in the motor end plate on skeletal muscle fibers. Instead, most of the fine terminal axons have multiple *varicosities* distributed along their axes. At these points, the *Schwann cells* that envelop the axons are interrupted so that transmitter substance can be secreted through the walls of the varicosities. In the varicosities are vesicles similar to those in the skeletal muscle end plate that contain transmitter substance. However, in contrast to the vesicles of skeletal muscle junctions, which always contain acetylcholine, the vesicles of the autonomic nerve fiber endings contain acetylcholine in some fibers, norepinephrine in others, and occasionally other substances.

In a few cases, particularly in the multi-unit type of smooth muscle, the varicosities are separated from the muscle cell membrane by as little as 20 to 30 nanometers—the same width as the synaptic cleft that is found in the skeletal muscle junction. These are called *contact junctions*, and they function in much the same way as the skeletal muscle neuromuscular junction. The rapidity of contraction of these smooth muscle fibers is considerably faster than that of fibers stimulated by the diffuse junctions.

Excitatory and Inhibitory Transmitter Substances Secreted at the Smooth Muscle Neuromuscular Junction. The most important transmitter substances secreted by the autonomic nerves innervating smooth muscle are *acetylcholine* and *norepinephrine*, but they are never secreted by the same nerve fibers. Acetylcholine is an excitatory transmitter substance for smooth muscle fibers in some organs but an inhibitory transmitter for smooth muscle in other organs. When acetylcholine excites a muscle fiber, norepinephrine ordinarily inhibits it. Conversely, when acetylcholine inhibits a fiber, norepinephrine usually excites it.

Why are these responses different? The answer is that both acetylcholine and norepinephrine excite or inhibit smooth muscle by first binding with a *receptor protein* on the surface of the smooth muscle cell membrane. Some of the receptor proteins are *excitatory receptors*, whereas others are *inhibitory receptors*. Thus, the type of receptor determines whether the smooth muscle is inhibited or excited and which of the two transmitters, acetylcholine or norepinephrine, is effective in causing excitation or inhibition. These receptors are discussed in more detail in Chapter 61 in regard to function of the autonomic nervous system.

MEMBRANE POTENTIALS AND ACTION POTENTIALS IN SMOOTH MUSCLE

Membrane Potentials in Smooth Muscle. The quantitative voltage of the membrane potential of smooth muscle depends on the momentary condition of the muscle. In the normal resting state, the intracellular potential is usually about −50 to −60 millivolts, which is about 30 millivolts less negative than in skeletal muscle.

Action Potentials in Unitary Smooth Muscle. Action potentials occur in unitary smooth muscle (e.g., visceral muscle) in the same way that they occur in skeletal muscle. They do not normally occur in most multi-unit types of smooth muscle, as discussed in a subsequent section.

The action potentials of visceral smooth muscle occur in one of two forms: (1) spike potentials or (2) action potentials with plateaus.

Spike Potentials. Typical spike action potentials, such as those seen in skeletal muscle, occur in most types of unitary smooth muscle. The duration of this type of action potential is 10 to 50 milliseconds, as shown in **Fig. 8.7A**. Such action potentials can be elicited in many ways—for example, by electrical stimulation, by the action of hormones on the smooth muscle, by the action of transmitter substances from nerve fibers, by stretch, or as a result of spontaneous generation in the muscle fiber itself, as discussed subsequently.

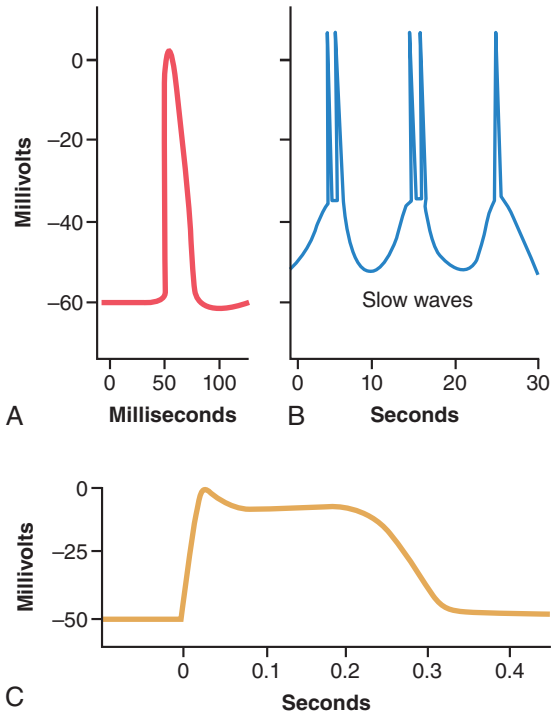

Figure 8.7 (A) Typical smooth muscle action potential (spike potential) elicited by an external stimulus. (B) Repetitive spike potentials, elicited by slow rhythmical electrical waves that occur spontaneously in the smooth muscle of the intestinal wall. (C) Action potential with a plateau, recorded from a smooth muscle fiber of the uterus.

Action Potentials With Plateaus. Fig. 8.7C shows a smooth muscle action potential with a plateau. The onset of this action potential is similar to that of the typical spike potential. However, instead of rapid repolarization of the muscle fiber membrane, the repolarization is delayed for several hundred to as much as 1000 milliseconds (1 second). This plateau accounts for the prolonged contraction that occurs in some types of smooth muscle, such as the ureter, the uterus under some conditions, and certain types of vascular smooth muscle. Also, this is the type of action potential seen in cardiac muscle fibers that have a prolonged period of contraction, as discussed in Chapters 9 and 10.

Calcium Channels Are Important in Generating the Smooth Muscle Action Potential. The smooth muscle cell membrane has far more voltage-gated Ca^{2+} channels than skeletal muscle but few voltage-gated sodium channels. Therefore, sodium does not participate much in the generation of the action potential in most smooth muscle. Instead, the flow of Ca^{2+} to the interior of the fiber is mainly responsible for the action potential. This flow occurs in the same self-regenerative way as occurs for the sodium channels in nerve fibers and in skeletal muscle fibers. However, the Ca^{2+} channels open many times more slowly than sodium channels, and they also remain open much longer. These characteristics largely account for the prolonged plateau action potentials of some smooth muscle fibers.

Another important feature of Ca^{2+} entry into the cells during the action potential is that Ca^{2+} acts directly on the smooth muscle contractile mechanism to cause contraction. Thus, Ca^{2+} performs two tasks at once.

Slow Wave Potentials in Unitary Smooth Muscle Can Lead to Spontaneous Generation of Action Potentials. Some smooth muscle is self-excitatory—that is, action potentials arise within the smooth muscle cells without an extrinsic stimulus. This activity is often associated with a basic *slow wave rhythm* of the membrane potential. A typical slow wave in a visceral smooth muscle of the gut is shown in Fig. 8.7B. The slow wave is not the action potential. That is, it is not a self-regenerative process that spreads progressively over the membranes of the muscle fibers. Instead, it is a local property of the smooth muscle fibers that make up the muscle mass.

The cause of the slow wave rhythm is uncertain. One suggestion is that the slow waves are caused by waxing and waning of the pumping of positive ions (presumably sodium ions) outward through the muscle fiber membrane. That is, the membrane potential becomes more negative when sodium is pumped rapidly and less negative when the sodium pump becomes less active. Another suggestion is that the conductances of the ion channels increase and decrease rhythmically.

The importance of the slow waves is that when they are strong enough, they can initiate action potentials. The slow waves themselves cannot cause muscle contraction. However, when the peak of the negative slow wave potential inside the cell membrane rises in the positive direction, from −60 to about −35 millivolts (the approximate threshold for eliciting action potentials in most visceral smooth muscle), an action potential develops and spreads over the muscle mass and contraction occurs. Fig. 8.7B demonstrates this effect, showing that at each peak of the slow wave, one or more action potentials occur. These repetitive sequences of action potentials elicit rhythmical contraction of the smooth muscle mass. Therefore, the slow waves are called *pacemaker waves*. In Chapter 63, we see that this type of pacemaker activity controls the rhythmical contractions of the gut.

Excitation of Visceral Smooth Muscle By Muscle Stretch. When visceral (unitary) smooth muscle is stretched sufficiently, spontaneous action potentials are usually generated. They result from a combination of the following: (1) the normal slow wave potentials; and (2) a decrease in overall negativity of the membrane potential caused by the stretch. This response to stretch allows the gut wall, when excessively stretched, to contract automatically and rhythmically. For example, when the gut is overfilled by intestinal contents, local automatic contractions often set up peristaltic waves that move the contents away from the overfilled intestine, usually in the direction of the anus.

DEPOLARIZATION OF MULTI-UNIT SMOOTH MUSCLE WITHOUT ACTION POTENTIALS

The smooth muscle fibers of multi-unit smooth muscle (e.g., the muscle of the iris of the eye or the piloerector muscle of each hair) normally contract mainly in response to nerve stimuli. The nerve endings secrete acetylcholine in the case of some multi-unit smooth muscles and norepinephrine in the case of others. In both cases, the transmitter substances cause depolarization of the smooth muscle membrane, and this depolarization in turn elicits contraction. Action potentials usually do not develop because the fibers are too small to generate an action potential. (When action potentials are elicited in *visceral unitary smooth muscle*, 30 to 40 smooth muscle fibers must depolarize simultaneously before a self-propagating action potential ensues.) However, in small smooth muscle cells, even without an action potential, the local depolarization (called the *junctional potential*) caused by the nerve transmitter substance spreads "electrotonically" over the entire fiber and is all that is necessary to cause muscle contraction.

Local Tissue Factors and Hormones Can Cause Smooth Muscle Contraction Without Action Potentials

Approximately half of all smooth muscle contraction is likely initiated by stimulatory factors acting directly on the smooth muscle contractile machinery and without action potentials. Two types of non-nervous and nonaction potential stimulating factors often involved are (1) local tissue chemical factors and (2) various hormones.

Smooth Muscle Contraction in Response to Local Tissue Chemical Factors. In Chapter 17, we discuss control of contraction of the arterioles, metarterioles, and precapillary sphincters. The smallest of these vessels have little or no nervous supply. Yet, the smooth muscle is highly contractile, responding rapidly to changes in local chemical conditions in the surrounding interstitial fluid and to stretch caused by changes in blood pressure.

In the normal resting state, many of these small blood vessels remain contracted. However, when extra blood flow to the tissue is necessary, multiple factors can relax the vessel wall, thus allowing for increased flow. In this way, powerful local feedback systems control the blood flow to the local tissue area. Some of the specific control factors are as follows:

1. Lack of oxygen in the local tissues causes smooth muscle relaxation and, therefore, vasodilation.
2. Excess carbon dioxide causes vasodilation.
3. Increased hydrogen ion concentration causes vasodilation.

Adenosine, lactic acid, increased potassium ions, nitric oxide, and increased body temperature can all cause local vasodilation. Decreased blood pressure, by causing decreased stretch of the vascular smooth muscle, also causes these small blood vessels to dilate.

Effects of Hormones on Smooth Muscle Contraction. Many circulating hormones in the blood affect smooth muscle contraction to some degree, and some have profound effects. Among the more important of these hormones are *norepinephrine, epinephrine, angiotensin II, endothelin, vasopressin, oxytocin, serotonin*, and *histamine*.

A hormone causes contraction of smooth muscle when the muscle cell membrane contains *hormone-gated excitatory receptors* for the respective hormone. Conversely, the hormone causes inhibition if the membrane contains *inhibitory receptors* for the hormone rather than excitatory receptors.

Mechanisms of Smooth Muscle Excitation or Inhibition By Hormones or Local Tissue Factors. Some hormone receptors in the smooth muscle membrane open sodium or Ca^{2+} channels and depolarize the membrane, the same as after nerve stimulation. Sometimes, action potentials result, or action potentials that are already occurring may be enhanced. In other cases, depolarization occurs without action potentials, and this depolarization allows Ca^{2+} entry into the cell, which promotes the contraction.

Inhibition, in contrast, occurs when the hormone (or other tissue factor) *closes the sodium and Ca^{2+} channels* to prevent entry of these positive ions; inhibition also occurs if the normally closed potassium channels are opened, allowing positive potassium ions to diffuse out of the cell. Both these actions increase the degree of negativity inside the muscle cell, a state called *hyperpolarization*, which strongly inhibits muscle contraction.

Sometimes, smooth muscle contraction or inhibition is initiated by hormones without directly altering the membrane potential. In these cases, the hormone may activate a membrane receptor that does not open any ion channels but, instead, causes an internal change in the muscle fiber, such as release of Ca^{2+} from the intracellular sarcoplasmic reticulum; the Ca^{2+} then induces contraction. To inhibit contraction, other receptor mechanisms are known to activate the enzyme adenylate cyclase or guanylate cyclase in the cell membrane. The portions of the receptors that protrude to the interior of the cells are coupled to these enzymes, causing the formation of cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate (cGMP), so-called *second messengers*. cAMP or cGMP has many effects, one of which is to change the degree of phosphorylation of several enzymes that indirectly inhibit contraction. The pump that moves Ca^{2+} from the sarcoplasm into the sarcoplasmic reticulum is activated, as well as the cell membrane pump that moves Ca^{2+} out of the cell; these effects reduce the Ca^{2+} concentration in the sarcoplasm, thereby inhibiting contraction.

Smooth muscles have considerable diversity in how they initiate contraction or relaxation in response to different hormones, neurotransmitters, and other substances. In some cases, the same substance may cause either relaxation or contraction of smooth muscles in different locations. For example, norepinephrine inhibits contraction of smooth muscle in the intestine but stimulates contraction of smooth muscle in blood vessels.

CHAPTER 9

Cardiac Muscle; The Heart as a Pump and Function of the Heart Valves

The heart, shown in **Fig. 9.1**, is actually two separate pumps, a *right heart* that pumps blood through the lungs and a *left heart* that pumps blood through the systemic circulation that provides blood flow to the other organs and tissues of the body. Each of these is a pulsatile, two-chamber pump composed of an *atrium* and a *ventricle*. Each atrium is a weak primer pump for the ventricle, helping to move blood into the ventricle. The ventricles then supply the main pumping force that propels the blood either (1) through the pulmonary circulation by the right ventricle or (2) through the systemic circulation by the left ventricle. The heart is surrounded by a two-layer sac called the *pericardium*, which protects the heart and holds it in place.

Special mechanisms in the heart cause a continuing succession of contractions called *cardiac rhythmicity*, transmitting action potentials throughout the cardiac muscle to cause the heart's rhythmical beat. This rhythmical control system is discussed in Chapter 10. In this chapter, we explain how the heart operates as a pump, beginning with the special features of cardiac muscle (**Video 9-1**).

CARDIAC MUSCLE PHYSIOLOGY

The heart is composed of three major types of cardiac muscle—*atrial muscle, ventricular muscle*, and specialized *excitatory* and *conductive muscle* fibers. The atrial and ventricular types of muscle contract in much the same way as skeletal muscle, except that the duration of contraction is much longer. The specialized excitatory and conductive fibers of the heart, however, contract feebly because they contain few contractile fibrils; instead, they exhibit automatic rhythmical electrical discharge in the form of action potentials or conduction of the action potentials through the heart, providing an excitatory system that controls the rhythmical beating of the heart.

CARDIAC MUSCLE ANATOMY

Fig. 9.2 shows the cardiac muscle histology, demonstrating cardiac muscle fibers arranged in a latticework, with the fibers dividing, recombining, and then spreading again. Note that cardiac muscle is *striated* in the same manner as in skeletal muscle. Furthermore, cardiac muscle has typical myofibrils that contain *actin* and *myosin filaments* almost identical to those found in skeletal muscle; these filaments lie side by side and slide during contraction in the same manner as occurs in skeletal muscle (see Chapter 6). In other ways, however, cardiac muscle is quite different from skeletal muscle, as we shall see.

Left Ventricular Rotation (Torsion) Aids Left Ventricular Ejection and Relaxation. The left ventricle is organized into complex muscle fiber layers that run in different directions and allow the heart to contract in a twisting motion during systole. The subepicardial (outer) layer spirals in a leftward direction, and the subendocardial (inner) layer spirals in the opposite direction (rightward). These fibers are arranged in a double helix, surrounding midwall fibers, which run circumferentially. When viewed from the apex to the base of the heart, contraction of the subepicardial fibers rotates the left ventricular apex counterclockwise, and the base rotates clockwise. The subendocardial fibers rotate the apex and base of the left ventricle in opposite directions. The outer subepicardial fibers have a greater impact on rotational direction due to their larger radius of rotation, causing a net counterclockwise rotation of the apex of the left ventricle and clockwise rotation of the base of the left ventricle when viewed from the apex to the base (**Fig. 9.3**). This causes a wringing or twisting motion of the left ventricle, pulling the base downward toward the apex during systole (contraction). At the end of systole, the left ventricle is similar to a loaded spring and recoils or untwists during diastole (relaxation) to allow blood to enter the pumping chambers rapidly.

Cardiac Muscle Is a Syncytium. The dark areas crossing the cardiac muscle fibers in **Fig. 9.2** are called *intercalated discs;* they are actually cell membranes that separate individual cardiac muscle cells from one another. That is, cardiac muscle fibers are made up of many individual cells connected in series and in parallel with one another.

At each intercalated disc, the cell membranes fuse with one another to form permeable communicating junctions (gap junctions) that allow rapid diffusion of ions. Therefore, ions move with ease in the intracellular fluid along the longitudinal axes of the cardiac muscle fibers so that action

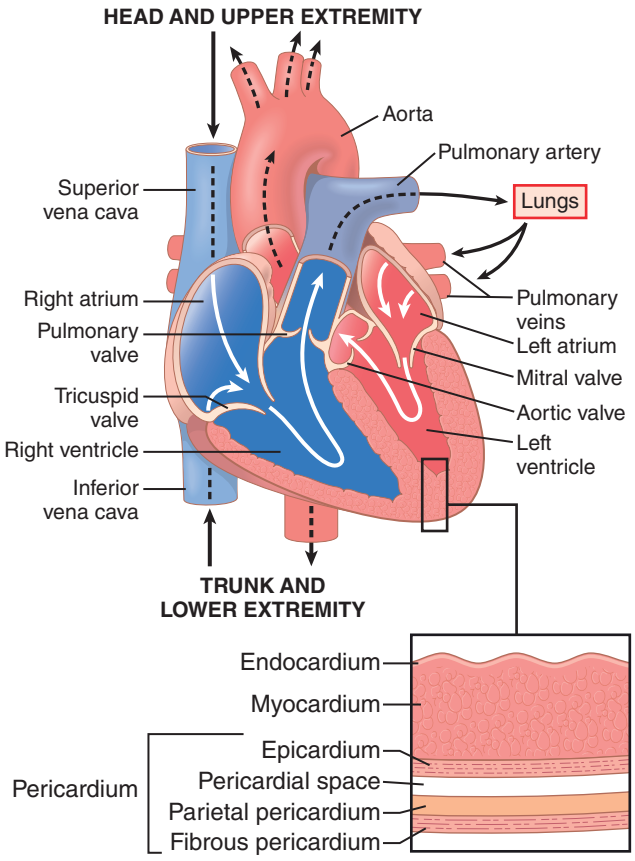

Figure 9.1 Structure of the heart and course of blood flow through the heart chambers and heart valves. The heart consists of multiple layers, including the inner endocardium, myocardium, and more outward epicardium and pericardium layers.

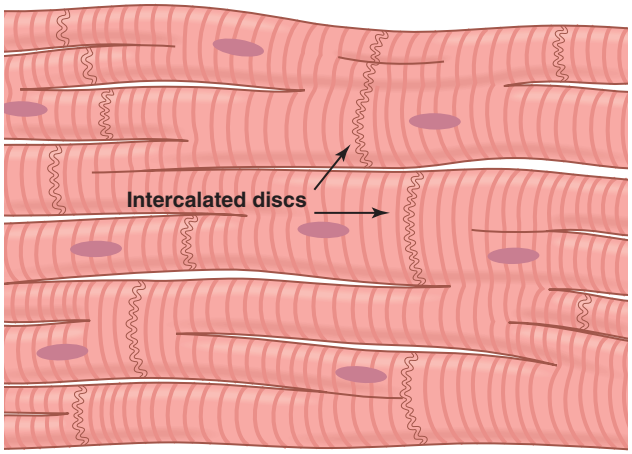

Figure 9.2 Syncytial interconnecting nature of cardiac muscle fibers.

potentials travel easily from one cardiac muscle cell to the next, past the intercalated discs. Thus, cardiac muscle is a *syncytium* of many heart muscle cells in which the cardiac cells are so interconnected that when one cell becomes excited, the action potential rapidly spreads to all of them.

The heart actually is composed of two syncytia; the *atrial syncytium*, which constitutes the walls of the two atria; and the *ventricular syncytium*, which constitutes

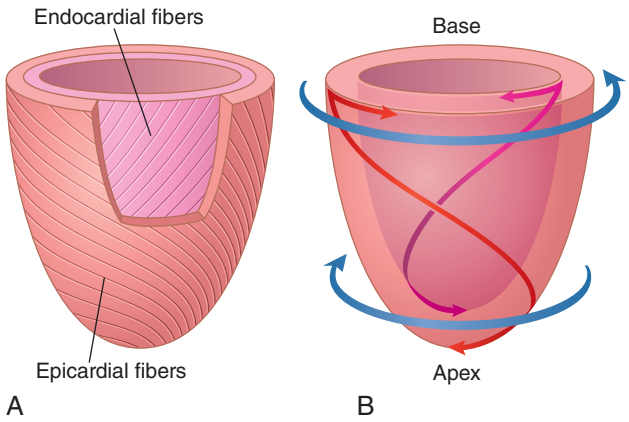

Figure 9.3 (A) The left ventricular inner subendocardial fibers (*lavender shade*) run obliquely to the outer subepicardial fibers (*red shade*). (B) The subepicardial muscle fibers are wrapped in a left-handed helix and subendocardial fibers are arranged in a right-handed helix. During left ventricular contraction there is a net clockwise rotation of the base of the heart and counterclockwise rotation of the apex when viewed from the heart's apex.

the walls of the two ventricles. The atria are separated from the ventricles by fibrous tissue that surrounds the atrioventricular (AV) valvular openings between the atria and ventricles. Normally, potentials are not conducted from the atrial syncytium into the ventricular syncytium directly through this fibrous tissue. Instead, they are only conducted by way of a specialized conductive system called the *AV bundle*, a bundle of conductive fibers several millimeters in diameter that is discussed in Chapter 10.

This division of the muscle of the heart into two functional syncytia allows the atria to contract a short time ahead of ventricular contraction, which is important for the effectiveness of heart pumping.

Wolff-Parkinson-White Syndrome. *Wolff-Parkinson-White syndrome* is a congenital abnormality that arises from abnormal cardiac tissue that allows electrical potentials to be conducted through an "accessory pathway" rather than through the AV node, which is the normal gatekeeper between atrial and ventricular conduction. In some cases, this accessory pathway allows conduction of abnormal electrical stimuli, leading to potentially fatal *tachyarrhythmias* (abnormal rhythms with a ventricular heart rate of 100 beats per minute or more).

ACTION POTENTIALS IN CARDIAC MUSCLE

The *action potential* recorded in a ventricular muscle fiber, shown in **Fig. 9.4**, averages about 105 millivolts, which means that the intracellular potential rises from a very negative value between beats, about −85 millivolts, to a slightly positive value, about +20 millivolts, during each beat. After the initial *spike*, the membrane remains depolarized for about 0.2 second, exhibiting a *plateau*, followed at the end of the plateau by abrupt repolarization.

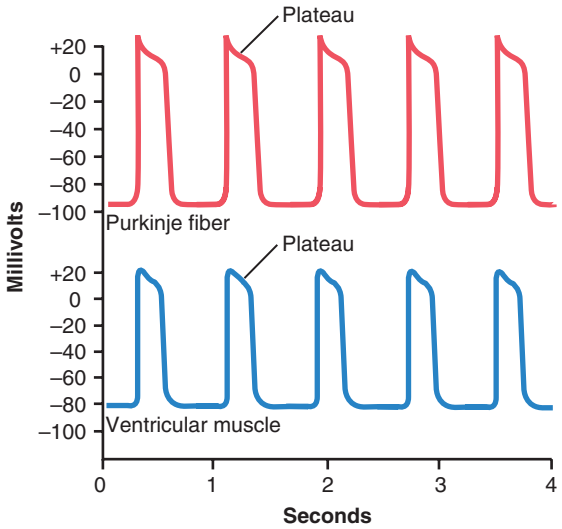

Figure 9.4 Rhythmical action potentials (in millivolts) from a Purkinje fiber and from a ventricular muscle fiber, recorded by microelectrodes.

The presence of this plateau in the action potential causes ventricular contraction to last as much as 15 times longer in cardiac muscle than in skeletal muscle.

What Causes the Long Action Potential and Plateau in Cardiac Muscle? At least two major differences between the membrane properties of cardiac and skeletal muscle account for the prolonged action potential and the plateau in cardiac muscle. First, the *action potential of skeletal muscle* is caused almost entirely by the sudden opening of large numbers of *fast sodium channels* that allow tremendous numbers of sodium ions to enter the skeletal muscle fiber from the extracellular fluid. These channels are called *fast channels* because they remain open for only a few thousandths of a second and then abruptly close. At the end of this closure, repolarization occurs, and the action potential is over within about another thousandth of a second.

In cardiac muscle, the action potential is caused by the opening of two types of channels: (1) the same *voltage-activated fast sodium channels* as those in skeletal muscle; and (2) another entirely different population of *L-type calcium channels (slow calcium channels)*, which are also called *calcium-sodium channels*. This second population of channels differs from the fast sodium channels in that they are slower to open and, even more importantly, remain open for several tenths of a second. During this time, a large quantity of both calcium and sodium ions flows through these channels to the interior of the cardiac muscle fiber, and this activity maintains a prolonged period of depolarization, *causing the plateau* in the action potential. Furthermore, the calcium ions that enter during this plateau phase activate the muscle contractile process, whereas the calcium ions that cause skeletal muscle contraction are derived from the intracellular sarcoplasmic reticulum.

The second major functional difference between cardiac muscle and skeletal muscle that helps account for

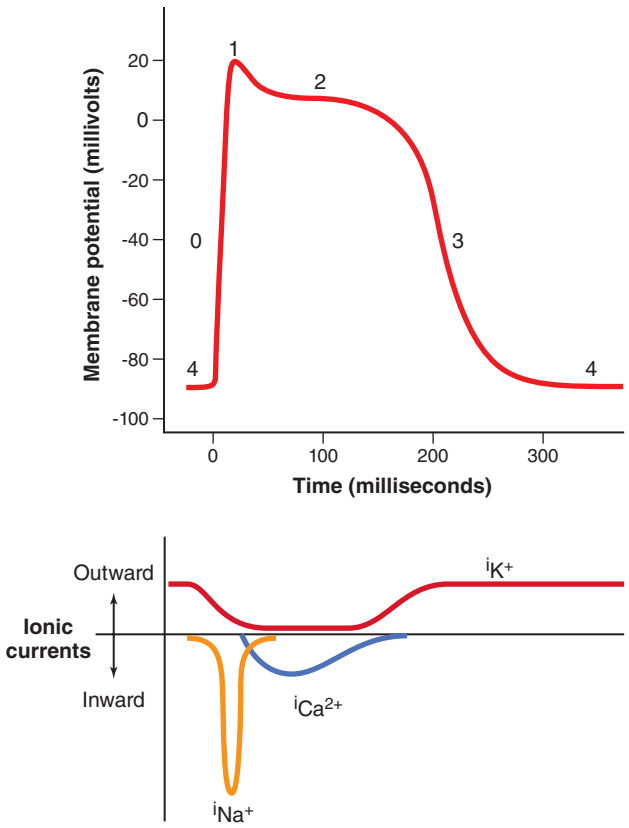

Figure 9.5 Phases of action potential of cardiac ventricular muscle cell and associated ionic currents for sodium ($^{i}Na^{+}$), calcium ($^{i}Ca^{2+}$), and potassium ($^{i}K^{+}$).

both the prolonged action potential and its plateau is that immediately after the onset of the action potential, the permeability of the cardiac muscle membrane for potassium ions *decreases* about 5-fold, an effect that does not occur in skeletal muscle. This decreased potassium permeability may result from excess calcium influx through the calcium channels just noted. Regardless of the cause, the decreased potassium permeability greatly decreases the efflux of positively charged potassium ions during the action potential plateau and thereby prevents early return of the action potential voltage to its resting level. When the slow calcium-sodium channels do close at the end of 0.2 to 0.3 second, and the influx of calcium and sodium ions ceases, the membrane permeability for potassium ions also increases rapidly. This rapid loss of potassium from the fiber immediately returns the membrane potential to its resting level, thus ending the action potential.

Phases of Cardiac Muscle Action Potential. Fig. 9.5 summarizes the phases of the action potential in cardiac muscle and the ion flows that occur during each phase.

Phase 0 (Depolarization): Fast Sodium Channels Open. When the cardiac cell is stimulated and depolarizes, the membrane potential becomes more positive. Voltage-gated sodium channels (fast sodium channels) open and permit sodium to rapidly flow into the cell and depolarize it. The membrane potential reaches about +20 millivolts before the sodium channels close.

Phase 1 (Initial Repolarization): Fast Sodium Channels Close. The sodium channels close, the cell begins to repolarize, and potassium ions leave the cell through open potassium channels.

Phase 2 (Plateau): Calcium Channels Open and Fast Potassium Channels Close. A brief initial repolarization occurs and the action potential then plateaus as a result of increased calcium ion permeability and decreased potassium ion permeability. The voltage-gated calcium ion channels open slowly during phases 1 and 0, and calcium enters the cell. Potassium channels then close, and the combination of decreased potassium ion efflux and increased calcium ion influx causes the action potential to plateau.

Phase 3 (Rapid Repolarization): Calcium Channels Close and Slow Potassium Channels Open. The closure of calcium ion channels and increased potassium ion permeability, permitting potassium ions to exit the cell rapidly, ends the plateau and returns the cell membrane potential to its resting level.

Phase 4 (Resting Membrane Potential). This averages about −80 to −90 millivolts.

Velocity of Signal Conduction in Cardiac Muscle. The velocity of conduction of the excitatory action potential signal along both *atrial and ventricular muscle fibers* is about 0.3 to 0.5 m/sec, or about 1/250 the velocity in very large nerve fibers and about 1/10 the velocity in skeletal muscle fibers. The velocity of conduction in the specialized heart conductive system—in the *Purkinje fibers*—is as high as 4 m/sec in most parts of the system, allowing rapid conduction of the excitatory signal to the different parts of the heart, as explained in Chapter 10.

Refractory Period of Cardiac Muscle. Cardiac muscle, like all excitable tissue, is refractory to restimulation during the action potential. Therefore, the refractory period of the heart is the interval of time, as shown to the left in **Fig. 9.6**, during which a normal cardiac impulse cannot re-excite an already excited area of cardiac muscle. The normal refractory period of the ventricle is 0.25 to 0.30 second, which is about the duration of the prolonged plateau action potential. There is an additional *relative refractory period* of about 0.05 second during which the muscle is more difficult to excite than normal but can be excited by a very strong excitatory signal, as demonstrated by the early premature contraction in the second example of **Fig. 9.6**. The refractory period of atrial muscle is much shorter than that for the ventricles (about 0.15 second for the atria compared with 0.25 to 0.30 second for the ventricles).

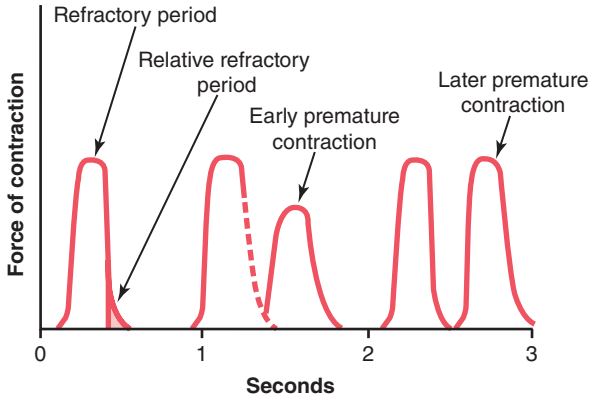

Figure 9.6 Force of ventricular heart muscle contraction, showing also the duration of the refractory period and relative refractory period, plus the effect of premature contraction. Note that premature contractions do not cause wave summation, as occurs in skeletal muscle.

EXCITATION-CONTRACTION COUPLING—FUNCTION OF CALCIUM IONS AND THE TRANSVERSE TUBULES

The term *excitation-contraction coupling* refers to the mechanism whereby the action potential causes the myofibrils of muscle to contract. This mechanism was discussed for skeletal muscle in Chapter 7. Again, there are differences in this mechanism in cardiac muscle that have important effects on the characteristics of heart muscle contraction.

As is true for skeletal muscle, when an action potential passes over the cardiac muscle membrane, the action potential spreads to the interior of the cardiac muscle fiber along the membranes of the *transverse* (T) *tubules*. The T tubule action potentials then act on the membranes of the *longitudinal sarcoplasmic tubules* to cause release of calcium ions into the muscle sarcoplasm from the sarcoplasmic reticulum. In another few thousandths of a second, these calcium ions diffuse into the myofibrils and catalyze the chemical reactions that promote sliding of the actin and myosin filaments along one another, which produces the muscle contraction.

Thus far, this mechanism of excitation-contraction coupling is the same as that for skeletal muscle, but there is a second effect that is quite different. In addition to the calcium ions that are released into the sarcoplasm from the cisternae of the sarcoplasmic reticulum, calcium ions also diffuse into the sarcoplasm from the T tubules at the time of the action potential, which opens voltage-dependent calcium channels in the membrane of the T tubule (**Fig. 9.7**). Calcium entering the cell then activates *calcium release channels*, also called *ryanodine receptor channels*, in the sarcoplasmic reticulum membrane, triggering the release of calcium into the sarcoplasm. Calcium ions in the sarcoplasm then interact with troponin to initiate cross-bridge formation and contraction by the same basic mechanism as that described for skeletal muscle in Chapter 6.

Without the calcium from the T tubules, the strength of cardiac muscle contraction would be reduced considerably because the sarcoplasmic reticulum of cardiac muscle is less well developed than that of skeletal muscle and does not store enough calcium to provide full contraction.

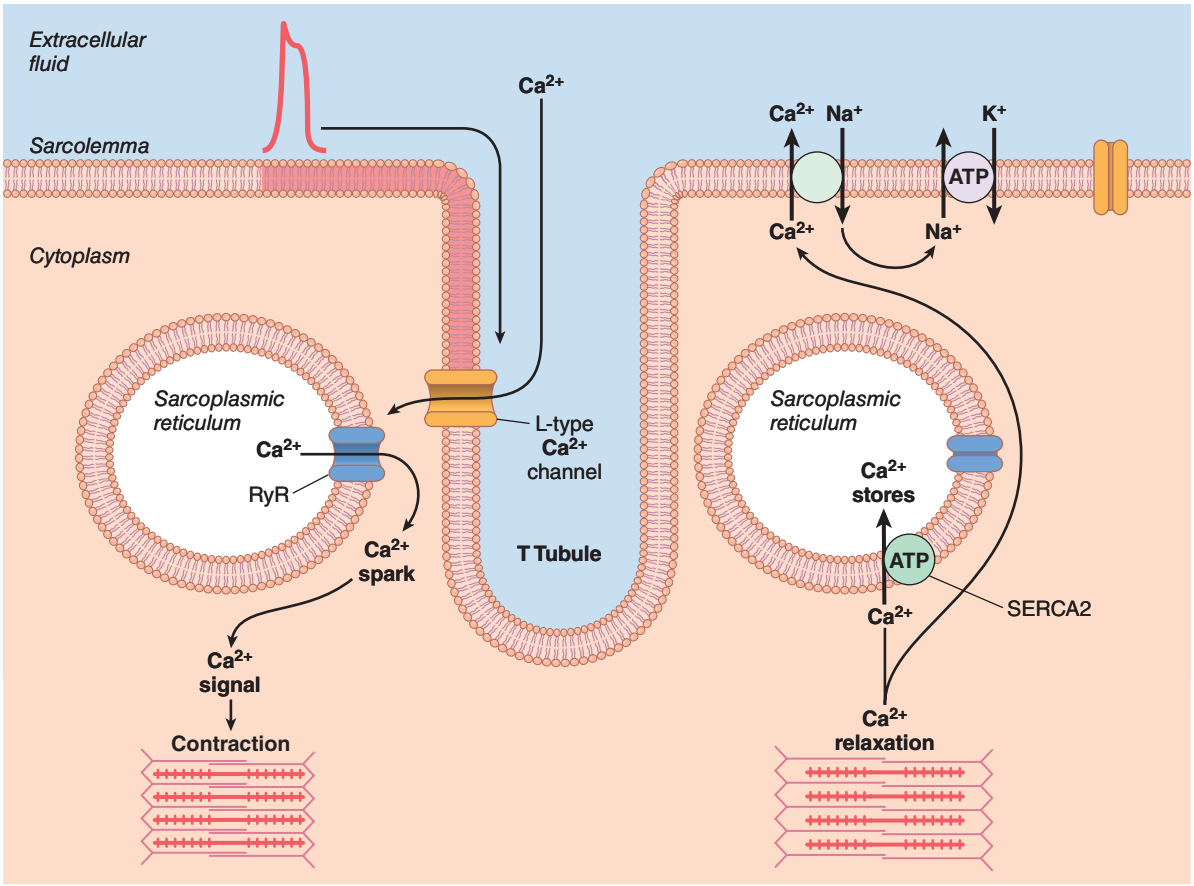

Figure 9.7 Mechanisms of excitation-contraction coupling and relaxation in cardiac muscle. *ATP*, Adenosine triphosphate; *RyR*, ryanodine receptor Ca^{2+} release channel; *SERCA*, sarcoplasmic reticulum Ca^{2+}-ATPase.

The T tubules of cardiac muscle, however, have a diameter five times as great as that of the skeletal muscle tubules, which means a volume 25 times as great. Also, inside the T tubules is a large quantity of mucopolysaccharides that are electronegatively charged and bind an abundant store of calcium ions, keeping them available for diffusion to the interior of the cardiac muscle fiber when a T tubule action potential appears.

The strength of contraction of cardiac muscle depends to a great extent on the concentration of calcium ions in the extracellular fluids. In fact, a heart placed in a calcium-free solution will quickly stop beating. The reason for this response is that the openings of the T tubules pass directly through the cardiac muscle cell membrane into the extracellular spaces surrounding the cells, allowing the same extracellular fluid that is in the cardiac muscle interstitium to percolate through the T tubules. Consequently, the quantity of calcium ions in the T tubule system (i.e., the availability of calcium ions to cause cardiac muscle contraction) depends to a great extent on the extracellular fluid calcium ion concentration.

In contrast, the strength of skeletal muscle contraction is hardly affected by moderate changes in extracellular fluid calcium concentration. This is because skeletal muscle contraction is caused almost entirely by calcium ions released from the sarcoplasmic reticulum *inside* the skeletal muscle fiber.

At the end of the plateau of the cardiac action potential, the influx of calcium ions to the interior of the muscle fiber is suddenly cut off, and calcium ions in the sarcoplasm are rapidly pumped back out of the muscle fibers into the sarcoplasmic reticulum and T tubule–extracellular fluid space. Transport of calcium back into the sarcoplasmic reticulum is achieved with the help of a calcium–adenosine triphosphatase (ATPase) pump (the sarcoplasmic endoplasmic reticulum calcium ATPase, SERCA2; see **Fig. 9.7**). Calcium ions are also removed from the cell by a sodium-calcium exchanger. The sodium that enters the cell during this exchange is then transported out of the cell by the sodium-potassium ATPase pump. As a result, the contraction ceases until a new action potential comes along.

Duration of Contraction. Cardiac muscle begins to contract a few milliseconds after the action potential begins and continues to contract until a few milliseconds after the action potential ends. Therefore, the duration of contraction of cardiac muscle is mainly a function of the duration of the action potential, *including the plateau*—about 0.2 second in atrial muscle and 0.3 second in ventricular muscle.

THE CARDIAC CYCLE

The cardiac events that occur from the beginning of one heartbeat to the beginning of the next are called the *cardiac cycle*. The cardiac cycle is similar for the left and right ventricles although there are slight differences in ventricular depolarization and pressures related to differences in pulmonary and systemic pressures.

Each cardiac cycle is initiated by the spontaneous generation of an action potential in the *sinus node*, as explained in Chapter 10. This node is located in the superior lateral wall of the right atrium near the opening of the superior vena cava, and the action potential travels from here rapidly through both atria and then through the AV bundle into the ventricles. Because of this special arrangement of the conducting system from the atria into the ventricles, there is a delay of more than 0.1 second during passage of the cardiac impulse from the atria into the ventricles. This delay allows the atria to contract ahead of ventricular contraction, thereby pumping blood into the ventricles before the strong ventricular contraction begins. Thus, the atria act as *primer pumps* for the ventricles, and the ventricles in turn provide the major source of power for moving blood through the body's vascular system.

Systole and Diastole

The total *duration of the cardiac cycle*, including systole and diastole, is the reciprocal of the heart rate. For example, if the heart rate is 72 beats/min, the duration of the cardiac cycle is 1/72 min/beat—about 0.0139 min/beat, or 0.833 sec/beat.

Fig. 9.8 shows the different events during the cardiac cycle for the left side of the heart. The top three curves show the pressure changes in the aorta, left ventricle, and left atrium, respectively. The fourth curve depicts the changes in left ventricular volume, the fifth depicts the *electrocardiogram*, and the sixth depicts a *phonocardiogram*, which is a recording of the sounds produced by the heart—mainly by the heart valves—as it pumps. It is especially important that the reader study this figure in detail and understand the causes of all the events shown.

Increasing Heart Rate Decreases Duration of Cardiac Cycle. When heart rate increases, the duration of each cardiac cycle decreases, including the contraction and relaxation phases. The duration of the action potential and systole also decrease, but not by as great a percentage as diastole. At a normal heart rate of 72 beats/min, systole comprises about 0.4 of the entire cardiac cycle. At three times the normal heart rate, systole is about 0.65 of the entire cardiac cycle. This means that the heart beating very rapidly does not remain relaxed long enough to allow complete filling of the cardiac chambers before the next contraction.

Relationship of the Electrocardiogram to the Cardiac Cycle

The electrocardiogram in **Fig. 9.8** shows the *P, Q, R, S,* and *T waves*, discussed in Chapters 11 through 13. These

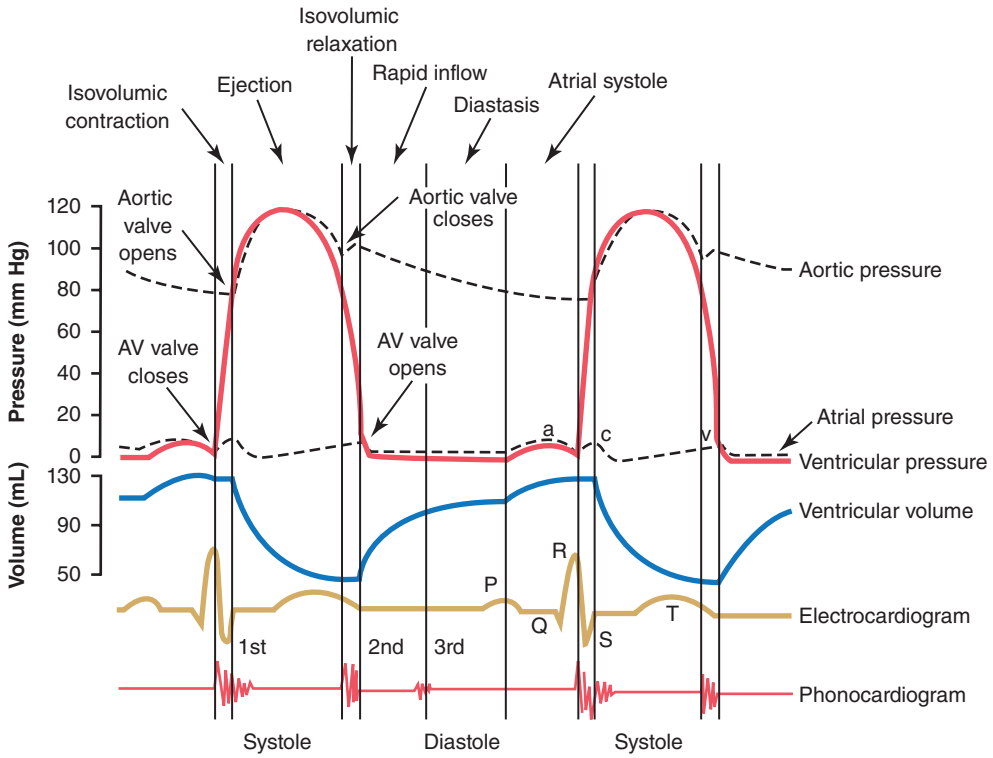

Figure 9.8 Events of the cardiac cycle for left ventricular function, showing changes in left atrial pressure, left ventricular pressure, aortic pressure, ventricular volume, the electrocardiogram, and the phonocardiogram. *AV*, Atrioventricular.

are electrical voltages generated by the heart and recorded by the electrocardiogram from the surface of the body.

The *P wave* is caused by the *spread of depolarization* through the atria and is followed by atrial contraction, which causes a slight rise in the atrial pressure curve immediately after the electrocardiographic P wave.

About 0.16 second after the onset of the P wave, the *QRS waves* appear as a result of electrical depolarization of the ventricles, which initiates contraction of the ventricles and causes the ventricular pressure to begin rising. Therefore, the QRS complex begins slightly before the onset of ventricular systole.

Finally, the *ventricular T wave* represents the stage of repolarization of the ventricles when the ventricular muscle fibers begin to relax. Therefore, the T wave occurs slightly before the end of ventricular contraction.

The Atria Function as Primer Pumps for the Ventricles

The atria play important roles in ventricular filling and cardiac function in three phases. Initially, blood empties from the great veins and pulmonary veins into the atria (called the *reservoir phase*). In early diastole, about 70% to 80% of the blood flows directly through the atria into the ventricles, even before the atria contract (the *conduit phase*). Then, atrial contraction acts as a "booster-pump," causing an additional 20% to 30% filling of the ventricles (the *contractile phase*). Therefore, the atria function as primer pumps that increase the ventricular pumping effectiveness as much as 30%. However, the heart can continue to operate under most conditions even without this extra effectiveness because it normally has the capability of pumping 300% to 400% more blood than is required by the resting body. Therefore, when the atria fail to function, the difference is unlikely to be noticed unless a person exercises; then, symptoms of heart failure occasionally develop, especially shortness of breath.

Pressure Changes in the Atria—a, c, and v Waves. In the atrial pressure curve of **Fig. 9.8**, three minor pressure elevations, called *a, c,* and *v atrial pressure waves*, are shown.

The *a wave* is caused by atrial contraction. Ordinarily, the *right* atrial pressure increases 4 to 6 mm Hg during atrial contraction, and the *left* atrial pressure increases about 7 to 8 mm Hg.

The *c wave* occurs when the ventricles begin to contract; it is caused partly by slight backflow of blood into the atria at the onset of ventricular contraction, but mainly by bulging of the AV valves backward toward the atria because of increasing pressure in the ventricles.

The *v wave* occurs toward the end of ventricular contraction; it results from slow flow of blood into the atria from the veins while the AV valves are closed during ventricular contraction. Then, when ventricular contraction is over, the AV valves open, allowing this stored atrial blood to flow rapidly into the ventricles, causing the v wave to disappear.

FUNCTION OF THE VENTRICLES AS PUMPS

The Ventricles Fill With Blood During Diastole. During ventricular systole, large amounts of blood accumulate in the right and left atria because of the closed AV valves. Therefore, as soon as systole is over, and the ventricular pressures fall again to their low diastolic values, the moderately increased pressures that have developed in the atria during ventricular systole immediately push the AV valves open and allow blood to flow rapidly into the ventricles, as shown by the rise of the left *ventricular volume curve* in **Fig. 9.8**. This period is called the *period of rapid filling of the ventricles*.

In a healthy heart, the period of rapid filling lasts for about the first third of diastole. During the middle third of diastole, only a small amount of blood normally flows into the ventricles. This is blood that continues to empty into the atria from the veins and passes through the atria directly into the ventricles. During the last third of diastole, the atria contract and give an additional thrust to the inflow of blood into the ventricles.

The ventricles stiffen with aging or diseases that cause cardiac fibrosis, such as high blood pressure or diabetes mellitus. This causes less blood to fill the ventricles in the early portion of diastole and requires more volume (preload; discussed later) or more filling from the later atrial contraction to maintain adequate cardiac output.

Outflow of Blood From the Ventricles During Systole

Period of Isovolumic (Isometric) Contraction. Immediately after ventricular contraction begins, the ventricular pressure rises abruptly, as shown in **Fig. 9.8**, causing the AV valves to close. Then, an additional 0.02 to 0.03 second is required for the ventricle to build up sufficient pressure to push the semilunar (aortic and pulmonary) valves open against the pressures in the aorta and pulmonary artery. Therefore, during this period, contraction is occurring in the ventricles, but no emptying occurs. This period is called the period of *isovolumic* or *isometric contraction*, meaning that cardiac muscle tension is increasing but little or no shortening of the muscle fibers is occurring.

Period of Ejection. Normally, when the left ventricular pressure rises slightly above 80 mm Hg (and the right ventricular pressure rises slightly above 8 mm Hg), the ventricular pressures push the semilunar valves open. Immediately, blood is ejected out of the ventricles into the aorta and pulmonary artery. Approximately 60% of the blood in the ventricles at the end of diastole is ejected during systole (this is called the *ejection fraction*); about 70% of this portion flows out during the first third of the ejection period, with the remaining 30% emptying during the next two-thirds. Therefore, the first third is called the *period of rapid ejection*, and the last two-thirds is called the *period of slow ejection*.

Period of Isovolumic (Isometric) Relaxation. At the end of systole, ventricular relaxation begins suddenly, allowing the right and left *intraventricular pressures* to decrease rapidly. The elevated pressures in the distended large arteries that have just been filled with blood from the contracted ventricles immediately push blood back toward the ventricles, which snaps the aortic and pulmonary valves closed. For another 0.03 to 0.06 second, the ventricular muscle continues to relax, even though the ventricular volume does not change, giving rise to the period of *isovolumic* or *isometric relaxation*. During this period, the intraventricular pressures rapidly decrease back to their low diastolic levels. Then, the AV valves open to begin a new cycle of ventricular pumping.

End-Diastolic Volume, End-Systolic Volume, and Stroke Volume Output. During diastole, normal filling of the ventricles increases the volume of each ventricle to about 110 to 120 mL. This volume is called the *end-diastolic volume*. Then, as the ventricles empty during systole, the volume decreases by about 70 mL, which is called the *stroke volume output*. The remaining volume in each ventricle, about 40 to 50 mL, is called the *end-systolic volume*. The fraction of the end-diastolic volume that is ejected is called the *ejection fraction*, usually equal to about 0.6 (or 60%). The ejection fraction percentage is often used clinically to assess cardiac systolic (pumping) capability and to classify types of heart failure, as discussed in Chapter 22.

When the heart contracts strongly, the end-systolic volume may decrease to as little as 10 to 20 mL. Conversely, when large amounts of blood flow into the ventricles during diastole, the ventricular end-diastolic volumes can become as much as 150 to 180 mL in the healthy heart. By both increasing the end-diastolic volume and decreasing the end-systolic volume, the stroke volume output can be increased to more than double that which is normal.

THE HEART VALVES PREVENT BACKFLOW OF BLOOD DURING SYSTOLE

Atrioventricular Valves. The *AV valves* (i.e., the *tricuspid* and *mitral valves*) prevent backflow of blood from the ventricles to the atria during systole, and the *semilunar valves* (i.e., the *aortic* and *pulmonary artery valves*) prevent backflow from the aorta and pulmonary arteries into the ventricles during diastole. These valves, shown in **Fig. 9.9** for the left ventricle, close and open *passively*. That is, they close when a backward pressure gradient pushes blood backward, and they open when a forward pressure gradient forces blood in the forward direction. For anatomical reasons, the thin AV valves require almost no backflow to cause closure, whereas the much heavier semilunar valves require rather rapid backflow for a few milliseconds.

Function of the Papillary Muscles. **Fig. 9.9** also shows papillary muscles that attach to the vanes of the AV valves by the *chordae tendineae*. The papillary muscles contract

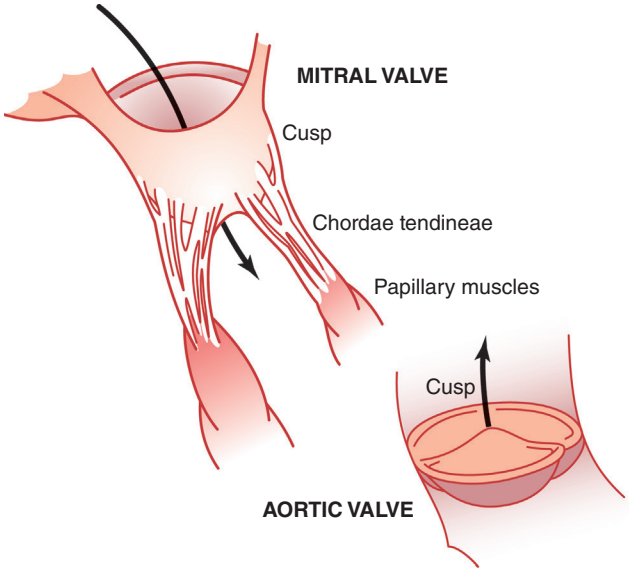

Figure 9.9 Mitral and aortic valves (the left ventricular valves).

when the ventricular walls contract but, contrary to what might be expected, they *do not* help the valves to close. Instead, they pull the vanes of the valves inward toward the ventricles to prevent their bulging too far backward toward the atria during ventricular contraction. If a chorda tendinea becomes ruptured, or if one of the papillary muscles becomes paralyzed due to low blood flow from a myocardial infarction, the valve bulges far backward during ventricular contraction, sometimes so far that it leaks severely, causing heart failure symptoms or even death in severe cases.

Aortic and Pulmonary Artery Valves. The aortic and pulmonary artery semilunar valves function quite differently from the AV valves. First, the high pressures in the arteries at the end of systole cause the semilunar valves to snap closed, in contrast to the much softer closure of the AV valves. Second, because of smaller openings, the velocity of blood ejection through the aortic and pulmonary valves is much greater than that through the much larger AV valves. Also, because of the rapid closure and rapid ejection, the edges of the aortic and pulmonary valves are subjected to much greater mechanical abrasion than the AV valves. Finally, the AV valves are supported by the chordae tendineae, which is not true for the semilunar valves. It is obvious from the anatomy of the aortic and pulmonary valves (as shown for the aortic valve at the bottom of **Fig. 9.9**) that they must be constructed with an especially strong, yet very pliable, fibrous tissue to withstand the extra physical stresses.

AORTIC PRESSURE CURVE

When the left ventricle contracts, the ventricular pressure increases rapidly until the aortic valve opens. Then, after the valve opens, the pressure in the ventricle rises much less rapidly, as shown in **Fig. 9.8**, because blood

immediately flows out of the ventricle into the aorta and then into the systemic distribution arteries.

The entry of blood into the arteries during systole causes the walls of these arteries to stretch and the pressure to increase to about 120 mm Hg. Next, at the end of systole, after the left ventricle stops ejecting blood and the aortic valve closes, the elastic walls of the arteries maintain a high pressure in the arteries, even during diastole.

An *incisura* occurs in the aortic pressure curve when the aortic valve closes. This is caused by a short period of backward flow of blood immediately before closure of the valve, followed by the sudden cessation of backflow.

After the aortic valve closes, pressure in the aorta decreases slowly throughout diastole because the blood stored in the distended elastic arteries flows continually through the peripheral vessels back to the veins. Before the ventricle contracts again, the aortic pressure usually has fallen to about 80 mm Hg (diastolic pressure), which is two-thirds the maximal pressure of 120 mm Hg (systolic pressure) that occurs in the aorta during ventricular contraction.

The pressure curves in the *right ventricle* and *pulmonary artery* are similar to those in the aorta, except that the pressures are only about one-sixth as great, as discussed in Chapter 14.

Relationship of the Heart Sounds to Heart Pumping

When listening to the heart with a stethoscope, one does not hear the opening of the valves because this is a relatively slow process that normally makes no noise. However, when the valves close, the vanes of the valves and the surrounding fluids vibrate under the influence of sudden pressure changes, giving off sound that travels in all directions through the chest.

When the ventricles contract, one first hears a sound caused by closure of the AV valves. The vibration pitch is low and relatively long-lasting and is known as the *first heart sound (S1)*. When the aortic and pulmonary valves close at the end of systole, one hears a rapid snap because these valves close rapidly, and the surroundings vibrate for a short period. This sound is called the *second heart sound (S2)*. The precise causes of the heart sounds are discussed more fully in Chapter 23 in relation to listening to the sounds with the stethoscope.

Work Output of the Heart

The *stroke work output* of the heart is the amount of energy that the heart converts to work during each heartbeat while pumping blood into the arteries. Work output of the heart is in two forms. First, the major proportion is used to move the blood from the low-pressure veins to the high-pressure arteries. This is called *volume-pressure work* or *external work*. Second, a minor proportion of the energy is used to accelerate the blood to its velocity of ejection through the aortic and pulmonary valves, which is the *kinetic energy of blood flow* component of the work output.

Right ventricular external work output is normally about one-sixth the work output of the left ventricle because of the 6-fold difference in systolic pressures pumped by the two ventricles. The additional work output of each ventricle required to create kinetic energy of blood flow is proportional to the mass of blood ejected times the square of velocity of ejection.

Ordinarily, the work output of the left ventricle required to create kinetic energy of blood flow is only about 1% of the total work output of the ventricle and therefore is ignored in the calculation of the total stroke work output. In certain abnormal conditions, however, such as aortic stenosis, in which blood flows with great velocity through the stenosed valve, more than 50% of the total work output may be required to create kinetic energy of blood flow.

VENTRICULAR VOLUME-PRESSURE RELATIONSHIP

Fig. 9.10 shows a diagram that is especially useful in explaining the pumping mechanics of the *left* ventricle. The most important components of the diagram are the two curves labeled "diastolic pressure" and "systolic pressure." These curves are volume-pressure curves.

The diastolic pressure curve is determined by filling the heart with progressively greater volumes of blood and then measuring the diastolic pressure immediately before ventricular contraction occurs, which is the *end-diastolic pressure* of the ventricle.

The systolic pressure curve is determined by recording the systolic pressure achieved during ventricular contraction at each volume of filling.

Until the volume of the noncontracting ventricle rises above about 150 mL, the diastolic pressure does not increase much. Therefore, up to this volume, blood can flow easily into the ventricle from the atrium. Above 150 mL, the ventricular diastolic pressure increases rapidly, partly because of fibrous tissue in the heart that will stretch no more, and partly because the pericardium that surrounds the heart becomes filled nearly to its limit.

During ventricular contraction, the systolic pressure increases, even at low ventricular volumes, and reaches a maximum at a ventricular volume of 150 to 170 mL. Then, as the volume increases further, the systolic pressure actually decreases under some conditions, as demonstrated by the falling systolic pressure curve in **Fig. 9.10**. This occurs because at these great volumes, the actin and myosin filaments of the cardiac muscle fibers are pulled apart far enough that the strength of each cardiac fiber contraction becomes less than optimal.

Note especially in the figure that the maximum systolic pressure for the normal *left* ventricle is between 250 and 300 mm Hg, but this varies widely with each person's heart strength and degree of heart stimulation by cardiac nerves. For the normal *right* ventricle, the maximum systolic pressure is between 60 and 80 mm Hg.

Volume-Pressure Loops; Cardiac Work Output. The red lines in **Fig. 9.10** form a loop called the

volume-pressure diagram of the cardiac cycle for normal function of the *left* ventricle. A more detailed version of this loop is shown in **Fig. 9.11**. It is divided into four phases.

Phase I: Period of Filling. Phase I in the volume-pressure diagram begins at a ventricular volume of about 50 mL and a diastolic pressure of 2 to 3 mm Hg. The amount of blood that remains in the ventricle after the previous heartbeat, 50 mL, is called the *end-systolic volume*. As venous blood flows into the ventricle from the left atrium, the ventricular volume normally increases to about 120 mL, called the *end-diastolic volume*, an increase of 70 mL. Therefore, the volume-pressure diagram during phase I extends along the line in **Fig. 9.10** labeled "I" and from point A to point B in **Fig. 9.11**, with the volume increasing to 120 mL and the diastolic pressure rising to about 5 to 7 mm Hg.

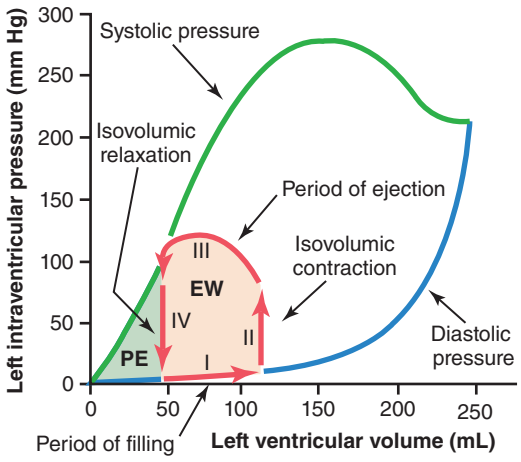

Figure 9.10 Relationship between left ventricular volume and intraventricular pressure during diastole and systole. Also shown by the *red lines* is the "volume-pressure diagram," demonstrating changes in intraventricular volume and pressure during the normal cardiac cycle. *EW*, Net external work; *PE*, potential energy.

Phase II: Isovolumic Contraction. During isovolumic contraction, the volume of the ventricle does not change because all valves are closed. However, the pressure inside the ventricle increases to equal the pressure in the aorta, at a pressure value of about 80 mm Hg, as depicted by point C (see **Fig. 9.11**).

Phase III: Period of Ejection. During ejection, the systolic pressure rises even higher because of still more contraction of the ventricle. At the same time, the volume of the ventricle decreases because the aortic valve has now opened, and blood flows out of the ventricle into the aorta. Therefore, in **Fig. 9.10**, the curve labeled "III," or "period of ejection," traces the changes in volume and systolic pressure during this period of ejection.

Phase IV: Isovolumic Relaxation. At the end of the period of ejection (point D, **Fig. 9.11**), the aortic valve closes, and the ventricular pressure falls back to the diastolic pressure level. The line labeled "IV" (**Fig. 9.10**) traces this decrease in intraventricular pressure without any change in volume. Thus, the ventricle returns to its starting point, with about 50 mL of blood left in the ventricle at a pressure of 2 to 3 mm Hg.

The area subtended by this functional volume-pressure diagram (the shaded area, labeled "EW") represents the *net external work output* of the ventricle during its contraction cycle. In experimental studies of cardiac

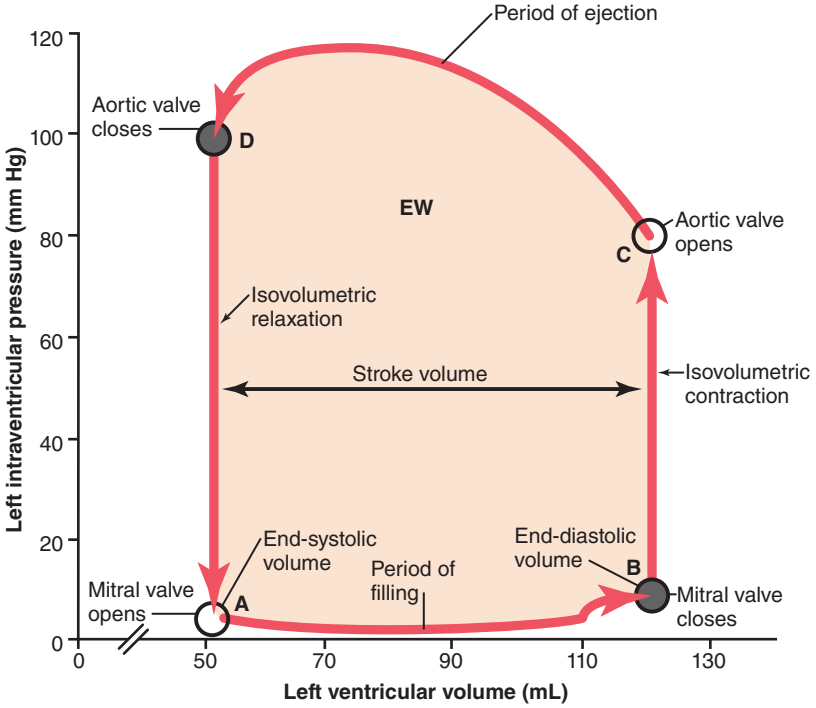

Figure 9.11 The volume-pressure diagram demonstrating changes in intraventricular volume and pressure during a single cardiac cycle (*red line*). The *shaded area* represents the net external work (EW) output by the left ventricle during the cardiac cycle.

contraction, this diagram is used for calculating cardiac work output.

When the heart pumps large quantities of blood, the area of the work diagram becomes larger. That is, it extends far to the right because the ventricle fills with more blood during diastole, it rises higher because the ventricle contracts with greater pressure, and it usually extends farther to the left because the ventricle contracts to a smaller volume—especially if the ventricle is stimulated to increased activity by the sympathetic nervous system.

Cardiac Preload and Afterload. In assessing the contractile properties of muscle, it is important to specify the degree of tension on the muscle when it begins to contract, called the *preload*, and to specify the load against which the muscle exerts its contractile force, called the *afterload*.

For cardiac contraction, the *preload* is usually considered to be the end-diastolic pressure when the ventricle has become filled. The *afterload* of the ventricle is the pressure in the aorta leading from the ventricle. In **Fig. 9.10**, this corresponds to the systolic pressure described by the phase III curve of the volume-pressure diagram. (Sometimes the afterload is loosely considered to be the resistance in the circulation rather than the pressure.)

The importance of the concepts of preload and afterload is that in many abnormal functional states of the heart or circulation, the pressure during filling of the ventricle (the preload), the arterial pressure against which the ventricle must contract (the afterload), or both are altered from normal to a severe degree.

Chemical Energy Required for Cardiac Contraction: Oxygen Utilization By the Heart

Heart muscle, like skeletal muscle, uses chemical energy to provide the work of contraction. Approximately 70% to 90% of this energy is normally derived from oxidative metabolism of fatty acids, with about 10% to 30% coming from other nutrients, especially glucose and lactate. Therefore, the rate of oxygen consumption by the heart is an excellent measure of the chemical energy liberated while the heart performs its work. The different chemical reactions that liberate this energy are discussed in Chapters 68 and 69.

Experimental studies have shown that oxygen consumption of the heart and the chemical energy expended during contraction are directly related to the total shaded area in **Fig. 9.10**. This shaded portion consists of the *external work* (EW), as explained earlier, and an additional portion called the *potential energy*, labeled "PE." The potential energy represents additional work that could be accomplished by contraction of the ventricle if the ventricle could completely empty all the blood in its chamber with each contraction.

Oxygen consumption has also been shown to be nearly proportional to the *tension* that occurs in the heart muscle during contraction multiplied by the *duration of time* that the contraction persists; this is called the *tension-time index*. According to the law of Laplace, ventricular wall tension (T) is related to the left ventricular pressure (P) and the radius (r): $T = P \times r$.

Because tension is high when systolic pressure (and therefore left ventricular pressure) is high, correspondingly more oxygen is used. When systolic pressure is chronically elevated, wall stress and cardiac workload are also increased, inducing thickening of the left ventricular walls, which reduces the ventricular chamber radius (concentric hypertrophy) and at least partially relieves the increased wall tension. Also, much more chemical energy is expended, even at normal systolic pressures, when the ventricle is abnormally dilated (eccentric hypertrophy) because the heart muscle tension during contraction is proportional to pressure times the radius of the ventricle. This becomes especially important in heart failure when the ventricle is dilated and, paradoxically, the amount of chemical energy required for a given amount of work output is greater than normal, even though the heart is already failing.

Cardiac Efficiency. During heart muscle contraction, most of the expended chemical energy is converted into *heat*, and a much smaller portion is converted into *work output*. *Cardiac efficiency* is the ratio of work output to total chemical energy used to perform the work. Maximum efficiency of the normal heart is between 20% and 25%. In persons with heart failure, this efficiency can decrease to as low as 5%.

REGULATION OF HEART PUMPING

When a person is at rest, the heart pumps 4 to 6 liters of blood each minute. During strenuous exercise, the heart may pump four to seven times this amount. The basic mechanisms for regulating heart pumping are as follows: (1) intrinsic cardiac pumping regulation in response to changes in volume of blood flowing into the heart; and (2) control of heart rate and heart strength by the autonomic nervous system.

INTRINSIC REGULATION OF HEART PUMPING—THE FRANK-STARLING MECHANISM

In Chapter 20, we will learn that under most conditions the amount of blood pumped by the heart each minute is normally determined almost entirely by the rate of blood flow into the heart from the veins, which is called *venous return*. That is, each peripheral tissue of the body controls its own local blood flow, and all the local tissue flows combine and return by way of the veins to the right atrium. The heart, in turn, automatically pumps this incoming blood into the arteries so that it can flow around the circuit again.

This intrinsic ability of the heart to adapt to increasing volumes of inflowing blood is called the *Frank-Starling mechanism of the heart*, named in honor of Otto Frank and Ernest Starling, two great physiologists. Basically, the Frank-Starling mechanism means that the more the heart muscle is stretched during cardiac filling, the greater is the force of contraction, and the greater is the quantity of

blood pumped into the aorta. Or, stated another way—*within physiological limits, the heart pumps all the blood that returns to it by way of the veins.*

What Is the Explanation of the Frank-Starling Mechanism? When an extra amount of blood flows into the heart, the cardiac muscle is stretched to a greater length. This stretching causes the muscle to contract with increased force because the actin and myosin filaments are brought to a more nearly optimal degree of overlap for force generation. Therefore, the ventricle, because of its increased pumping, automatically pumps the extra blood into the arteries. This ability of stretched muscle, up to an optimal length, to contract with increased work output is characteristic of all striated muscle, as explained in Chapter 6, and is not simply a characteristic of cardiac muscle.

In addition to the important effect of lengthening the heart muscle, another factor increases heart pumping when its volume is increased. Stretch of the right atrial wall directly increases the heart rate by 10% to 20%, which also helps increase the amount of blood pumped each minute, although its contribution is much less than that of the Frank-Starling mechanism. As discussed in Chapter 18, stretch of the atrium also activates stretch receptors and a nervous reflex, the *Bainbridge reflex*, that is transmitted by the vagus nerve and may increase heart rate an additional 40% to 60%.

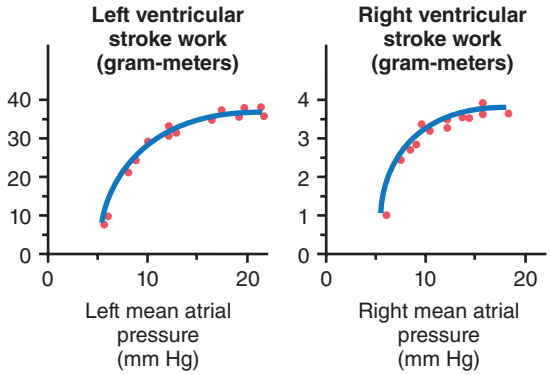

Figure 9.12 Left and right ventricular function curves recorded from dogs, depicting *ventricular stroke work output* as a function of left and right mean atrial pressures. *(Data from Sarnoff SJ. Myocardial contractility as described by ventricular function curves.* Physiol Rev. *1955;35:107.)*

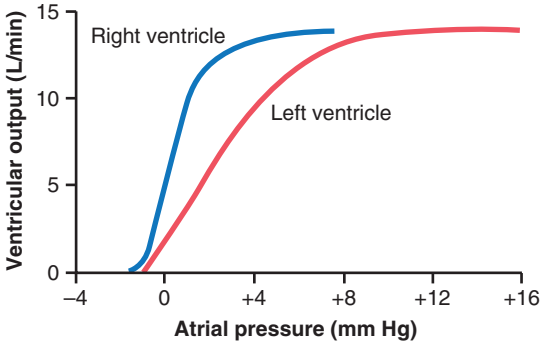

Figure 9.13 Approximate normal right and left *ventricular volume output curves* for the normal resting human heart as extrapolated from data obtained in dogs and data from humans.

Ventricular Function Curves

One of the best ways to express the functional ability of the ventricles to pump blood is by *ventricular function curves*. **Fig. 9.12** shows a type of ventricular function curve called the *stroke work output curve*. Note that as atrial pressure for each side of the heart increases, stroke work output for that side increases until it reaches the limit of the ventricle's pumping ability.

Fig. 9.13 shows another type of ventricular function curve called the *ventricular volume output curve*. The two curves of this figure represent function of the two ventricles of the human heart based on data extrapolated from experimental animal studies. As the right and left atrial pressures increase, the respective ventricular volume outputs per minute also increase.

Thus, *ventricular function curves* are another way of expressing the Frank-Starling mechanism of the heart. That is, as the ventricles fill in response to higher atrial pressures, ventricular volumes and strength of cardiac muscle contractions increase, causing the heart to pump increased quantities of blood into the arteries.

Control of the Heart By the Sympathetic and Parasympathetic Nerves

The pumping effectiveness of the heart also is controlled by the *sympathetic* and *parasympathetic (vagus)* nerves, which abundantly supply the heart, as shown in **Fig. 9.14**. For given levels of atrial pressure, the amount of blood pumped each minute *(cardiac output)* often can be increased more than 100% by sympathetic stimulation. By contrast, the output can be decreased to almost zero by parasympathetic (vagal) stimulation.

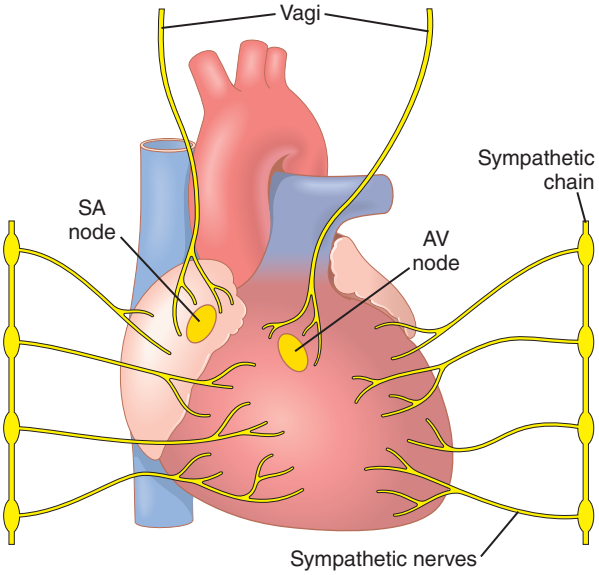

Figure 9.14 Cardiac *sympathetic* and *parasympathetic* nerves. (The vagus nerves to the heart are parasympathetic nerves.) *AV*, Atrioventricular; *SA*, sinoatrial.

Mechanisms of Excitation of the Heart By the Sympathetic Nerves. Strong sympathetic stimulation can increase the heart rate (increased *chronotropy*) in young adult humans from the normal rate of 70 beats/min up to 180 to 200 beats/min and, rarely, even 250 beats/min. Also, sympathetic stimulation may double the force of heart contraction (increased *inotropy*), thereby increasing the volume of blood pumped and increasing the ejection pressure. Thus, sympathetic stimulation often can increase the maximum cardiac output as much as 2-fold to 3-fold, in addition to the increased output caused by the Frank-Starling mechanism already discussed.

Conversely, *inhibition* of the sympathetic nerves to the heart can decrease cardiac pumping to a moderate extent. Under normal conditions, the sympathetic nerve fibers to the heart discharge continuously at a slow rate that maintains pumping at about 30% above that with no sympathetic stimulation. Therefore, when sympathetic nervous system activity is depressed below normal, both the heart rate and strength of ventricular muscle contraction decrease, thereby decreasing the level of cardiac pumping by as much as 30% below normal.

Parasympathetic (Vagal) Stimulation Reduces Heart Rate and Strength of Contraction. Strong stimulation of the parasympathetic nerve fibers in the vagus nerves to the heart can stop the heartbeat for a few seconds, but then the heart usually "escapes" and beats at a rate of 20 to 40 beats/min as long as the parasympathetic stimulation continues. In addition, strong vagal stimulation can decrease the strength of heart muscle contraction by 20% to 30%.

The vagal fibers are distributed mainly to the atria and not much to the ventricles, where the power contraction of the heart occurs. This distribution explains why the effect of vagal stimulation is mainly to decrease the heart rate rather than to decrease greatly the strength of heart contraction. Nevertheless, the great decrease in heart rate, combined with a slight decrease in heart contraction strength, can decrease ventricular pumping by 50% or more.

Effect of Sympathetic or Parasympathetic Stimulation on the Cardiac Function Curve. **Fig. 9.15** shows four cardiac function curves. These curves are similar to the ventricular function curves of **Fig. 9.13**. However, they represent function of the entire heart rather than that of a single ventricle. They show the relationship between right atrial pressure at the input of the right heart and cardiac output from the left ventricle into the aorta.

The curves of **Fig. 9.15** demonstrate that at any given right atrial pressure, the cardiac output increases during increased sympathetic stimulation and decreases during increased parasympathetic stimulation. These changes in output caused by autonomic nervous system stimulation result from *changes in heart rate* and from *changes in contractile strength of the heart.*

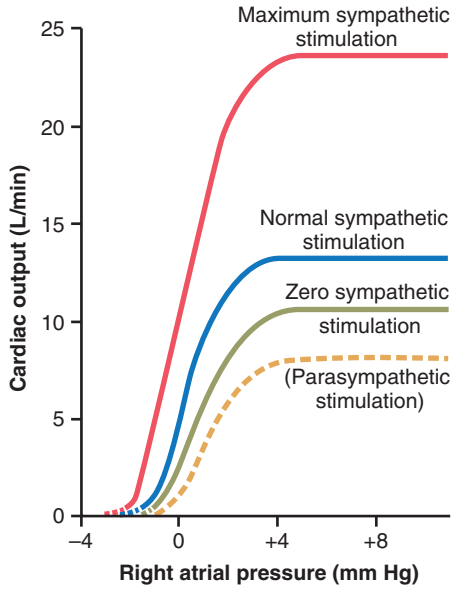

Figure 9.15 Effect on the cardiac output curve of different degrees of sympathetic or parasympathetic stimulation.

EFFECT OF POTASSIUM AND CALCIUM IONS ON HEART FUNCTION

In our discussion of membrane potentials in Chapter 5, we pointed out that potassium ions have a marked effect on membrane potentials, and in Chapter 6 we noted that calcium ions play an especially important role in activating the muscle contractile process. Therefore, it is not surprising that the concentrations of each of these two ions in the extracellular fluids have important effects on cardiac pumping.

Effect of Potassium Ions. Excess potassium in the extracellular fluids causes the heart to become dilated and flaccid and also slows the heart rate. Large quantities of potassium also can block conduction of the cardiac impulse from the atria to the ventricles through the AV bundle. Elevation of potassium concentration to only 8 to 12 mEq/L—two to three times the normal value—can cause severe weakness of the heart, abnormal rhythm, and death.

These effects result partially from the fact that a high potassium concentration in the extracellular fluids decreases the resting membrane potential in the cardiac muscle fibers, as explained in Chapter 5. That is, a high extracellular fluid potassium concentration partially depolarizes the cell membrane, causing the membrane potential to be less negative. As the membrane potential decreases, the intensity of the action potential also decreases, which makes contraction of the heart progressively weaker.

Effect of Calcium Ions. Excess calcium ions cause effects almost exactly opposite to those of potassium ions, causing the heart to move toward spastic contraction. This effect is caused by a direct effect of calcium ions to initiate the cardiac contractile process, as explained earlier in this chapter.

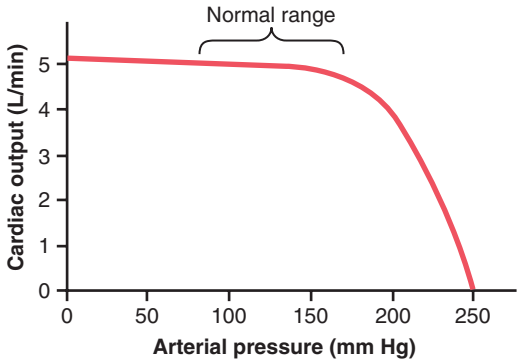

Figure 9.16 Constancy of cardiac output up to a pressure level of 160 mm Hg. Only when the arterial pressure rises above this normal limit does the increasing pressure load cause the cardiac output to fall significantly.

Conversely, deficiency of calcium ions causes cardiac weakness, similar to the effect of high potassium. Fortunately, calcium ion levels in the blood normally are regulated within a very narrow range. Therefore, cardiac effects of abnormal calcium concentrations are seldom of clinical concern.

EFFECT OF TEMPERATURE ON HEART FUNCTION

Increased body temperature, such as that which occurs during fever, greatly increases the heart rate, sometimes to double the normal rate. Decreased temperature greatly decreases the heart rate, which may fall to as low as a few beats per minute when a person is near death from hypothermia in the body temperature range of 60° to 70°F (15.5°–21°C). These effects presumably result from the fact that heat increases the permeability of the cardiac muscle membrane to ions that control heart rate, resulting in acceleration of the self-excitation process.

Contractile strength of the heart often is enhanced temporarily by a moderate increase in temperature, such as that which occurs during body exercise, but prolonged temperature elevation exhausts the metabolic systems of the heart and eventually causes weakness. Therefore, optimal heart function depends greatly on proper control of body temperature by the control mechanisms explained in Chapter 74.

INCREASING THE ARTERIAL PRESSURE LOAD (UP TO A LIMIT) DOES NOT DECREASE CARDIAC OUTPUT

Note in **Fig. 9.16** that increasing the arterial pressure in the aorta does not decrease cardiac output until the mean arterial pressure rises above about 160 mm Hg. In other words, during normal heart function at normal systolic arterial pressures (80–140 mm Hg), cardiac output is determined almost entirely by the ease of blood flow through the body's tissues, which in turn controls *venous return* of blood to the heart. This mechanism is the principal subject of Chapter 20.

CHAPTER 10

Rhythmical Excitation of the Heart

The human heart has a special system for rhythmic self-excitation and repetitive contraction approximately 100,000 times each day or 3 billion times in the average human lifetime. This impressive feat is performed by a system that does the following: (1) generates electrical impulses to initiate rhythmical contraction of the heart muscle; and (2) conducts these impulses rapidly through the heart. When this system functions normally, the atria contract about one-sixth of a second ahead of ventricular contraction, which allows filling of the ventricles before they pump blood through the lungs and peripheral circulation. Another especially important feature of the system is that it allows all portions of the ventricles to contract almost simultaneously, which is essential for the most effective pressure generation in the ventricular chambers.

This rhythmical and conductive system of the heart is susceptible to damage by heart disease, especially by ischemia resulting from inadequate coronary blood flow. The effect is often a bizarre heart rhythm or an abnormal sequence of contraction of the heart chambers, and the pumping effectiveness of the heart can be affected severely, even to the extent of causing death.

SPECIALIZED EXCITATORY AND CONDUCTIVE SYSTEM OF THE HEART

Fig. 10.1 shows the specialized excitatory and conductive system of the heart that controls cardiac contractions. The figure shows the sinus node (also called sinoatrial [SA] node), in which the normal rhythmical impulses are generated; the internodal pathways that conduct impulses from the sinus node to the atrioventricular (AV) node; the AV node, in which impulses from the atria are delayed before passing into the ventricles; the AV bundle, which conducts impulses from the atria into the ventricles; and the left and right bundle branches of Purkinje fibers, which conduct the cardiac impulses to all parts of the ventricles.

SINUS (SINOATRIAL) NODE

The sinus node is a small, flattened, ellipsoid strip of specialized cardiac muscle about 3 mm wide, 15 mm long, and 1 mm thick. It is located in the superior posterolateral wall of the right atrium immediately below and slightly lateral to the opening of the superior vena cava. The fibers of this node have almost no contractile muscle filaments and are each only 3 to 5 micrometers (μm) in diameter, in contrast to a diameter of 10 to 15 μm for the surrounding atrial muscle fibers. However, the sinus nodal fibers connect directly with the atrial muscle fibers so that any action potential that begins in the sinus node spreads immediately into the atrial muscle wall.

Self-Excitation of the Sinus Fibers

Some cardiac fibers have the capability of *self-excitation*, a process that can cause automatic rhythmical discharge and contraction. This capability is especially true of the heart's specialized conducting system, including fibers of the sinus node. For this reason, the sinus node ordinarily controls the beat rate of the entire heart, as discussed later in this chapter.

Sinus Nodal Automatic Rhythmicity. **Fig. 10.2** shows action potentials recorded from inside a sinus nodal fiber for three heartbeats and, by comparison, a single ventricular muscle fiber action potential. Note that the resting membrane potential of the sinus nodal fiber between discharges is about –55 to –60 millivolts, in comparison with –85 to –90 millivolts for the ventricular muscle fiber. The cause of this lower negativity is that the cell membranes of the sinus fibers are naturally leaky to sodium and calcium ions, and positive charges of the entering sodium and calcium ions neutralize some of the intracellular negativity.

Before we explain the rhythmicity of the sinus nodal fibers, first recall from the discussions of Chapters 5 and 9 that cardiac muscle has three main types of membrane ion channels that play important roles in causing the voltage changes of the action potential. They are (1) *fast sodium channels*, (2) *calcium channels (particularly L-type* or *"slow" calcium channels)*, and (3) *potassium channels* (see **Fig. 9.5**).

Opening of the fast sodium channels for a few 10,000ths of a second is responsible for the rapid upstroke spike of the action potential observed in ventricular muscle because of rapid influx of positive sodium ions to the interior of the fiber. Then, the plateau of the ventricular action potential is caused primarily by slower opening of the slow sodium-calcium channels, which lasts for about 0.3 second. Finally, opening of potassium channels allows

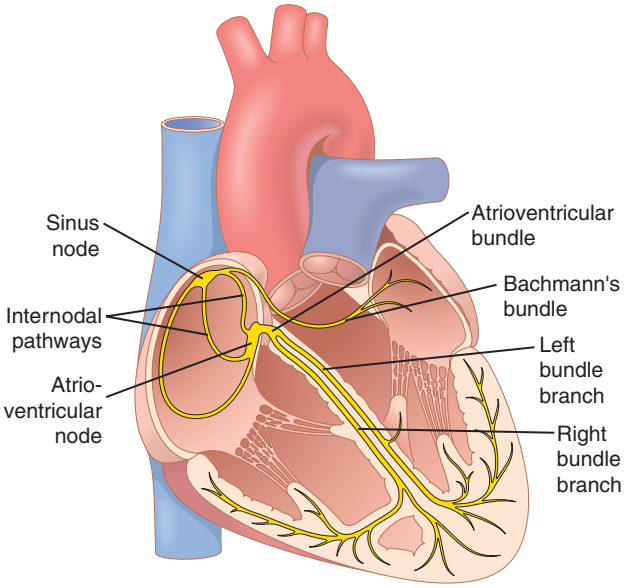

Figure 10.1 Sinus node and the Purkinje system of the heart, showing also Bachmann's bundle, the atrioventricular (AV) node, atrial internodal pathways, and ventricular bundle branches.

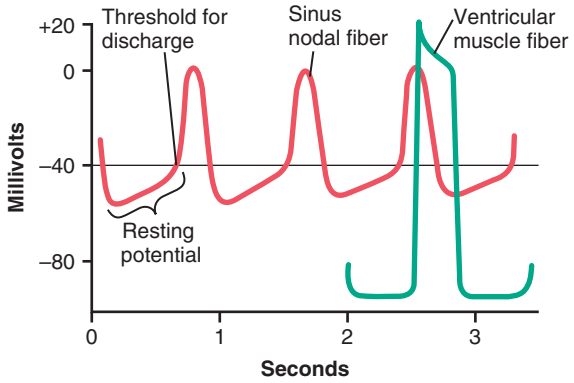

Figure 10.2 Rhythmical discharge of a sinus nodal fiber. Also, the sinus nodal action potential is compared with that of a ventricular muscle fiber.

for the diffusion of large amounts of positive potassium ions in the outward direction through the fiber membrane and returns the membrane potential to its resting level.

However, there is a difference in the function of these channels in the sinus nodal fiber because the resting potential is much less negative—only –55 millivolts in the nodal fiber instead of the –90 millivolts in the ventricular muscle fiber. At this level of –55 millivolts, the fast sodium channels mainly have already become inactivated, or blocked. This is because any time the membrane potential remains less negative than about –55 millivolts for more than a few milliseconds, the inactivation gates on the inside of the cell membrane that close the fast sodium channels become closed and remain so. Therefore, only the slow sodium-calcium channels can open (i.e., can become activated) and thereby cause the action potential. As a result, the atrial nodal action potential is slower to develop than the action potential of the ventricular muscle. Also, after the action potential does occur, return of the potential to its negative state occurs slowly as well, rather than the abrupt return that occurs for the ventricular fiber.

Leakiness of Sinus Nodal Fibers to Sodium and Calcium Causes Self-Excitation. Because of the high sodium ion concentration in the extracellular fluid outside the nodal fiber, as well as a moderate number of already open sodium channels, positive sodium ions from outside the fibers normally tend to leak to the inside through inward, "funny" currents. Therefore, between heartbeats, the influx of positively charged sodium ions causes a slow rise in the resting membrane potential in the positive direction. Thus, as shown in **Fig. 10.2**, the resting potential gradually rises and becomes less negative between each two heartbeats. When the potential reaches a threshold voltage of about –40 millivolts, the long-lasting or "L-type" calcium channels become activated, thus causing the action potential. Therefore, basically, the inherent leakiness of the sinus nodal fibers to sodium and calcium ions causes their self-excitation.

Why does this leakiness to sodium and calcium ions not cause the sinus nodal fibers to remain depolarized all the time? Two events occur during the course of the action potential to prevent such a constant state of depolarization. First, the L-type calcium channels become inactivated (i.e., they close) within about 100 to 150 milliseconds after opening; and second, at about the same time, greatly increased numbers of potassium channels open. Therefore, influx of positive calcium and sodium ions through the L-type calcium channels ceases, while at the same time large quantities of positive potassium ions diffuse out of the fiber. Both these effects reduce the intracellular potential back to its negative resting level and therefore terminate the action potential. Furthermore, the potassium channels remain open for another few tenths of a second, temporarily continuing movement of positive charges out of the cell, with resultant excess negativity inside the fiber; this process is called *hyperpolarization*. The hyperpolarization state initially carries the resting membrane potential down to about –55 to –60 millivolts at the termination of the action potential.

Why is this new state of hyperpolarization not maintained forever? The reason is that during the next few tenths of a second after the action potential is over, progressively more and more potassium channels close. The slow inward-leaking sodium ("funny" current) and calcium ions once again overbalance the outward flux of potassium ions, which causes the resting potential to drift upward once more, finally reaching the threshold level for discharge at a potential of about –40 millivolts. Then, the entire process begins again: self-excitation causes the action potential, recovery from the action potential, hyperpolarization after the action potential is over, drift of the resting potential to threshold, and finally re-excitation to elicit another cycle.

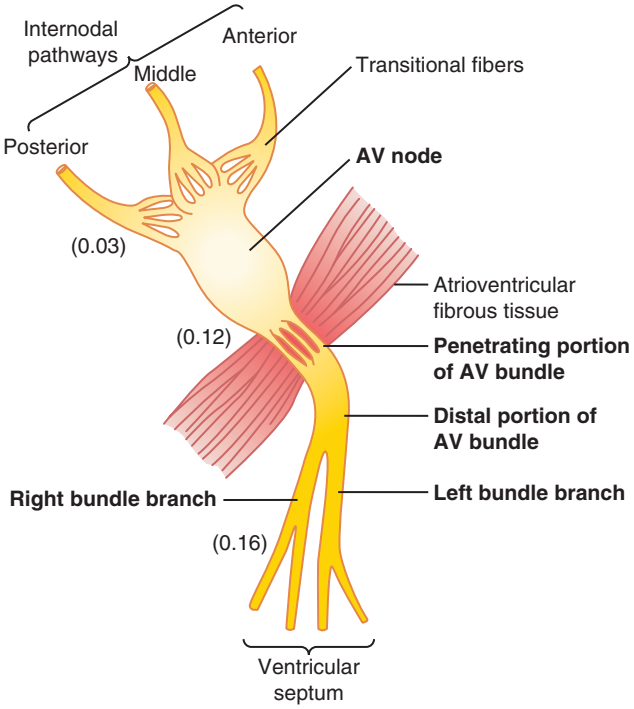

Figure 10.3 Organization of the atrioventricular (AV) node. The numbers represent the interval of time from the origin of the impulse in the sinus node. The values have been extrapolated to humans.

CARDIAC IMPULSES ARE TRANSMITTED THROUGH THE ATRIA BY INTERNODAL AND INTERATRIAL PATHWAYS

The ends of the sinus nodal fibers connect directly with the surrounding atrial muscle fibers. Therefore, action potentials originating in the sinus node travel outward into these atrial muscle fibers. In this way, the action potential spreads through the entire atrial muscle mass and, eventually, to the AV node. The velocity of conduction in most atrial muscle is about 0.3 m/sec, but conduction is more rapid, about 1 m/sec, in several small bands of atrial fibers. One of these bands, called the *anterior interatrial band* (also called *Bachmann's bundle*), passes through the anterior walls of the atria to the left atrium. In addition, three other small bands curve through the anterior, lateral, and posterior atrial walls and terminate in the AV node, shown in **Fig. 10.1** and **Fig. 10.3**; these are called, respectively, the *anterior, middle*, and *posterior internodal pathways*. The cause of more rapid velocity of conduction in these bands is the presence of specialized conduction fibers. These fibers are similar to even more rapidly conducting Purkinje fibers of the ventricles, discussed next.

THE ATRIOVENTRICULAR NODE DELAYS IMPULSE CONDUCTION FROM THE ATRIA TO THE VENTRICLES

The atrial conductive system is organized so that the cardiac impulse does not travel from the atria into the ventricles too rapidly; this delay allows time for the atria to empty their blood into the ventricles before ventricular contraction begins. It is primarily the AV node and its adjacent conductive fibers that delay this transmission into the ventricles.

The AV node is located in the posterior wall of the right atrium, immediately behind the tricuspid valve, as shown in **Fig. 10.1**. **Fig. 10.3** diagrams the different parts of this node, plus its connections with the entering atrial internodal pathway fibers and the exiting AV bundle. This figure also shows the approximate intervals of time (in fractions of a second) between the initial onset of the cardiac impulse in the sinus node and its subsequent appearance in the AV nodal system. Note that the impulse, after traveling through the internodal pathways, reaches the AV node about 0.03 second after its origin in the sinus node. Then, there is a delay of another 0.09 second in the AV node itself before the impulse enters the penetrating portion of the AV bundle, where it passes into the ventricles. A final delay of another 0.04 second occurs mainly in this penetrating AV bundle, which is composed of multiple small fascicles passing through the fibrous tissue separating the atria from the ventricles.

Thus, the total delay in the AV nodal and AV bundle system is about 0.13 second. This delay, in addition to the initial conduction delay of 0.03 second from the sinus node to the AV node, makes a total delay of 0.16 second before the excitatory signal finally reaches the contracting muscle of the ventricles.

Cause of the Slow Conduction in the Atrioventricular Bundle. The slow conduction in the transitional, nodal, and penetrating AV bundle fibers is caused mainly by diminished numbers of gap junctions between successive cells in the conducting pathways, so there is great resistance to conduction of excitatory ions from one conducting fiber to the next. Therefore, it is easy to see why each succeeding cell is slow to be excited.

RAPID TRANSMISSION OF THE CARDIAC IMPULSE IN THE VENTRICULAR PURKINJE SYSTEM

Special Purkinje fibers lead from the AV node through the AV bundle into the ventricles. Except for the initial portion of these fibers, where they penetrate the AV fibrous barrier, they have functional characteristics that are the opposite of those of the AV nodal fibers. They are very large fibers, even larger than the normal ventricular muscle fibers, and they transmit action potentials at a velocity of 1.5 to 4.0 m/sec, a velocity about six times that in the usual ventricular muscle and 150 times that in some of the AV nodal fibers. This velocity allows almost instantaneous transmission of the cardiac impulse throughout the entire remainder of the ventricular muscle.

The rapid transmission of action potentials by Purkinje fibers is believed to be caused by a very high level of permeability of the gap junctions at the intercalated discs

between the successive cells that make up the Purkinje fibers. Therefore, ions are transmitted easily from one cell to the next, thus enhancing the velocity of transmission. The Purkinje fibers also have very few myofibrils, which means that they contract little or not at all during the course of impulse transmission.

The Atrioventricular Bundle Is Normally a One-Way Conduction Path. A special characteristic of the AV bundle is the inability, except in abnormal states, of action potentials to travel backward from the ventricles to the atria. This characteristic prevents reentry of cardiac impulses by this route from the ventricles to the atria, allowing only forward conduction from the atria to the ventricles.

Furthermore, it should be recalled that everywhere, except at the AV bundle, the atrial muscle is separated from the ventricular muscle by a continuous fibrous barrier, a portion of which is shown in **Fig. 10.3**. This barrier normally acts as an insulator to prevent passage of the cardiac impulse between atrial and ventricular muscle through any other route besides forward conduction through the AV bundle. In rare cases, an abnormal muscle bridge, or an accessory pathway as in Wolff-Parkinson-White syndrome, does penetrate the fibrous barrier elsewhere besides at the AV bundle. Under such conditions, the cardiac impulse can reenter the atria from the ventricles and cause serious cardiac arrhythmias.

The Ventricular Purkinje Fibers Are Distributed Into the Left and Right Bundle Branches. After penetrating the fibrous tissue between the atrial and ventricular muscle, the distal portion of the AV bundle passes downward in the ventricular septum for 5 to 15 mm toward the apex of the heart, as shown in **Figs. 10.1** and **10.3**. Then, the bundle divides into left and right bundle branches that lie beneath the endocardium on the two respective sides of the ventricular septum. Each branch spreads downward toward the apex of the ventricle, progressively dividing into smaller branches. These branches, in turn, course sidewise around each ventricular chamber and back toward the base of the heart. The ends of the Purkinje fibers penetrate about one-third of the way into the muscle mass and finally become continuous with the cardiac muscle fibers.

The total elapsed time averages only 0.03 second from the time the cardiac impulse enters the bundle branches in the ventricular septum until it reaches the terminations of the Purkinje fibers. Therefore, once the cardiac impulse enters the ventricular Purkinje conductive system, it spreads almost immediately to the entire ventricular muscle mass.

TRANSMISSION OF THE CARDIAC IMPULSE IN THE VENTRICULAR MUSCLE

Once the impulse reaches the ends of the Purkinje fibers, it is transmitted through the ventricular muscle mass by the ventricular muscle fibers themselves. The velocity of transmission is now only 0.3 to 0.5 m/sec, one-sixth that in the Purkinje fibers.

The cardiac muscle wraps around the heart in a double spiral, with fibrous septa between the spiraling layers; therefore, the cardiac impulse does not necessarily travel directly outward toward the surface of the heart but, instead, angulates toward the surface along the directions of the spirals. Because of this angulation, transmission from the endocardial surface to the epicardial surface of the ventricle requires as much as another 0.03 second, approximately equal to the time required for transmission through the entire ventricular portion of the Purkinje system. Thus, the total time for transmission of the cardiac impulse from the initial bundle branches to the last of the ventricular muscle fibers in the normal heart is about 0.06 second.

SUMMARY OF THE SPREAD OF THE CARDIAC IMPULSE THROUGH THE HEART

Fig. 10.4 summarizes the transmission of the cardiac impulse through the human heart. The numbers on the figure represent the intervals of time, in fractions of a second, that lapse between the origin of the cardiac impulse in the sinus node and its appearance at each respective

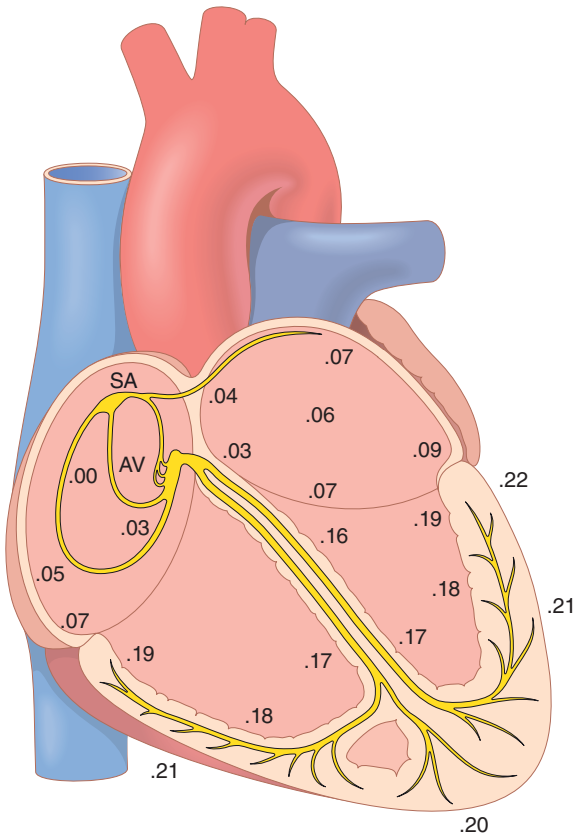

Figure 10.4 Transmission of the cardiac impulse through the heart, showing the time of appearance (in fractions of a second after initial appearance at the sinoatrial node) in different parts of the heart. *AV*, Atrioventricular; *SA*, sinoatrial.

point in the heart. Note that the impulse spreads at moderate velocity through the atria but is delayed more than 0.1 second in the AV nodal region before appearing in the ventricular septal AV bundle. Once it has entered this bundle, it spreads very rapidly through the Purkinje fibers to the entire endocardial surfaces of the ventricles. Then, the impulse once again spreads slightly less rapidly through the ventricular muscle to the epicardial surfaces.

It is important that the student learn in detail the course of the cardiac impulse through the heart and the precise times of its appearance in each separate part of the heart. A thorough quantitative knowledge of this process is essential for understanding electrocardiography, which is discussed in Chapters 11 through 13.

CONTROL OF EXCITATION AND CONDUCTION IN THE HEART

THE SINUS NODE IS THE NORMAL PACEMAKER OF THE HEART

In discussing the genesis and transmission of the cardiac impulse through the heart, we have noted that the impulse normally arises in the sinus node. In some abnormal conditions, this is not the case. Other parts of the heart can also exhibit intrinsic rhythmical excitation in the same way as the sinus nodal fibers; this is particularly true of the AV nodal and Purkinje fibers.

The AV nodal fibers, when not stimulated from some outside source, discharge at an intrinsic rhythmical rate of 40 to 60 times per minute, and the Purkinje fibers discharge at a rate somewhere between 15 and 40 times per minute. These rates are in contrast to the normal rate of the sinus node of 70 to 80 times per minute.

Why then does the sinus node rather than the AV node or the Purkinje fibers control the heart's rhythmicity? The answer derives from the fact that the discharge rate of the sinus node is considerably faster than the natural self-excitatory discharge rate of either the AV node or the Purkinje fibers. Each time the sinus node discharges, its impulse is conducted into both the AV node and Purkinje fibers, also discharging their excitable membranes. However, the sinus node discharges again before either the AV node or Purkinje fibers can reach their own thresholds for self-excitation. Therefore, the new impulse from the sinus node discharges both the AV node and Purkinje fibers before self-excitation can occur in either of these sites.

Thus, the sinus node controls the beat of the heart because its rate of rhythmical discharge is faster than that of any other part of the heart. Therefore, the sinus node is almost always the pacemaker of the normal heart.

Abnormal Pacemakers—Ectopic Pacemaker. Occasionally, some other part of the heart develops a rhythmical discharge rate that is more rapid than that of the sinus node. For example, this development sometimes occurs in the AV node or in the Purkinje fibers when one of these becomes abnormal. In either case, the pacemaker of the heart shifts from the sinus node to the AV node or to the excited Purkinje fibers. Under rarer conditions, a place in the atrial or ventricular muscle develops excessive excitability and becomes the pacemaker.

A pacemaker elsewhere than the sinus node is called an *ectopic pacemaker*. An ectopic pacemaker causes an abnormal sequence of contraction of the different parts of the heart and can cause significant weakening of heart pumping.

Another cause of shift of the pacemaker is blockage of transmission of the cardiac impulse from the sinus node to the other parts of the heart. The new pacemaker then usually occurs at the AV node or in the penetrating portion of the AV bundle on the way to the ventricles.

When AV block occurs—that is, when the cardiac impulse fails to pass from the atria into the ventricles through the AV nodal and bundle system—the atria continue to beat at the normal rate of rhythm of the sinus node while a new pacemaker usually develops in the Purkinje system of the ventricles and drives the ventricular muscle at a new rate, somewhere between 15 and 40 beats per minute. After sudden AV bundle block, the Purkinje system does not begin to emit its intrinsic rhythmical impulses until 5 to 20 seconds later because, before the blockage, the Purkinje fibers had been "overdriven" by the rapid sinus impulses and, consequently, are in a suppressed state. During these 5 to 20 seconds, the ventricles fail to pump blood, and the person faints after the first 4 to 5 seconds because of lack of blood flow to the brain. This delayed pickup of the heartbeat is called *Stokes-Adams syndrome*. If the delay period is too long, it can lead to death. Therefore, if there is a severe AV nodal or Purkinje system block leading to dizziness, fainting, or other signs of cardiac compromise such as heart failure, a small electronic pacemaker can be implanted to maintain a sufficient heart rate and cardiac output to prevent these symptoms.

ROLE OF THE PURKINJE SYSTEM IN CAUSING SYNCHRONOUS CONTRACTION OF THE VENTRICULAR MUSCLE

The rapid conduction of the Purkinje system normally permits the cardiac impulse to arrive at almost all portions of the ventricles within a narrow span of time, exciting the first ventricular muscle fiber only 0.03 to 0.06 second ahead of excitation of the last ventricular muscle fiber. This timing causes all portions of the ventricular muscle in both ventricles to begin contracting at almost the same time and then to continue contracting for about another 0.3 second.

Effective pumping by the two ventricular chambers requires this synchronous type of contraction. If the cardiac impulse should travel through the ventricles slowly, much of the ventricular mass would contract before contraction of the remainder, in which case the overall pumping effect would be greatly depressed. Indeed, in

some types of cardiac dysfunction, several of which are discussed in Chapters 12 and 13, slow transmission does occur, and the pumping effectiveness of the ventricles is decreased as much as 20% to 30%. Implantable cardiac resynchronization devices are types of pacemakers using electrical wires or leads that can be inserted into the cardiac chambers to restore appropriate timing between the atria and both ventricles to improve pumping effectiveness in patients with enlarged and weakened hearts.

SYMPATHETIC AND PARASYMPATHETIC NERVES CONTROL HEART RHYTHMICITY AND IMPULSE CONDUCTION BY THE CARDIAC NERVES

The heart is supplied with both sympathetic and parasympathetic nerves, as shown in **Fig. 9.14** of Chapter 9. The parasympathetic nerves (the vagi) are distributed mainly to the SA and AV nodes, to a lesser extent to the muscle of the two atria, and very little directly to the ventricular muscle. The sympathetic nerves, conversely, are distributed to all parts of the heart, with strong representation in the ventricular muscle, as well as in all the other areas.

Parasympathetic (Vagal) Stimulation Slows the Cardiac Rhythm and Conduction. Stimulation of the parasympathetic nerves to the heart (the vagi) causes *acetylcholine* to be released at the vagal endings. This neurotransmitter has two major effects on the heart. First, it decreases the rate of rhythm of the sinus node, and second, it decreases the excitability of the AV junctional fibers between the atrial musculature and the AV node, thereby slowing transmission of the cardiac impulse into the ventricles.

Weak to moderate vagal stimulation slows the rate of heart pumping, often to as little as one-half normal. Furthermore, strong stimulation of the vagi can completely stop the rhythmical excitation by the sinus node or completely block transmission of the cardiac impulse from the atria into the ventricles through the AV node. In either case, rhythmical excitatory signals are no longer transmitted into the ventricles. The ventricles may stop beating for 5 to 20 seconds, but then some small area in the Purkinje fibers, usually in the ventricular septal portion of the AV bundle, develops a rhythm of its own and causes ventricular contraction at a rate of 15 to 40 beats per minute. This phenomenon is called *ventricular escape*.

Mechanism of the Vagal Effects. The acetylcholine released at the vagal nerve endings greatly increases the permeability of the fiber membranes to potassium ions, which allows rapid leakage of potassium out of the conductive fibers. This process causes increased negativity inside the fibers, an effect called *hyperpolarization*, which makes this excitable tissue much less excitable, as explained in Chapter 5.

In the sinus node, the state of hyperpolarization makes the resting membrane potential of the sinus nodal fibers considerably more negative than usual—that is, −65 to −75 millivolts rather than the normal level of −55 to −60 millivolts. Therefore, the initial rise of the sinus nodal membrane potential caused by inward sodium and calcium leakage requires much longer to reach the threshold potential for excitation. This requirement greatly slows the rate of rhythmicity of these nodal fibers. If the vagal stimulation is strong enough, it is possible to stop the rhythmical self-excitation of this node entirely.

In the AV node, a state of hyperpolarization caused by vagal stimulation makes it difficult for the small atrial fibers entering the node to generate enough electricity to excite the nodal fibers. Therefore, the safety factor for transmission of the cardiac impulse through the transitional fibers into the AV nodal fibers decreases. A moderate decrease simply delays conduction of the impulse, but a large decrease blocks conduction entirely.

Sympathetic Stimulation Increases the Cardiac Rhythm and Conduction. Sympathetic stimulation causes essentially the opposite effects on the heart as those caused by vagal stimulation, as follows.

1. It increases the rate of sinus nodal discharge.
2. It increases the rate of conduction, as well as the level of excitability in all portions of the heart.
3. It increases greatly the force of contraction of all the cardiac musculature, both atrial and ventricular, as discussed in Chapter 9.

In short, sympathetic stimulation increases the overall activity of the heart. Maximal stimulation can almost triple the heartbeat frequency and can increase the strength of heart contraction as much as 2-fold.

Mechanism of the Sympathetic Effects on the Heart. Stimulation of the sympathetic nerves releases *norepinephrine* at the sympathetic nerve endings. Norepinephrine, in turn, stimulates *beta-1 adrenergic receptors*, which mediate the effects on heart rate. The precise mechanism whereby beta-1 adrenergic stimulation acts on cardiac muscle fibers is somewhat unclear, but is thought to increase the permeability of the fiber membrane to sodium and calcium ions. In the sinus node, an increase of sodium-calcium permeability causes a more positive resting potential. It also causes an increased rate of upward drift of the diastolic membrane potential toward the threshold level for self-excitation, thus accelerating self-excitation and, therefore, increasing the heart rate.

In the AV node and AV bundles, increased sodium-calcium permeability makes it easier for the action potential to excite each succeeding portion of the conducting fiber bundles, thereby decreasing the conduction time from the atria to the ventricles.

The increase in permeability to calcium ions is at least partially responsible for the increase in contractile strength of the cardiac muscle under the influence of sympathetic stimulation. This is because calcium ions play a powerful role in exciting the contractile process of the myofibrils.

CHAPTER 11

Fundamentals of Electrocardiography

When a cardiac impulse passes through the heart, electrical current also spreads from the heart into the adjacent tissues surrounding the heart. A small portion of the current spreads all the way to the surface of the body. If electrodes are placed on the skin on opposite sides of the heart, electrical potentials generated by the current can be recorded; the recording is known as an *electrocardiogram* (ECG). A normal ECG for two beats of the heart is shown in **Fig. 11.1**.

WAVEFORMS OF THE NORMAL ELECTROCARDIOGRAM

The normal ECG (see **Fig. 11.1**) is composed of a P wave, a QRS complex, and a T wave. The QRS complex is often, but not always, three separate waves: the Q wave, the R wave, and the S wave.

The *P wave* is caused by electrical potentials generated when the atria depolarize before atrial contraction begins. The *QRS complex* is caused by potentials generated when the ventricles depolarize before contraction—that is, as the depolarization wave spreads through the ventricles. Therefore, both the P wave and the components of the QRS complex are *depolarization waves*.

The *T wave* is caused by potentials generated as the ventricles recover from depolarization. This process normally occurs in ventricular muscle 0.25 to 0.35 second after depolarization. The T wave is known as a *repolarization wave*.

Thus, the ECG is composed of both depolarization and repolarization waves. The principles of depolarization and repolarization are discussed in Chapter 5. The distinction between depolarization waves and repolarization waves is so important in electrocardiography that further clarification is necessary.

CARDIAC DEPOLARIZATION WAVES VERSUS REPOLARIZATION WAVES

Fig. 11.2 shows a single cardiac muscle fiber in four stages of depolarization and repolarization, with the color red designating depolarization. During depolarization, the normal negative potential inside the fiber reverses and becomes slightly positive inside and negative outside.

In **Fig. 11.2A**, depolarization, demonstrated by red positive charges inside and red negative charges outside, is traveling from left to right. The first half of the fiber has already depolarized while the remaining half is still polarized. Therefore, the left electrode on the outside of the fiber is in an area of negativity, and the right electrode is in an area of positivity, which causes the meter to record positively. To the right of the muscle fiber is shown a record of changes in potential between the two electrodes, as recorded by a high-speed recorder. Note that when depolarization has reached the halfway mark in **Fig. 11.2A**, the recording on the right has risen to a maximum positive value.

In **Fig. 11.2B**, depolarization has extended over the entire muscle fiber, and the recording to the right has returned to the zero baseline because both electrodes are now in areas of equal negativity. The completed wave is a depolarization wave because it results from the spread of depolarization along the muscle fiber membrane.

Fig. 11.2C shows halfway repolarization of the same muscle fiber, with positivity returning to the outside of the fiber. At this point, the left electrode is in an area of positivity, and the right electrode is in an area of negativity. This polarity is opposite to the polarity in **Fig. 11.2A**. Consequently, the recording, as shown to the right, becomes negative.

In **Fig. 11.2D**, the muscle fiber has completely repolarized, and both electrodes are now in areas of positivity so that no potential difference is recorded between them. Thus, in the recording on the right, the potential returns once more to zero. This completed negative wave is a repolarization wave because it results from the spread of repolarization along the muscle fiber membrane.

Relation of the Monophasic Action Potential of Ventricular Muscle to the QRS and T Waves in the Standard Electrocardiogram. The monophasic action potential of ventricular muscle, discussed in Chapter 10, normally lasts between 0.25 and 0.35 second. The top part of **Fig. 11.3** shows a monophasic action potential recorded from a microelectrode inserted into a single ventricular muscle fiber. The upsweep of this action potential is caused by depolarization, and the return of the potential to the baseline is caused by repolarization.

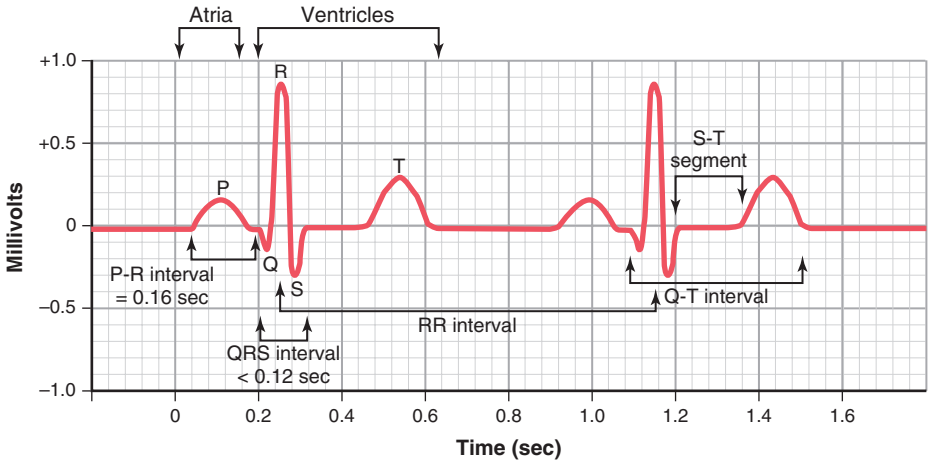

Figure 11.1 Normal electrocardiogram.

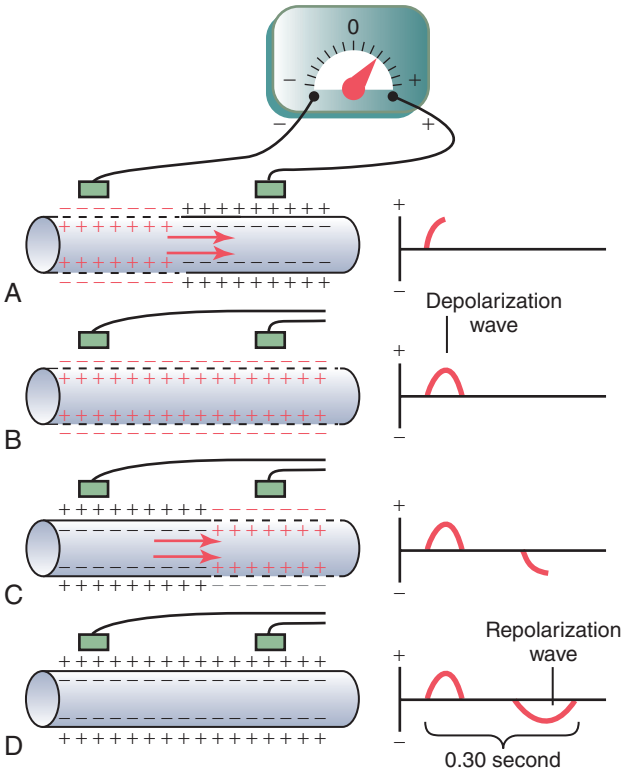

Figure 11.2 Recording the depolarization wave (A–B) and the repolarization wave (C–D) from a cardiac muscle fiber.

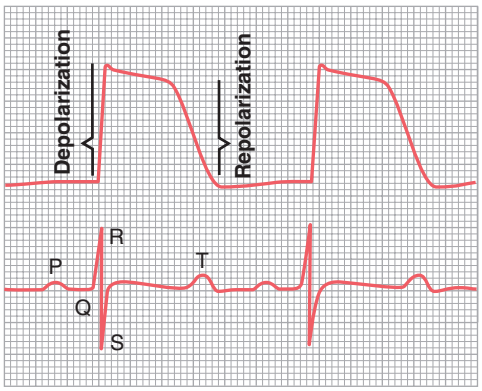

Figure 11.3 *Top*, Monophasic action potential from a ventricular muscle fiber during normal cardiac function showing rapid depolarization and then repolarization occurring slowly during the plateau stage but rapidly toward the end. *Bottom*, Electrocardiogram recorded simultaneously.

The lower half of **Fig. 11.3** shows a simultaneous recording of the ECG from this same ventricle. Note that the QRS waves appear at the beginning of the monophasic action potential, and the T wave appears at the end. Note especially that *no potential is recorded in the ECG when the ventricular muscle is either completely polarized or completely depolarized*. Only when the muscle is partly polarized and partly depolarized does current flow from one part of the ventricles to another part, and therefore current also flows to the surface of the body to produce the ECG waves.

RELATIONSHIP OF ATRIAL AND VENTRICULAR CONTRACTION TO THE ELECTROCARDIOGRAM WAVES

Before contraction of muscle can occur, depolarization must spread through the muscle to initiate the chemical processes of contraction. Refer again to **Fig. 11.1**; the P wave occurs at the beginning of contraction of the atria, and the QRS complex of waves occurs at the beginning of contraction of the ventricles. The ventricles remain contracted until after repolarization has occurred—that is, until after the end of the T wave.

The atria repolarize about 0.15 to 0.20 second after termination of the P wave, which is also approximately when the QRS complex is being recorded in the ECG. Therefore, the atrial repolarization wave, known as the *atrial T wave*, is usually obscured by the much larger QRS complex. For this reason, an atrial T wave is seldom observed on the ECG.

The ventricular repolarization wave is the T wave of the normal ECG. Ordinarily, ventricular muscle begins to repolarize in some fibers about 0.20 second after the beginning of the depolarization wave (the QRS complex), but in many other fibers, it takes as long as 0.35 second. Thus, the process of ventricular repolarization extends over a long period, about 0.15 second. For this reason, the T wave in the normal ECG is a prolonged wave, but the voltage of the T wave is considerably less than the voltage of the QRS complex, partly because of its prolonged length.

Sometimes, a small positive deflection (U wave) can be observed after the T wave. Although its origin is uncertain, this U wave may represent late repolarization of the Purkinje system or delayed repolarization of mid-myocardial cells (M cells) and is often more prominent at low heart rates or with low potassium levels (hypokalemia).

ELECTROCARDIOGRAPHIC VOLTAGE AND TIME CALIBRATION AND DISPLAY

All recordings of ECGs are made with appropriate calibration lines on the display grid. Historically, ECGs were recorded electronically and printed onto paper; ECGs are now usually displayed digitally. As shown in **Fig. 11.1**, the horizontal calibration lines are arranged so that 10 of the small line divisions upward or downward in the standard ECG represent 1 millivolt, with positivity in the upward direction and negativity in the downward direction.

The vertical lines on the ECG are time calibration lines. A typical ECG is run at a speed of 25 millimeters per second, although faster speeds are sometimes used. Therefore, each 25 millimeters in the horizontal direction is 1 second, and each 5-millimeter segment, indicated by the dark vertical lines, represents 0.20 second. The 0.20-second intervals are then broken into five smaller intervals by thin lines, each of which represents 0.04 second.

Normal Voltages in the Electrocardiogram. The recorded voltages of the waves in the normal ECG depend on the manner in which the electrodes are applied to the surface of the body and how close the electrodes are to the heart. When one electrode is placed directly over the ventricles, and a second electrode is placed elsewhere on the body remote from the heart, the voltage of the QRS complex may be as high as 3 to 4 millivolts. Even this voltage is small in comparison with the monophasic action potential of 110 millivolts recorded directly at the heart muscle membrane. When ECGs are recorded from electrodes on the two arms or on one arm and one leg, the voltage of the QRS complex usually is 1.0 to 1.5 millivolts from the top of the R wave to the bottom of the S wave, the voltage of the P wave is between 0.1 and 0.3 millivolts, and the voltage of the T wave is between 0.2 and 0.3 millivolts. These voltages may be even smaller when ECGs are recorded on people with more tissue surrounding the chest wall, including breast, fat, or muscle tissue.

P-Q or P-R Interval. The time between the beginning of the P wave and the beginning of the QRS complex is the interval between the beginning of electrical excitation of the atria and the beginning of excitation of the ventricles. This period is called the *P-Q interval*. The normal P-Q interval is about 0.16 second. (Often, this interval is called the *P-R interval* because the Q wave is likely to be absent.) The P-R interval includes the time for atrial depolarization (P wave) and conduction through the atrioventricular (AV) node and His-Purkinje system. The P-R interval shortens at faster heart rates due to increased sympathetic or decreased parasympathetic activity, which increases atrioventricular node conduction speed. Conversely, the P-R interval lengthens with slower heart rates as a consequence of slower atrioventricular nodal conduction caused by increased parasympathetic tone or withdrawal of sympathetic activity.

QRS Interval. The QRS complex includes the Q wave, the R wave, and the S wave and represents the time of ventricular depolarization. The normal QRS duration is about 0.08 second and is considered slightly prolonged after 0.10 second and abnormal when longer than 0.12 second. The QRS duration increases when electrical conduction takes longer to travel through ventricular muscle.

Q-T Interval. Contraction of the ventricle lasts almost from the beginning of the Q wave (or R wave, if the Q wave is absent) to the end of the T wave. This interval is called the *Q-T interval* and ordinarily is about 0.35 second. The Q-T interval is shorter at faster heart rates and longer at lower heart rates. Measurement of the Q-T interval is often corrected for the heart rate (QTc) and is usually calculated by dividing the Q-T interval by the square root of the R-R interval (see next section).

Heart Rate as Determined From the Electrocardiogram. The rate of the heartbeat can be determined easily from an ECG because the heart rate is the reciprocal of the time interval between two successive heartbeats (the R-R interval). If the interval between two beats as determined from the time calibration lines is 1 second, the heart rate is 60 beats/min. The normal interval between two successive QRS complexes in an adult is about 0.83 second, which is a heart rate of 60/0.83 times/min, or 72 beats/min.

FLOW OF CURRENT AROUND THE HEART DURING THE CARDIAC CYCLE

Recording Electrical Potentials From a Partially Depolarized Mass of Syncytial Cardiac Muscle

Fig. 11.4 shows a syncytial mass of cardiac muscle that has been stimulated at its most central point. Before stimulation, all the exteriors of the muscle cells had been positive, and the interiors had been negative. For reasons presented in Chapter 5 in the discussion of membrane potentials, as soon as an area of cardiac syncytium becomes depolarized, negative charges leak to the outsides

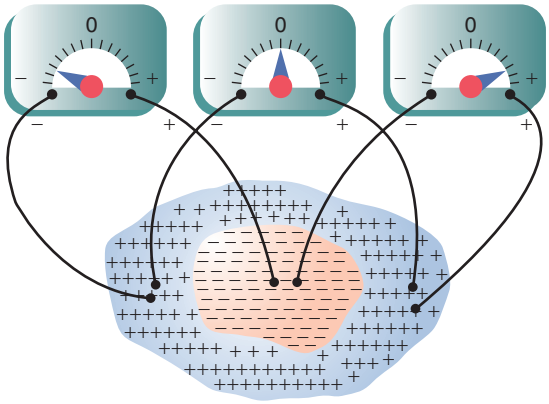

Figure 11.4 Instantaneous potentials develop on the surface of a cardiac muscle mass that has been depolarized in its center.

of the depolarized muscle fibers, making this part of the surface electronegative, as represented by the minus signs in **Fig. 11.4**. The remaining surface of the heart, which is still polarized, is represented by the plus signs. Therefore, a meter connected with its negative terminal on the area of depolarization and its positive terminal on one of the still polarized areas, as shown to the right in the figure, records positively.

Two other electrode placements and meter readings are also demonstrated in **Fig. 11.4**. These placements and readings should be studied carefully, and the reader should be able to explain the causes of the respective meter readings. Because the depolarization spreads in all directions through the heart, the potential differences shown in the figure persist for only a few thousandths of a second, and the actual voltage measurements can be accomplished only with a high-speed recording apparatus.

Flow of Electrical Currents in the Chest Around the Heart

Fig. 11.5 shows the ventricular muscle lying within the chest. Even the lungs, although mostly filled with air, conduct electricity to a surprising extent, and fluids in other tissues surrounding the heart conduct electricity even more easily. Therefore, the heart is actually suspended in a conductive medium. When one portion of the ventricles depolarizes and therefore becomes electronegative with respect to the remainder, electrical current flows from the depolarized area to the polarized area in large circuitous routes, as noted in the figure.

It should be recalled from the discussion of the Purkinje system in Chapter 10 that the cardiac impulse first arrives in the ventricles in the septum and shortly thereafter spreads to the inside surfaces of the remainder of the ventricles, as shown by the red areas and the negative signs in **Fig. 11.5**. This process provides electronegativity on the insides of the ventricles and electropositivity on the outer walls of the ventricles, with electrical current flowing through the fluids surrounding the ventricles along elliptical paths, as demonstrated by the curving arrows in the figure. If one algebraically averages all the lines of

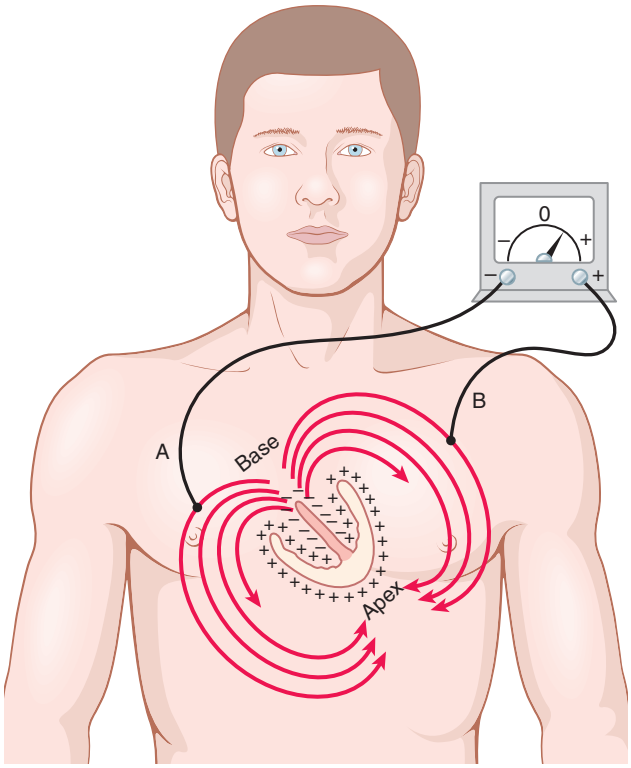

Figure 11.5 Flow of current in the chest around partially depolarized ventricles. *A* and *B* are electrodes.

current flow (the elliptical lines), *the average current flow occurs with negativity toward the base of the heart and with positivity toward the apex.*

During most of the remainder of the depolarization process, current also continues to flow in this same direction, whereas depolarization spreads from the endocardial surface outward through the ventricular muscle mass. Then, immediately before depolarization has completed its course through the ventricles, the average direction of current flow reverses for about 0.01 second, flowing from the ventricular apex toward the base, because the last part of the heart to become depolarized are the outer walls of the ventricles near the base of the heart.

Thus, in normal heart ventricles, current flows from negative to positive primarily in the direction from the base of the heart toward the apex during almost the entire cycle of depolarization, except at the very end. If a meter is connected to electrodes on the surface of the body, as shown in **Fig. 11.5**, the electrode nearer the base will be negative, whereas the electrode nearer the apex will be positive, and the recording meter will show a positive recording in the ECG.

ELECTROCARDIOGRAPHIC LEADS

Three Standard Bipolar Limb Leads

Fig. 11.6 shows electrical connections between the patient's limbs and the electrocardiograph for recording ECGs from the so-called *standard bipolar limb leads.*

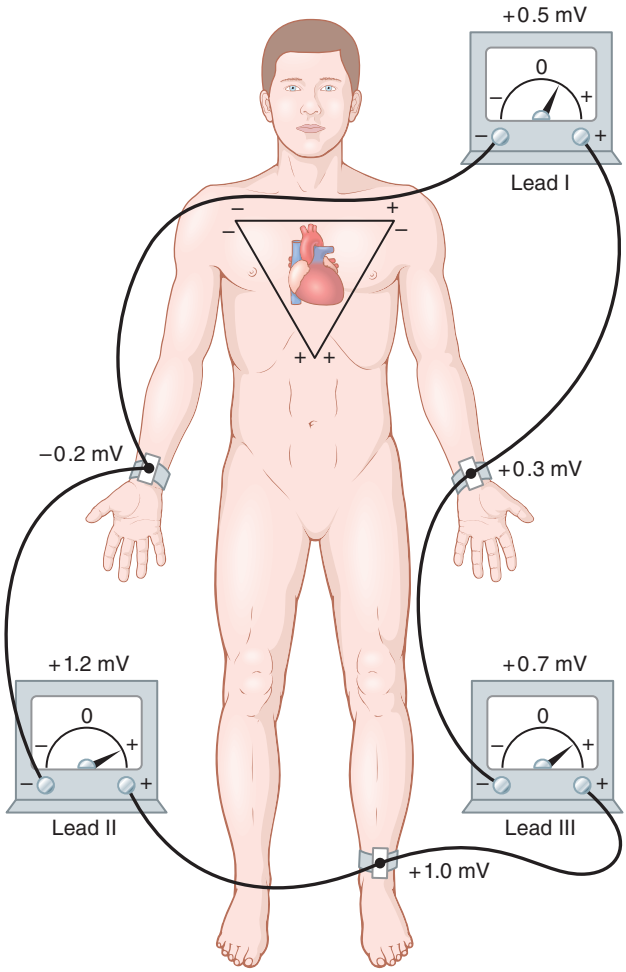

Figure 11.6 Conventional arrangement of electrodes for recording the standard electrocardiographic leads. Einthoven's triangle is superimposed on the chest.

The term *bipolar* means that the ECG is recorded from two electrodes located on different sides of the heart—in this case, on the limbs. Thus, a lead is not a single wire connecting from the body but a combination of two wires and their electrodes to make a complete circuit between the body and the electrocardiograph. The electrocardiograph in each case is represented by an electrical meter in the diagram, although the actual electrocardiograph is a high-speed, computer-based system with an electronic display.

Lead I. In recording limb lead I, the negative terminal of the electrocardiograph is connected to the right arm, and the positive terminal is connected to the left arm. Therefore, when the point where the right arm connects to the chest is electronegative with respect to the point where the left arm connects, the electrocardiograph records positively—that is, above the zero-voltage line in the ECG. When the opposite is true, the electrocardiograph records below the line.

Lead II. To record limb lead II, the negative terminal of the electrocardiograph is connected to the right arm and the positive terminal is connected to the left leg. Therefore, when the right arm is negative with respect to the left leg, the electrocardiograph records positively.

Lead III. To record limb lead III, the negative terminal of the electrocardiograph is connected to the left arm, and the positive terminal is connected to the left leg. This configuration means that the electrocardiograph records positively when the left arm is negative with respect to the left leg.

Einthoven's Triangle. In **Fig. 11.6**, the triangle, called *Einthoven's triangle*, is drawn around the area of the heart. This triangle illustrates that the two arms and left leg form apices of a triangle surrounding the heart. The two apices at the upper part of the triangle represent the points at which the two arms connect electrically with the fluids around the heart, and the lower apex is the point at which the left leg connects with the fluids.

Einthoven's Law. Einthoven's law states that if the ECGs are recorded simultaneously with the three limb leads, the sum of the potentials recorded in leads I and III will equal the potential in lead II:

Lead I potential + Lead III potential = Lead II potential

In other words, if the electrical potentials of any two of the three bipolar limb electrocardiographic leads are known at any given instant, the third one can be determined by simply summing the first two. Note, however, that the positive and negative signs of the different leads must be observed when making this summation.

For instance, let us assume that momentarily, as noted in **Fig. 11.6**, the right arm is −0.2 millivolts (negative) with respect to the average potential in the body, the left arm is +0.3 millivolts (positive), and the left leg is +1.0 millivolts (positive). Observing the meters in the figure, one can see that lead I records a positive potential of +0.5 millivolts because this is the summation between the −0.2 millivolts on the right arm and the +0.3 millivolts on the left arm. Similarly, lead III records a positive potential of +0.7 millivolts, and lead II records a positive potential of +1.2 millivolts because these are the instantaneous potential differences between the respective pairs of limbs.

Now, note that the sum of the voltages in leads I and III equals the voltage in lead II; that is, 0.5 plus 0.7 equals 1.2. Mathematically, this principle, called Einthoven's law, holds true at any given instant while the three "standard" bipolar ECGs are being recorded.

Normal Electrocardiograms Recorded From the Three Standard Bipolar Limb Leads. **Fig. 11.7** shows recordings of the ECGs in leads I, II, and III. It is obvious that the ECGs in these three leads are similar to one another because they all record positive P waves and positive T waves, and the major portion of the QRS complex is also positive in each ECG. On analysis of

Figure 11.7 Normal electrocardiograms recorded from the three standard electrocardiographic leads (I–III).

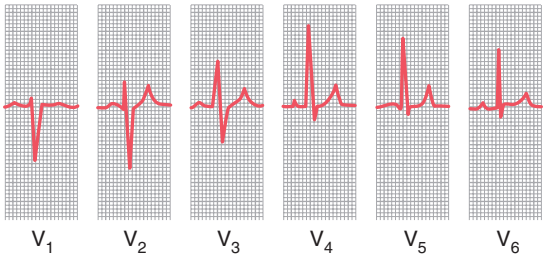

Figure 11.9 Normal electrocardiograms recorded from the six standard chest leads.

the three ECGs, it can be shown, with careful measurements and proper observance of polarities, that at any given instant, the sum of the potentials in leads I and III equals the potential in lead II, thus illustrating the validity of Einthoven's law.

Because the recordings from all the bipolar limb leads are similar to one another, it does not matter greatly which lead is recorded when one wants to diagnose different cardiac arrhythmias, because diagnosis of arrhythmias depends mainly on the time relationships between the different waves of the cardiac cycle. However, when one wants to diagnose damage in the ventricular or atrial muscle or in the Purkinje conducting system, it matters greatly which leads are recorded, because abnormalities of cardiac muscle contraction or cardiac impulse conduction change the patterns of the ECGs markedly in some leads yet may not affect other leads. Electrocardiographic interpretation of these two types of conditions—cardiomyopathies and cardiac arrhythmias—is discussed separately in Chapters 12 and 13.

Precordial Leads

Often ECGs are recorded with one electrode placed on the anterior surface of the chest directly over the heart at one of the points shown in **Fig. 11.8**. This electrode is connected to the positive terminal of the electrocardiograph, and the negative electrode, called the *indifferent electrode* or *Wilson central terminal*, is connected through equal electrical resistances to the right arm, left arm, and left leg all at the same time, as also shown in the figure. Usually, six standard chest leads are recorded, one at a time, from the anterior chest wall, with the chest electrode being placed sequentially at the six points shown in the diagram. The different recordings are known as leads V_1, V_2, V_3, V_4, V_5, and V_6.

Fig. 11.9 illustrates the ECGs of the healthy heart as recorded from these six standard chest leads. Because the heart surfaces are close to the chest wall, each chest lead records mainly the electrical potential of the cardiac musculature immediately beneath the electrode. Therefore, relatively minute abnormalities in the ventricles, particularly in the anterior ventricular wall, can cause marked changes in the ECGs recorded from individual chest leads.

In leads V_1 and V_2, the QRS recordings of the normal heart are mainly negative because, as shown in **Fig. 11.8**, the chest electrode in these leads is closer to the base of the heart than to the apex, and the base of the heart is the

direction of electronegativity during most of the ventricular depolarization process. Conversely, the QRS complexes in leads V_4, V_5, and V_6 are mainly positive because the chest electrode in these leads is closer to the heart apex, which is the direction of electropositivity during most of depolarization.

Augmented Limb Leads

Another system of leads in wide use is the *augmented limb leads*. In this type of recording, two of the limbs are connected through electrical resistances to the negative terminal of the electrocardiograph, and the third limb is connected to the positive terminal. When the positive terminal is on the right arm, the lead is known as the aVR lead; when on the left arm, it is known as the aVL lead; and when on the left leg, it is known as the aVF lead.

Normal recordings of the augmented limb leads are shown in **Fig. 11.10**. They are all similar to the standard limb lead recordings, except that the recording from the aVR lead is inverted. (Why does this inversion occur? Study the polarity connections to the electrocardiograph to determine the answer to this question.)

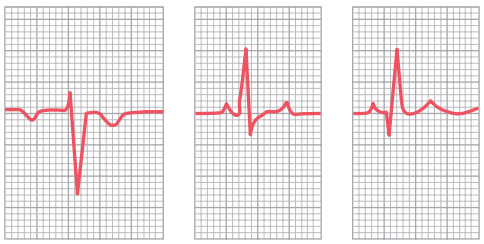

Figure 11.10 Normal electrocardiograms recorded from the three augmented unipolar limb leads.

Electrocardiographic Display

Leads are typically displayed into three groupings, as in **Fig. 11.11**: the standard bipolar limb leads (I, II, III) followed by the augmented leads (aVR, aVL, and aVF) and then the precordial leads (V_1–V_6).

Ambulatory Electrocardiography

Standard ECGs provide an assessment of cardiac electrical events over a brief duration, usually while the patient is resting. In conditions associated with infrequent but important abnormalities of cardiac rhythms, it may be useful to examine the ECG over a longer period, thereby permitting evaluation of changing cardiac electrical phenomena that are transient and may be missed with a standard resting ECG. Extending the ECG to allow assessment of cardiac electrical events while the patient is ambulating during normal daily activities is called *ambulatory electrocardiography*.

Ambulatory electrocardiographic monitoring is typically used when a patient demonstrates symptoms that are thought to be caused by transient arrhythmias or other transient cardiac abnormalities. These symptoms may include chest pain, syncope (fainting) or near syncope, dizziness, and irregular heartbeats (palpitations). The crucial information needed to diagnose serious transient arrhythmias or other cardiac conditions is a recording of an ECG during the precise time that the symptom is occurring. These devices can also be used to detect asymptomatic cardiac arrhythmias such as atrial fibrillation that may increase the risk of embolus formation, which can, in turn, cause strokes. Because the daily variability in the frequency of arrhythmias is substantial, detection often requires ambulatory electrocardiographic monitoring throughout the day and often for several days.

There are several categories of ambulatory electrocardiographic recorders. Continuous recorders (Holter monitors) are typically used for 24 to 48 hours to investigate the relationship between symptoms and electrocardiographic events that are likely to occur within that time

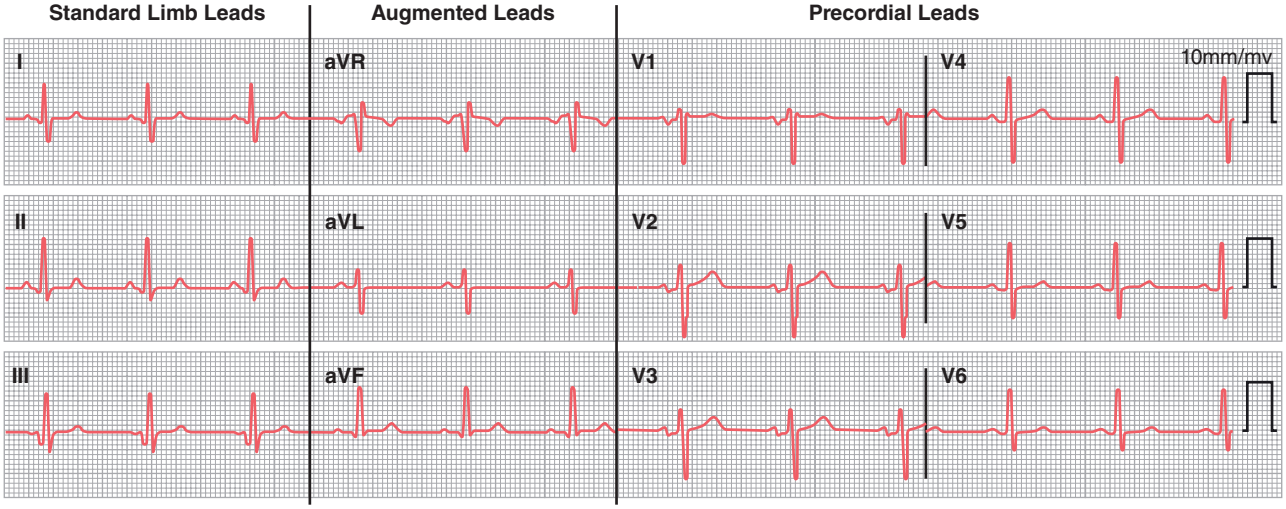

Figure 11.11 Normal 12-lead electrocardiogram.

frame. Intermittent event recorders are used for longer periods (weeks to months) to provide brief intermittent recordings for detection of events that occur infrequently; these recordings are usually initiated by the patient when experiencing symptoms. In some cases, a small device, about the size of a large paper clip and called an ***implantable loop recorder***, is implanted just under the skin in the chest to monitor the heart's electrical activity continuously for as long as 2 to 3 years. The device can be programmed to initiate a recording when the heart rate falls below, or rises above, a predetermined level, or it can be activated manually by the patient when a symptom such as dizziness occurs. Improvements in solid-state digital technology and recorders equipped with microprocessors now permit continuous or intermittent transmission of digital electrocardiographic data over telephone lines, and sophisticated software systems provide rapid online computerized analysis of the data as they are acquired. Newer wearable devices, including watches or handheld electrocardiographic monitoring devices, have been developed for home-based heart rhythm monitoring.

CHAPTER 12

Electrocardiographic Interpretation of Cardiac Muscle and Coronary Blood Flow Abnormalities: Vectorial Analysis

From the discussion in Chapter 10 of impulse transmission through the heart, it is obvious that changes in the pattern of this transmission can cause abnormal electrical potentials around the heart and, consequently, alter the shapes of the waves in the electrocardiogram (ECG). For this reason, many serious abnormalities of the heart muscle can be diagnosed by analyzing the contours of the waves in the different electrocardiographic leads.

VECTORIAL ANALYSIS OF ELECTROCARDIOGRAMS

VECTORS CAN REPRESENT ELECTRICAL POTENTIALS

To understand how cardiac abnormalities affect the contours of the ECG, one must first become familiar with the concept of *vectors* and *vectorial analysis* as applied to electrical potentials in and around the heart. In Chapter 11, we pointed out that heart current flows in a particular direction in the heart at a given instant during the cardiac cycle. A vector is an arrow that points in the direction of the electrical potential generated by the current flow, *with the arrowhead in the positive direction*. Also, by convention, the length of the arrow is drawn *proportional to the voltage of the potential*.

Resultant Vector in the Heart at Any Given Instant. The shaded area and the minus signs in **Fig. 12.1** show depolarization of the ventricular septum and of parts of the apical endocardial walls of the two ventricles. At the instant of heart excitation, electrical current flows between the depolarized areas inside the heart and the nondepolarized areas on the outside of the heart, as indicated by the long elliptical arrows. Some current also flows inside the heart chambers directly from the depolarized areas toward the still polarized areas. Overall, considerably more current flows downward from the base of the ventricles toward the apex than in the upward direction. Therefore, the summated vector of the generated potential at this particular instant, called the *instantaneous mean vector*, is represented by the long *black arrow* drawn through the center of the ventricles in a direction from the base toward the apex. Furthermore, because the summated current is quite large, the potential is large, and the vector is long.

THE DIRECTION OF A VECTOR IS DENOTED IN TERMS OF DEGREES

When a vector is exactly horizontal and directed toward the person's left side, the vector is said to extend in the direction of 0 degrees, as shown in **Fig. 12.2**. From this zero reference point, the scale of vectors rotates clockwise; when the vector extends from above and straight downward, it has a direction of +90 degrees; when it extends from the person's left to right, it has a direction of +180 degrees; and when it extends straight upward, it has a direction of −90 (or +270) degrees.

In a normal heart, the average direction of the vector during spread of the depolarization wave through the ventricles, called the *mean QRS vector*, is about +59 degrees, which is shown by vector *A* drawn through the center of **Fig. 12.2** in the +59-degree direction. This means that during most of the depolarization wave, the apex of the heart remains positive with respect to the base of the heart, as discussed later in this chapter.

AXIS FOR EACH STANDARD BIPOLAR LEAD AND EACH UNIPOLAR LIMB LEAD

In Chapter 11, the three standard bipolar and the three unipolar limb leads are described. Each lead is actually a pair of electrodes connected to the body on opposite sides of the heart, and the direction from negative electrode to positive electrode is called the *axis* of the lead. Lead I is recorded from two electrodes placed, respectively, on the two arms. Because the electrodes lie exactly in the horizontal direction, with the positive electrode to the left, the axis of lead I is 0 degrees.

In recording lead II, electrodes are placed on the right arm and left leg. The right arm connects to the torso in the upper right-hand corner, and the left leg connects in the lower left-hand corner. Therefore, the direction of this lead is about +60 degrees.

By similar analysis, lead III has an axis of about +120 degrees; lead aVR, +210 degrees; lead aVF, +90 degrees; and lead aVL, −30 degrees. The directions of the axes of all these leads are shown in **Fig. 12.3**, which is known as the *hexagonal reference system*. The polarities of the electrodes are shown by the plus and minus signs in the

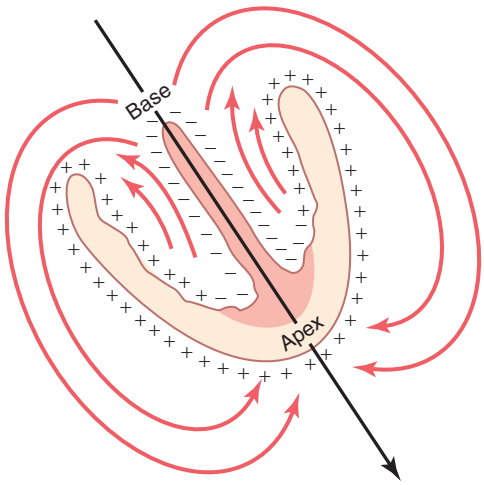

Figure 12.1 Mean vector through the partially depolarized ventricles goes from the base of the left ventricle toward the apex.

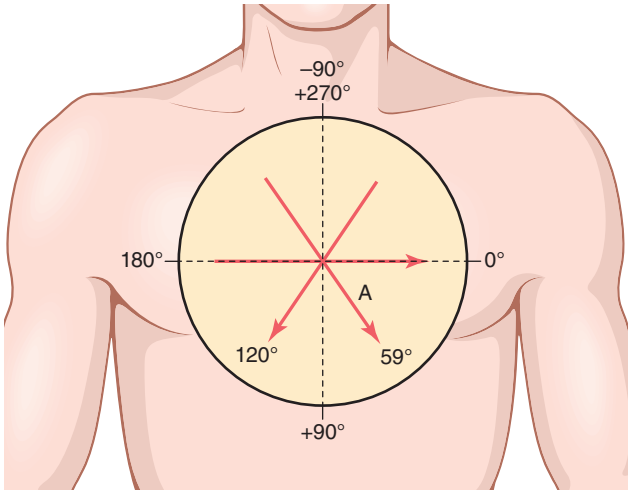

Figure 12.2 Vectors drawn to represent potentials for several different hearts and the axis of the potential (expressed in degrees) for each heart.

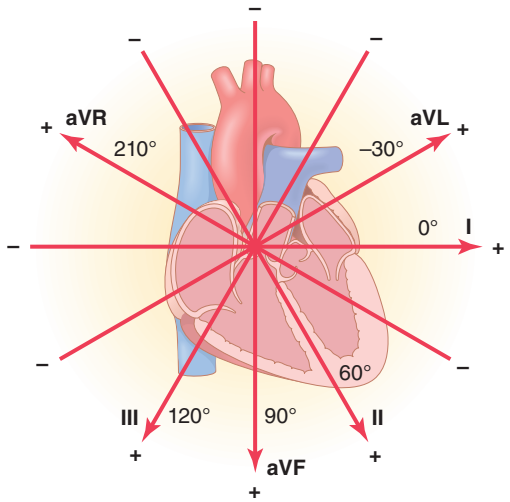

Figure 12.3 Axes of the three bipolar and three unipolar leads.

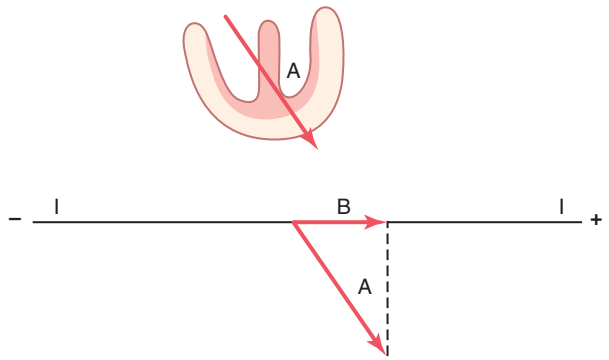

Figure 12.4 Determination of a projected vector B along the axis of lead I when vector A represents the instantaneous potential in the ventricles.

figure. *The reader must learn these axes and their polarities, particularly for the bipolar limb leads I, II, and III, to understand the remainder of this chapter.*

VECTORIAL ANALYSIS OF POTENTIALS RECORDED IN DIFFERENT LEADS

Fig. 12.4 shows a partially depolarized heart, with vector *A* representing the instantaneous mean direction of current flow in the ventricles. In this case, the direction of the vector is +55 degrees, and the voltage of the potential, represented by the length of vector *A*, is 2 millivolts. In the diagram below the heart, vector *A* is shown again, and a line is drawn to represent the axis of lead I in the 0-degree direction. To determine how much of the voltage in vector *A* will be recorded in lead I, a line perpendicular to the axis of lead I is drawn from the tip of vector *A* to the lead I axis, and a so-called *projected vector (B)* is drawn along the lead I axis. The arrow of this projected vector points toward the positive end of the lead I axis, which means that the potential momentarily being recorded in the ECG of lead I is positive. The instantaneous recorded voltage will be equal to the length of *B* divided by the length of *A* times 2 millivolts, or about 1 millivolt.

Fig. 12.5 shows another example of vectorial analysis. In this example, vector *A* represents the electrical potential and its axis at a given instant during ventricular depolarization in a heart in which the left side of the heart depolarizes more rapidly than the right side. In this case, the instantaneous vector has a direction of 100 degrees, and its voltage is again 2 millivolts. To determine the potential actually recorded in lead I, we draw a perpendicular line from the tip of vector *A* to the lead I axis and find projected vector *B*. Vector *B* is very short, and this time it is in the negative direction, indicating that at this particular instant, the recording in lead I will be negative (below the zero line in the ECG), and the voltage recorded will be small, about −0.3 millivolts. This figure demonstrates that *when the vector in the heart is in a direction almost perpendicular to the axis of the lead, the voltage recorded in the ECG of this lead is very low*. Conversely, *when the heart vector has almost exactly the same axis as*

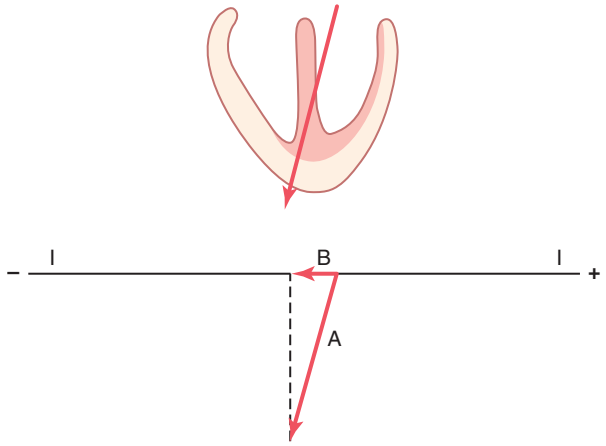

Figure 12.5 Determination of the projected vector B along the axis of lead I when vector A represents the instantaneous potential in the ventricles.

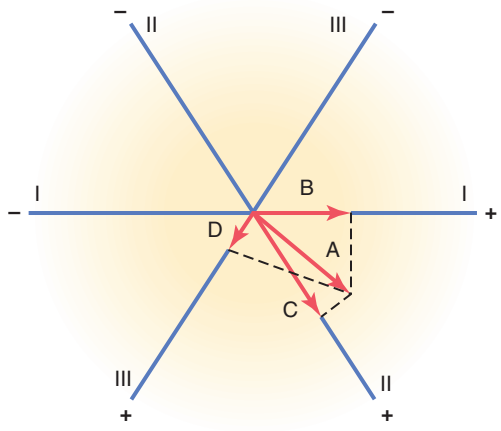

Figure 12.6 Determination of projected vectors in leads I, II, and III when vector A represents the instantaneous potential in the ventricles.

the lead axis, essentially the entire voltage of the vector will be recorded.

Vectorial Analysis of Potentials in the Three Standard Bipolar Limb Leads. In **Fig. 12.6**, vector *A* depicts the instantaneous electrical potential of a partially depolarized heart. To determine the potential recorded at this instant in the ECG for each one of the three standard bipolar limb leads, perpendicular lines (the *dashed lines*) are drawn from the tip of vector *A* to the three lines representing the axes of the three different standard leads, as shown in the figure. The projected vector *B* depicts the potential recorded at that instant in lead I, projected vector *C* depicts the potential in lead II, and projected vector *D* depicts the potential in lead III. In each of these, the record in the ECG is positive—that is, above the zero line—because the projected vectors point in positive directions along the axes of all the leads. The potential in lead I (vector *B*) is about half of that of the actual potential in the heart (vector *A*). In lead II (vector *C*), the potential is almost equal to that in the heart and in lead III (vector *D*) it is about one-third that in the heart.

An identical analysis can be used to determine potentials recorded in augmented limb leads, except that the respective axes of the augmented leads (see **Fig. 12.3**) are used in place of the standard bipolar limb lead axes used for **Fig. 12.6**.

VECTORIAL ANALYSIS OF THE NORMAL ELECTROCARDIOGRAM

VECTORS THAT OCCUR AT SUCCESSIVE INTERVALS DURING DEPOLARIZATION OF THE VENTRICLES—THE QRS COMPLEX

When the cardiac impulse enters the ventricles through the atrioventricular bundle, the first part of the ventricles to become depolarized is the left endocardial surface of the septum. Then, depolarization spreads rapidly to involve both endocardial surfaces of the septum, as shown by the darker shaded portion of the ventricle in **Fig. 12.7A**. Next, depolarization spreads along the endocardial surfaces of the remainder of the two ventricles, as shown in **Fig. 12.7B–C**. Finally, it spreads through the ventricular muscle to the outside of the heart, as shown progressively in **Fig. 12.7C–E**.

At each stage in **Fig. 12.7A–E**, the instantaneous mean electrical potential of the ventricles is represented by a red vector superimposed on the ventricle in each figure. Each of these vectors is then analyzed by the method described in the preceding section to determine the voltages that will be recorded at each instant in each of the three standard electrocardiographic leads. To the right in each figure is shown progressive development of the electrocardiographic QRS complex. *Keep in mind that a positive vector in a lead will cause recording in the ECG above the zero line, whereas a negative vector will cause recording below the zero line.*

Before proceeding with further consideration of vectorial analysis, it is essential that this analysis of the successive normal vectors presented in **Fig. 12.7** be understood. Each of these analyses should be studied in detail by the procedure given here. A short summary of this sequence follows.

In **Fig. 12.7A**, the ventricular muscle has just begun to be depolarized, representing an instant about 0.01 second after the onset of depolarization. At this time, the vector is short because only a small portion of the ventricles—the septum—is depolarized. Therefore, all electrocardiographic voltages are low, as recorded to the right of the ventricular muscle for each of the leads. The voltage in lead II is greater than the voltages in leads I and III because the heart vector extends mainly in the same direction as the axis of lead II.

In **Fig. 12.7B**, which represents about 0.02 second after onset of depolarization, the heart vector is long because much of the ventricular muscle mass has become depolarized. Therefore, the voltages in all electrocardiographic leads have increased.

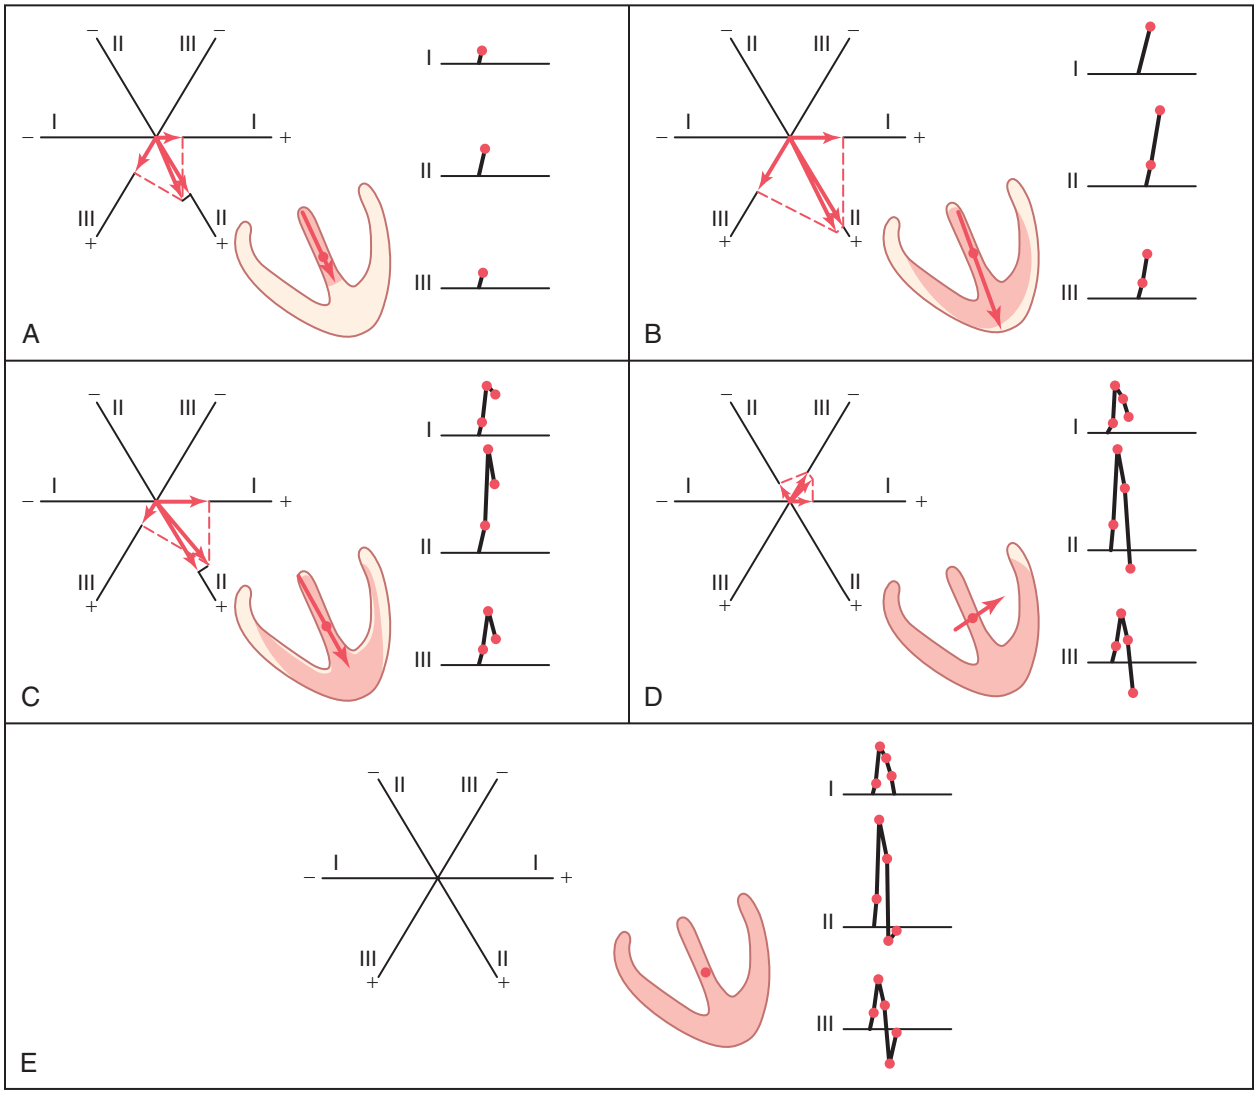

Figure 12.7 Shaded areas of the ventricles are depolarized (–); nonshaded areas are still polarized (+). Shown are the ventricular vectors and QRS complexes 0.01 second after onset of ventricular depolarization (A), 0.02 second after onset of depolarization (B), 0.035 second after onset of depolarization (C), 0.05 second after onset of depolarization (D), and after depolarization of the ventricles is complete, 0.06 second after onset (E).

In **Fig. 12.7C**, about 0.035 second after onset of depolarization, the heart vector is becoming shorter, and the recorded electrocardiographic voltages are lower, because the outside of the heart apex is now electronegative, neutralizing much of the positivity on the other epicardial surfaces of the heart. Also, the axis of the vector is beginning to shift toward the left side of the chest because the left ventricle is slightly slower to depolarize than the right ventricle. Therefore, the ratio of the voltage in lead I to that in lead III is increasing.

In **Fig. 12.7D**, about 0.05 second after onset of depolarization, the heart vector points toward the base of the left ventricle, and it is short because only a minute portion of the ventricular muscle is still polarized positive. Because of the direction of the vector at this time, the voltages recorded in leads II and III are both negative—that is, below the line—whereas the voltage of lead I is still positive.

In **Fig. 12.7E**, about 0.06 second after onset of depolarization, the entire ventricular muscle mass is depolarized so that no current flows around the heart and no electrical potential is generated. The vector becomes zero, and the voltages in all leads become zero.

Thus, the QRS complexes are completed in the three standard bipolar limb leads.

Sometimes the QRS complex has a slight negative depression at its beginning in one or more of the leads, which is not shown in **Fig. 12.7**; this negative deflection is the Q wave. When it occurs, it is caused by initial depolarization of the left side of the septum before the right side, which creates a weak vector from left to right for a fraction of a second before the usual base to apex vector occurs. The major positive deflection shown in **Fig. 12.7** is the R wave, and the final negative deflection is the S wave.

ELECTROCARDIOGRAM DURING VENTRICULAR REPOLARIZATION—THE T WAVE

After the ventricular muscle has become depolarized, about 0.15 second later, repolarization begins and proceeds until complete, at about 0.35 second. This repolarization causes the T wave in the ECG.

Because the septum and endocardial areas of the ventricular muscle depolarize first, it seems logical that these areas should repolarize first as well. However, this is not the usual case, because the septum and other endocardial areas have a longer period of contraction than most of the external surfaces of the heart. Therefore, *the greatest portion of ventricular muscle mass to repolarize first is the entire outer surface of the ventricles, especially near the apex of the heart.* The endocardial areas, conversely, normally repolarize last. This sequence of repolarization is postulated to be caused by the high blood pressure inside the ventricles during contraction, which greatly reduces coronary blood flow to the endocardium, thereby slowing repolarization in the endocardial areas.

Because the outer apical surfaces of the ventricles repolarize before the inner surfaces, the positive end of the overall ventricular vector during repolarization is toward the apex of the heart. *As a result, the normal T wave in all three bipolar limb leads is positive, which is also the polarity of most of the normal QRS complex.*

In **Fig. 12.8**, five stages of repolarization of the ventricles are denoted by progressive increase of the light tan areas—the repolarized areas. At each stage, the vector extends from the base of the heart toward the apex until it disappears in the last stage. At first, the vector is relatively small because the area of repolarization is small. Later, the vector becomes stronger because of greater degrees of repolarization. Finally, the vector becomes weaker again because the areas of depolarization still persisting become so slight that the total quantity of current flow decreases. These changes also demonstrate that the vector is greatest when about half the heart is in the polarized state and about half is depolarized.

The changes in the ECGs of the three standard limb leads during repolarization are noted under each of the ventricles, depicting the progressive stages of repolarization. Thus, over about 0.15 second, the period of time required for the entire process to take place, the T wave of the ECG is generated.

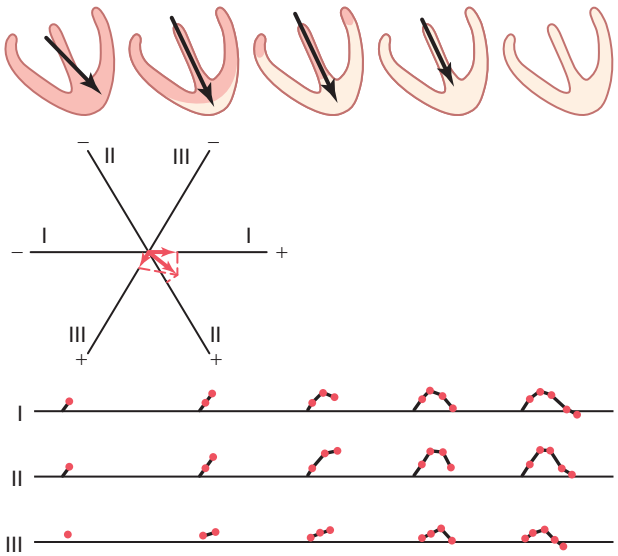

Figure 12.8 Generation of the T wave during repolarization of the ventricles, also showing vectorial analysis of the first stage of repolarization. The total time from the beginning of the T wave to its end is approximately 0.15 second.

ATRIAL DEPOLARIZATION—THE P WAVE

Depolarization of the atria begins in the sinus node and spreads in all directions over the atria. Therefore, the point of original electronegativity in the atria is at about the point of entry of the superior vena cava where the sinus node lies, and the direction of initial depolarization is denoted by the black vector in **Fig. 12.9**. Furthermore, the vector remains generally in this direction throughout the process of normal atrial depolarization. Because this direction is generally in the positive directions of the axes of the three standard bipolar limb leads I, II, and III, the ECGs recorded from the atria during depolarization are also usually positive in all three of these leads, as shown in **Fig. 12.9**. This record of atrial depolarization is known as the atrial P wave.

Repolarization of the Atria—the Atrial T Wave. Spread of depolarization through the atrial muscle is *much slower than in the ventricles* because the atria have no Purkinje system for fast conduction of the depolarization signal. Therefore, the musculature around the sinus node becomes depolarized a long time before the musculature in distal parts of the atria. Consequently, *the area in the atria that also becomes repolarized first is the sinus nodal region, the*

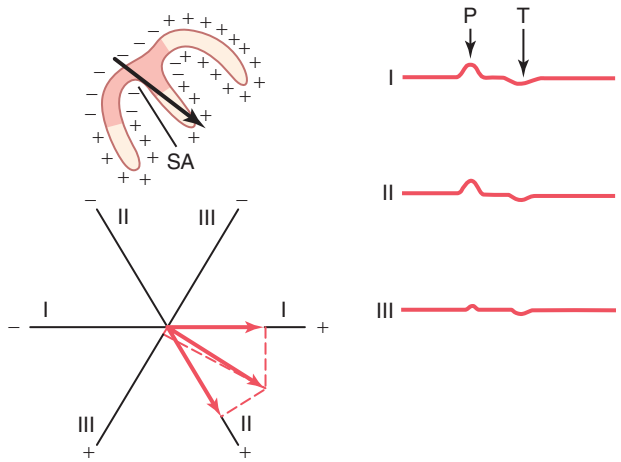

Figure 12.9 Depolarization of the atria and generation of the P wave showing the maximum vector through the atria and the resultant vectors in the three standard leads. At the *right* are the atrial P and T waves. *SA*, Sinoatrial node.

area that had originally become depolarized first. Thus, when repolarization begins, the region around the sinus node becomes positive with respect to the remainder of the atria. Therefore, the atrial repolarization vector is *backward to the vector of depolarization.* (Note that this is opposite to the effect that occurs in the ventricles.) Therefore, as shown to the right in **Fig. 12.9**, the so-called atrial T wave follows about 0.15 second after the atrial P wave, but this T wave is on the opposite side of the zero reference line from the P wave; that is, it is normally negative rather than positive in the three standard bipolar limb leads.

In a normal ECG, the *atrial* T wave appears at about the same time that the QRS complex of the ventricles appears. Therefore, it is almost always totally obscured by the large *ventricular* QRS complex, although in some very abnormal states it does appear in the recorded ECG.

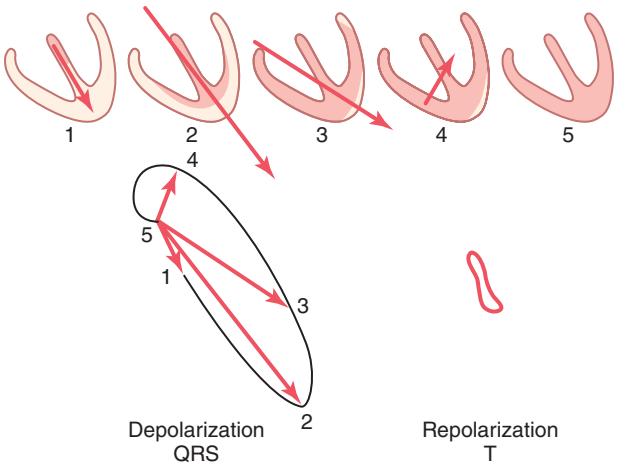

Figure 12.10 QRS and T vectorcardiograms.

Vectorcardiogram

As noted previously, the vector of current flow through the heart changes rapidly as the impulse spreads through the myocardium. It changes in two aspects. First, the vector increases and decreases in length because of increasing and decreasing voltage of the vector. Second, the vector changes direction because of changes in the average direction of the electrical potential from the heart. The *vectorcardiogram* depicts these changes at different times during the cardiac cycle, as shown in **Fig. 12.10**.

In the large vectorcardiogram of **Fig. 12.10**, point 5 is the *zero reference point*, and this point is the negative end of all the successive vectors. While the heart muscle is polarized between heartbeats, the positive end of the vector remains at the zero point because there is no vectorial electrical potential. However, as soon as current begins to flow through the ventricles at the beginning of ventricular depolarization, the positive end of the vector leaves the zero reference point.

When the septum first becomes depolarized, the vector extends downward toward the apex of the ventricles, but it is relatively weak, thus generating the first portion of the ventricular vectorcardiogram, as shown by the positive end of vector 1. As more of the ventricular muscle becomes depolarized, the vector becomes stronger and stronger, usually swinging slightly to one side. Thus, vector 2 of **Fig. 12.10** represents the state of depolarization of the ventricles about 0.02 second after vector 1. After another 0.02 second, vector 3 represents the potential, and vector 4 occurs in another 0.01 second. Finally, the ventricles become totally depolarized, and the vector becomes zero once again, as shown at point 5.

The elliptical figure generated by the positive ends of the vectors is called the *QRS vectorcardiogram.*

MEAN ELECTRICAL AXIS OF THE VENTRICULAR QRS AND ITS SIGNIFICANCE

The vectorcardiogram during ventricular depolarization (the QRS vectorcardiogram) shown in **Fig. 12.10** is that

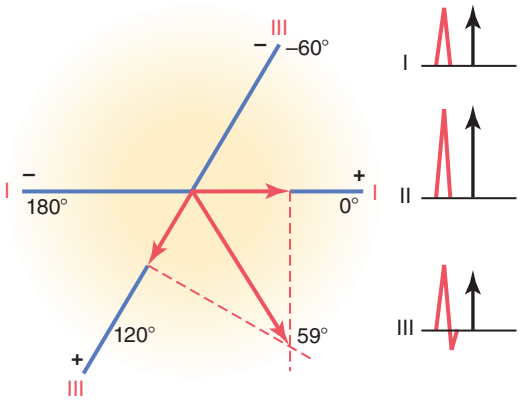

Figure 12.11 Plotting the mean electrical axis of the ventricles from two electrocardiographic leads (leads I and III).

of a normal heart. Note that during most of the cycle of ventricular depolarization, the direction of the electrical potential (negative to positive) is from the base of the ventricles toward the apex. This preponderant direction of the potential during depolarization from the base to the apex of the heart is called the *mean electrical axis of the ventricles.* The mean electrical axis of the normal ventricles is 59 degrees. In many pathological conditions of the heart, this direction changes markedly, sometimes even to opposite poles of the heart.

DETERMINING THE ELECTRICAL AXIS FROM STANDARD LEAD ELECTROCARDIOGRAMS

Clinically, the electrical axis of the heart is usually estimated from the standard bipolar limb lead ECGs rather than from the vectorcardiogram. **Fig. 12.11** shows a method for performing this estimation. After recording the standard leads, one determines the net potential and polarity of the recordings in leads I and III. In lead I of **Fig. 12.11**, the recording is positive, and in lead III, the recording is mainly positive but negative during part of

the cycle. If any part of a recording is negative, *this negative potential is subtracted from the positive part of the potential* to determine the *net potential* for that lead, as shown by the *arrow* to the right of the QRS complex for lead III. Then, each net potential for leads I and III is plotted on the axes of the respective leads, with the base of the potential at the point of intersection of the axes, as shown in **Fig. 12.11**.

To determine the vector of the total QRS ventricular mean electrical potential, one draws perpendicular lines (the *dashed lines* in the figure) from the apices of leads I and III, respectively. The point of intersection of these two perpendicular (dashed) lines represents, by vectorial analysis, the apex of the *mean* QRS vector in the ventricles, and the point of intersection of the lead I and lead III axes represents the negative end of the mean vector. Therefore, the *mean QRS vector* is drawn between these two points. The approximate average potential generated by the ventricles during depolarization is represented by the length of this mean QRS vector, and the mean electrical axis is represented by the direction of the mean vector. Thus, the orientation of the mean electrical axis of the normal ventricles, as determined in **Fig. 12.11**, is 59 degrees positive (+59 degrees).

ABNORMAL VENTRICULAR CONDITIONS THAT CAUSE AXIS DEVIATION

Although the mean electrical axis of the ventricles averages about 59 degrees, this axis can swing, even in a normal heart, from about 20 degrees to about 100 degrees. The causes of the normal variations are mainly anatomical differences in the Purkinje distribution system or in the musculature itself of different hearts. However, several abnormal conditions of the heart can cause axis deviation beyond the normal limits, as described below.

Change in the Position of the Heart in the Chest. If the heart is angulated to the left, the mean electrical axis of the heart also *shifts to the left*. Such shift occurs (1) at the end of deep expiration, (2) when a person lies down, because the abdominal contents press upward against the diaphragm, and (3) quite frequently in obese people, whose diaphragms normally press upward against the heart all the time as a result of increased visceral adiposity.

Likewise, angulation of the heart to the right causes the mean electrical axis of the ventricles to *shift to the right*. This shift occurs (1) at the end of deep inspiration, (2) when a person stands up, and (3) normally in tall, thin people whose hearts hang downward.

Ventricular Hypertrophy. When one ventricle hypertrophies greatly, *the axis of the heart shifts toward the hypertrophied ventricle* for two reasons. First, there is more muscle on the hypertrophied side of the heart than on the other side, which allows for generation of greater electrical potential on that side. Second, more time is required for the depolarization wave to travel through the hypertrophied ventricle than through the normal ventricle. Consequently, the *normal* ventricle becomes depolarized considerably in advance of the *hypertrophied* ventricle, and this situation causes a strong vector from the normal side of the heart toward the hypertrophied side, which remains strongly positively charged. Thus, the axis deviates toward the hypertrophied ventricle.

Vectorial Analysis of Left Axis Deviation Resulting From Left Ventricular Hypertrophy. **Fig. 12.12** shows the three standard bipolar limb lead ECGs. Vectorial analysis demonstrates left axis deviation, with the mean electrical axis pointing in the −15-degree direction. This is a typical ECG caused by increased muscle mass (hypertrophy) of the left ventricle. In this case, the axis deviation was caused by *hypertension* (high arterial blood pressure), which caused the left ventricle to hypertrophy so that it could pump blood against elevated systemic arterial pressure. A similar picture of left axis deviation occurs when the left ventricle hypertrophies as a result of *aortic valvular stenosis, aortic valvular regurgitation,* or *congenital heart conditions* in which the left ventricle enlarges while the right ventricle remains relatively normal in size.

Vectorial Analysis of Right Axis Deviation Resulting From Hypertrophy of the Right Ventricle. The ECG of **Fig. 12.13** shows intense right axis deviation, to an electrical axis of 170 degrees, which is 111 degrees to the right of the normal 59-degree mean ventricular QRS axis. The right axis deviation demonstrated in this figure was caused by hypertrophy of the right ventricle as a result of *congenital pulmonary valve stenosis*. Right axis deviation also can occur in other congenital heart conditions that cause hypertrophy of the right ventricle, such as *tetralogy of Fallot* and *interventricular septal defect*.

Bundle Branch Block Causes Axis Deviation. Ordinarily, the lateral walls of the two ventricles depolarize at almost the same instant because both the left and right

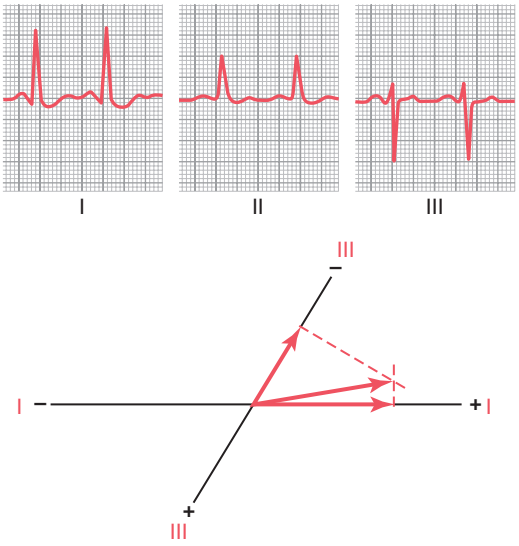

Figure 12.12 Left axis deviation in a *hypertensive heart (hypertrophic left ventricle)*. Note the slightly prolonged QRS complex as well.

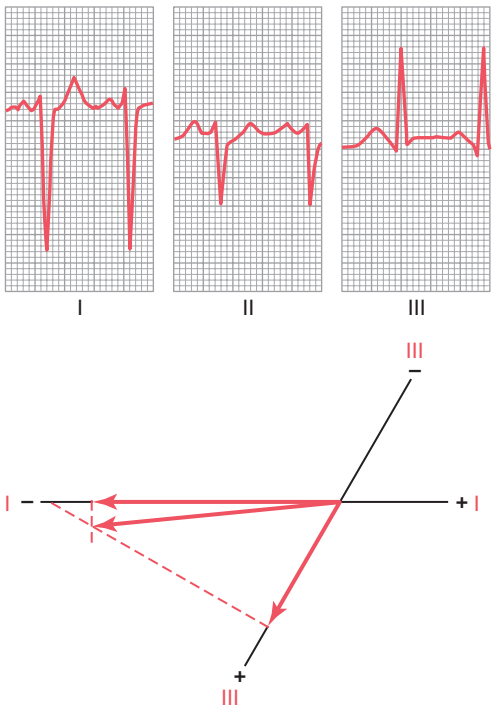

Figure 12.13 A high-voltage electrocardiogram for a person with *congenital pulmonary valve stenosis with right ventricular hypertrophy*. Intense right axis deviation and a slightly prolonged QRS complex are also seen.

bundle branches of the Purkinje system transmit the cardiac impulse to the two ventricular walls at almost the same time. As a result, the potentials generated by the two ventricles (on the two opposite sides of the heart) almost neutralize each other. However, if only one of the major bundle branches is blocked, the cardiac impulse spreads through the normal ventricle before it spreads through the other ventricle. Therefore, depolarization of the two ventricles does not occur, even nearly at the same time, and the depolarization potentials do not neutralize each other. As a result, axis deviation occurs as follows.

Vectorial Analysis of Left Axis Deviation in Left Bundle Branch Block. When the left bundle branch is blocked, cardiac depolarization spreads through the right ventricle two to three times as rapidly as through the left ventricle. Consequently, much of the left ventricle remains polarized for as long as 0.1 second after the right ventricle has become totally depolarized. Thus, the right ventricle becomes electronegative, whereas the left ventricle remains electropositive during most of the depolarization process, and a strong vector projects from the right ventricle toward the left ventricle. In other words, intense left axis deviation of about −50 degrees occurs because the positive end of the vector points toward the left ventricle. This situation is demonstrated in **Fig. 12.14**, which shows typical left axis deviation resulting from left bundle branch block.

Because of slowness of impulse conduction when the Purkinje system is blocked, in addition to axis deviation, the duration of the QRS complex is greatly prolonged as a result of extreme slowness of depolarization in the affected side of the heart. One can see this effect by observing the larger widths of the QRS waves in **Fig. 12.14** (discussed in greater detail later in this chapter). This extremely prolonged QRS complex differentiates bundle branch block from axis deviation caused by hypertrophy.

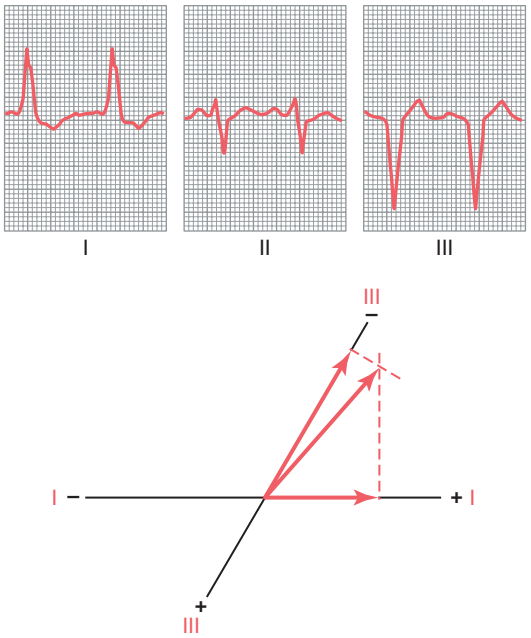

Figure 12.14 Left axis deviation caused by *left bundle branch block*. Note also the greatly prolonged QRS complex.

Vectorial Analysis of Right Axis Deviation in Right Bundle Branch Block. When the right bundle branch is blocked, the left ventricle depolarizes far more rapidly than the right ventricle, and thus the left side of the ventricles becomes electronegative as long as 0.1 second before the right. Therefore, a strong vector develops, with its negative end toward the left ventricle and its positive end toward the right ventricle. In other words, intense right axis deviation occurs. In **Fig. 12.15**, right axis deviation caused by right bundle branch block is demonstrated, and its vector is analyzed; this analysis shows an axis of about 105 degrees instead of the normal 59 degrees and a prolonged QRS complex because of slow conduction.

CONDITIONS THAT CAUSE ABNORMAL VOLTAGES OF THE QRS COMPLEX

INCREASED VOLTAGE IN THE STANDARD BIPOLAR LIMB LEADS

Normally, the voltages in the three standard bipolar limb leads, as measured from the peak of the R wave to the bottom of the S wave, vary between 0.5 and 2.0 millivolts, with lead III usually recording the lowest voltage and lead II the highest voltage. However, these relationships are not invariable, even for the normal heart. In general,

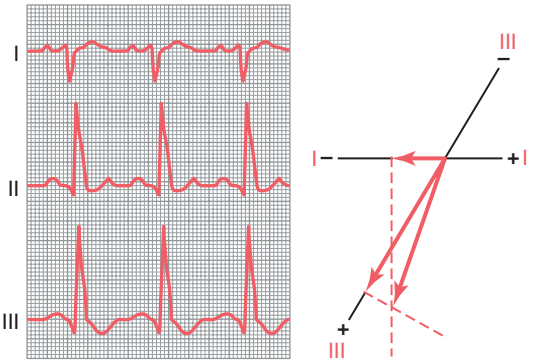

Figure 12.15 Right axis deviation caused by *right bundle branch block*. Note also the greatly prolonged QRS complex.

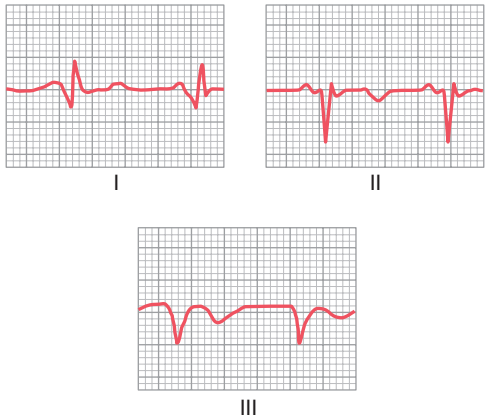

Figure 12.16 A low-voltage electrocardiogram following local damage throughout the ventricles caused by a *previous myocardial infarction*.

when the sum of the voltages of all the QRS complexes of the three standard leads is greater than 4 millivolts, the patient is considered to have a high-voltage ECG.

The cause of high-voltage QRS complexes is usually increased muscle mass of the heart, which ordinarily results from *hypertrophy of the muscle* in response to excessive load on one part of the heart or the other. For example, the right ventricle hypertrophies when it must pump blood through a stenotic pulmonary valve or when the pulmonary arterial pressure is elevated, and the left ventricle hypertrophies when a person has high systemic arterial blood pressure. The increased quantity of muscle generates increased electricity around the heart. As a result, the electrical potentials recorded in the electrocardiographic leads are considerably greater than normal, as shown in **Figs. 12.12** and **12.13**.

DECREASED VOLTAGE OF THE ELECTROCARDIOGRAM

Decreased Voltage Caused By Cardiomyopathies. One of the most common causes of decreased voltage of the QRS complex is a series of *old myocardial infarctions* with resultant *diminished muscle mass*. This condition also causes the depolarization wave to move through the ventricles slowly and prevents major portions of the heart from becoming massively depolarized all at once. Consequently, this condition causes some prolongation of the QRS complex, along with decreased voltage. **Fig. 12.16** shows a typical low-voltage ECG with prolongation of the QRS complex, which is common after multiple small infarctions of the heart have caused local delays of impulse conduction and reduced voltages due to loss of muscle mass throughout the ventricles. Infiltrative myocardial diseases also cause low ECG voltage. For example, in *cardiac amyloidosis*, abnormal proteins infiltrate the myocardium, leading to reduced voltages, particularly in the limb leads.

Decreased Voltage Caused By Abnormal Conditions Surrounding the Heart. One of the most important causes of decreased voltage in electrocardiographic leads is excessive *fluid in the pericardium (pericardial effusion)*. Because extracellular fluid easily conducts electrical currents, a large portion of the electricity flowing out of the heart is conducted from one part of the heart to another through the pericardial fluid. Thus, this effusion effectively "short-circuits" the electrical potentials generated by the heart, decreasing the electrocardiographic voltages that reach the outside surfaces of the body. *Pleural effusion*, to a lesser extent, also can short-circuit the electricity around the heart so that the voltages at the surface of the body and in the ECGs are decreased.

Pulmonary emphysema can decrease the electrocardiographic potentials, but for a different reason than that of pericardial effusion. In persons with pulmonary emphysema, conduction of electrical current through the lungs is depressed considerably because of increased air in the lungs. Also, the chest cavity enlarges, and the lungs tend to envelop the heart to a greater extent than normal. Therefore, the lungs act as an insulator to prevent the spread of electrical voltage from the heart to the surface of the body, which results in decreased electrocardiographic potentials in the various leads.

PROLONGED AND BIZARRE PATTERNS OF THE QRS COMPLEX

CARDIAC HYPERTROPHY OR DILATION PROLONG THE QRS COMPLEX

The QRS complex lasts as long as depolarization continues to spread through the ventricles—that is, as long as part of the ventricles is depolarized and part is still polarized. Therefore, *prolonged conduction* of the impulse through the ventricles always causes a prolonged QRS complex. Such prolongation often occurs when one or both ventricles are hypertrophied or dilated because of the longer pathway that the impulse must then travel. The normal QRS complex lasts 0.06 to 0.08 second, whereas in hypertrophy or dilation of the left or right ventricle, the QRS complex may be prolonged to 0.09 to 0.12 second.

PURKINJE SYSTEM BLOCK PROLONGS THE QRS COMPLEX

When the Purkinje fibers are blocked, the cardiac impulse must then be conducted by the ventricular muscle instead of through the Purkinje system. This action decreases the velocity of impulse conduction to about one-third of normal. Therefore, if complete block of one of the bundle branches occurs, the duration of the QRS complex is usually increased to 0.14 second or longer.

In general, a QRS complex is considered to be abnormally long when it lasts more than 0.09 second. When it lasts more than 0.12 second, the prolongation is almost certainly caused by a pathological block somewhere in the ventricular conduction system, as shown by the ECGs for bundle branch block in **Figs. 12.14** and **12.15**.

CONDITIONS THAT CAUSE BIZARRE QRS COMPLEXES

Bizarre patterns of the QRS complex are usually caused by one of the following conditions: (1) destruction of cardiac muscle in various areas throughout the ventricular system, with replacement of this muscle by scar tissue; or (2) multiple small local blocks in the conduction of impulses at many points in the Purkinje system. As a result, cardiac impulse conduction becomes irregular, causing rapid shifts in voltages and axis deviations. This irregularity often causes double or even triple peaks in some of the electrocardiographic leads, such as those shown in **Fig. 12.14**.

CURRENT OF INJURY ON THE ELECTROCARDIOGRAM

Many different cardiac abnormalities, especially those that damage the heart muscle, may cause part of the heart to remain partially or totally *depolarized all the time*. When this condition occurs, current flows between the pathologically depolarized and normally polarized areas, even between heartbeats. This condition is called a *current of injury*. Note especially that *the injured part of the heart is negative, because this is the part that is depolarized and emits negative charges into the surrounding fluids, whereas the remainder of the heart is neutral or in positive polarity*.

Some abnormalities that can cause a current of injury are as follows: (1) *mechanical trauma*, which sometimes makes the membranes remain so permeable that full repolarization cannot take place; (2) *infectious processes* that damage the muscle membranes; and (3) *ischemia of local areas of heart muscle caused by local coronary artery occlusions*, which is the most common cause of a current of injury in the heart. During ischemia, not enough nutrients from the coronary blood supply are available to the heart muscle to maintain normal membrane polarization.

EFFECT OF CURRENT OF INJURY ON THE QRS COMPLEX

In **Fig. 12.17**, a small area in the base of the left ventricle is newly infarcted (i.e., there is loss of coronary blood flow). Therefore, during the T-P interval, when the normal

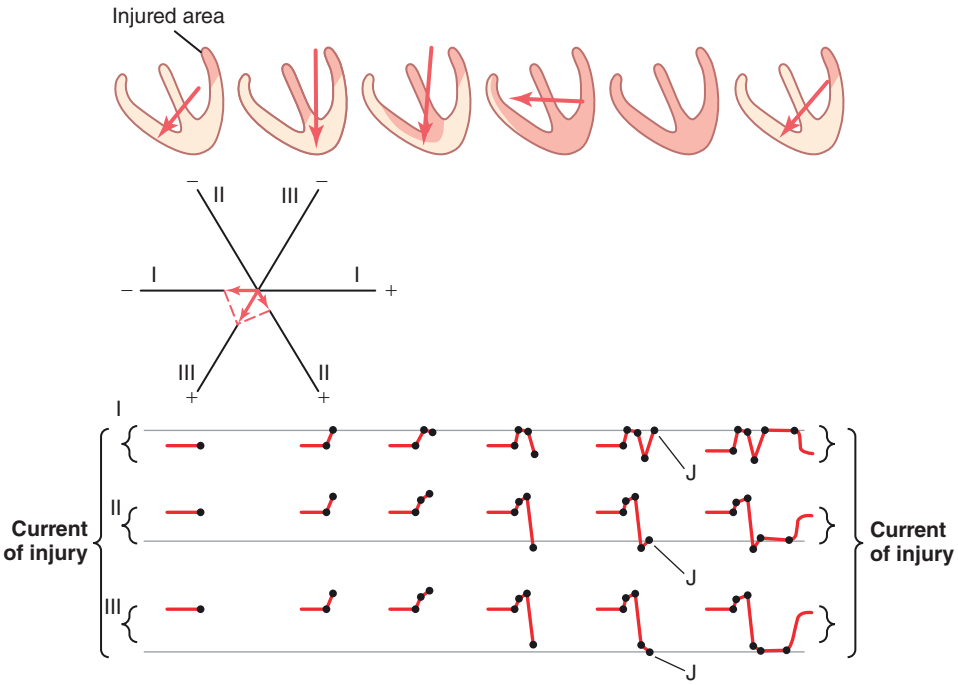

Figure 12.17 Effect of a current of injury on the electrocardiogram.

ventricular muscle is totally polarized, abnormal *negative* current still flows from the infarcted area at the base of the left ventricle and spreads toward the rest of the ventricles.

The vector of this current of injury, as shown in the first heart in **Fig. 12.17**, is in a direction of about 125 degrees, with the base of the vector, the *negative end*, toward the injured muscle. As shown in the lower portions of the figure, even before the QRS complex begins, *this vector causes an initial record in lead I below the zero potential line*, because the projected vector of the current of injury in lead I points toward the negative end of the lead I axis. In lead II, the record is above the line because the projected vector points more toward the positive terminal of the lead. In lead III, the projected vector points in the same direction as the positive terminal of lead III so that the record is positive. Furthermore, because the vector lies almost exactly in the direction of the axis of lead III, the voltage of the current of injury in lead III is much greater than in either lead I or lead II.

As the heart then proceeds through its normal process of depolarization, the septum first becomes depolarized; then the depolarization spreads down to the apex and back toward the bases of the ventricles. The last portion of the ventricles to become totally depolarized is the base of the right ventricle because the base of the left ventricle is already totally and permanently depolarized. By vectorial analysis, the successive stages of electrocardiographic generation by the depolarization wave traveling through the ventricles can be constructed graphically, as demonstrated in the lower part of **Fig. 12.17**.

When the heart becomes totally depolarized, at the end of the depolarization process (as noted by the next to last stage in **Fig. 12.17**), all the ventricular muscle is in a negative state. Therefore, at this instant in the ECG, no current flows from the ventricles to the electrocardiographic electrodes because now both the injured heart muscle and the contracting muscle are depolarized.

Next, as repolarization takes place, all the heart finally repolarizes, except the area of permanent depolarization in the injured base of the left ventricle. Thus, repolarization causes a return of the current of injury in each lead, as noted at the far right in **Fig. 12.17**.

THE J POINT IS THE ZERO REFERENCE POTENTIAL FOR ANALYZING CURRENT OF INJURY

One might think that ECG machines could determine when no current is flowing around the heart. However, many stray currents exist in the body, such as currents resulting from skin potentials and from differences in ionic concentrations in different fluids of the body. Therefore, when two electrodes are connected between the arms or between an arm and a leg, these stray currents make it impossible to predetermine the exact zero reference level in the ECG.

For these reasons, the following procedure must be used to determine the zero potential level: First, one notes *the exact point at which the wave of depolarization just completes its passage through the heart*, which occurs at the end of the QRS complex. At exactly this point, all parts of the ventricles have become depolarized, including both the damaged parts and the normal parts, so no current is flowing around the heart. Even the current of injury disappears at this point. Therefore, the potential of the electrocardiogram at this instant is at zero voltage. This point is known as the *J point* in the ECG, as shown in **Fig. 12.18**.

Then, for analysis of the electrical axis of the injury potential caused by a current of injury, a horizontal line is drawn in the ECG for each lead at the level of the J point. This horizontal line is then the *zero potential level* in the ECG from which all potentials caused by currents of injury must be measured.

Use of the J Point in Plotting Axis of Injury Potential. **Fig. 12.18** shows ECGs (leads I and III) from an injured heart. Both records show injury potentials. In other words, the J point of each of these two ECGs is not on the same line as the T-P segment. In the figure, a horizontal line has been drawn through the J point to represent the zero voltage level in each of the two recordings. The injury potential in each lead is the difference between the voltage of the ECG immediately before onset of the P wave and the zero voltage level determined from the J point. In lead I, the recorded voltage of the injury potential is above the zero potential level and is therefore positive. Conversely, in lead III, the injury potential is below the zero voltage level and therefore is negative.

At the bottom in **Fig. 12.18**, the respective injury potentials in leads I and III are plotted on the coordinates of these leads, and the resultant vector of the injury

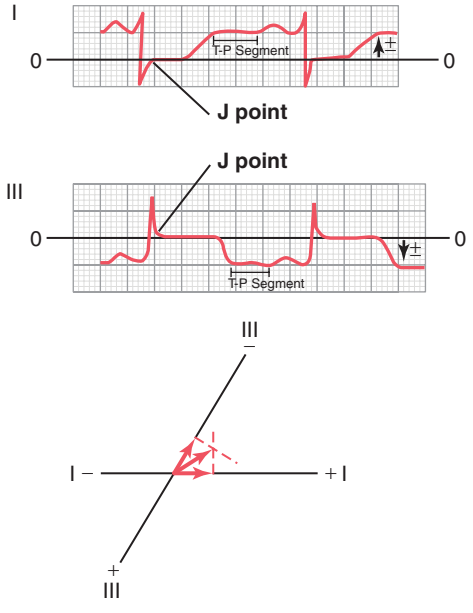

Figure 12.18 J point as the zero reference potential of the electrocardiograms for leads I and III. Also, the method for plotting the axis of the injury potential is shown in the *bottom panel*.

potential for the whole ventricular muscle mass is determined by vectorial analysis as described. In this case, the resultant vector extends from the right side of the ventricles toward the left and slightly upward, with an axis of about −30 degrees. If one places this vector for the injury potential directly over the ventricles, *the negative end of the vector points toward the permanently depolarized, "injured" area of the ventricles*. In the example shown in **Fig. 12.18**, the injured area would be in the lateral wall of the right ventricle.

This analysis is complex. However, it is essential that the student review it again and again until it is thoroughly understood. *No other aspect of electrocardiographic analysis is more important.*

CORONARY ISCHEMIA AS A CAUSE OF INJURY POTENTIAL

Insufficient blood flow to the cardiac muscle depresses the metabolism of the muscle for at least three reasons: (1) lack of oxygen; (2) excess accumulation of carbon dioxide; and (3) lack of sufficient nutrients. Consequently, repolarization of the muscle membrane cannot occur in areas of severe myocardial ischemia. Often, the heart muscle does not die because the blood flow is sufficient to maintain life of the muscle, even though it is not sufficient to cause normal repolarization of the membranes. As long as this state exists, an injury potential continues to flow during the diastolic portion (the T-P portion) of each heart cycle.

Extreme ischemia of the cardiac muscle occurs after coronary occlusion, and a strong current of injury flows from the infarcted area of the ventricles during the T-P interval between heartbeats, as shown in **Figs. 12.19** and **12.20**. Therefore, one of the most important diagnostic features of ECGs recorded after acute coronary thrombosis is the current of injury.

Acute Anterior Wall Infarction. **Fig. 12.19** shows the ECG in the three standard bipolar limb leads and in one chest lead (lead V_2) recorded from a patient with acute anterior wall cardiac infarction. The most important diagnostic feature of this ECG is the intense injury potential in chest lead V_2. If one draws a zero horizontal potential line through the J point of this ECG, a strong *negative* injury potential during the T-P interval is found, which means that the chest electrode over the front of the heart is in an area of strongly negative potential. In other words, the negative end of the injury potential vector in this heart is against the anterior chest wall. This means that the current of injury is emanating from the anterior wall of the ventricles, which diagnoses this condition as an *anterior wall infarction*.

When analyzing the injury potentials in leads I and III, one finds a negative potential in lead I and a positive potential in lead III. This finding means that the resultant vector of the injury potential in the heart is about +150 degrees, with the negative end pointing toward the left ventricle and the positive end pointing toward the right

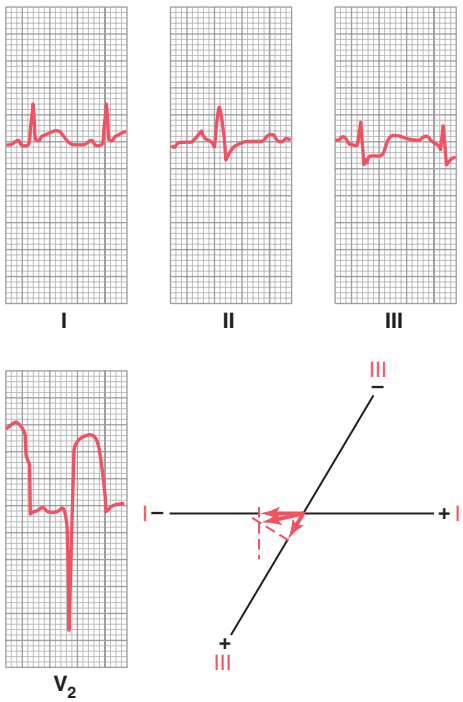

Figure 12.19 Current of injury in *acute anterior wall infarction*. Note the intense injury potential in lead V_2.

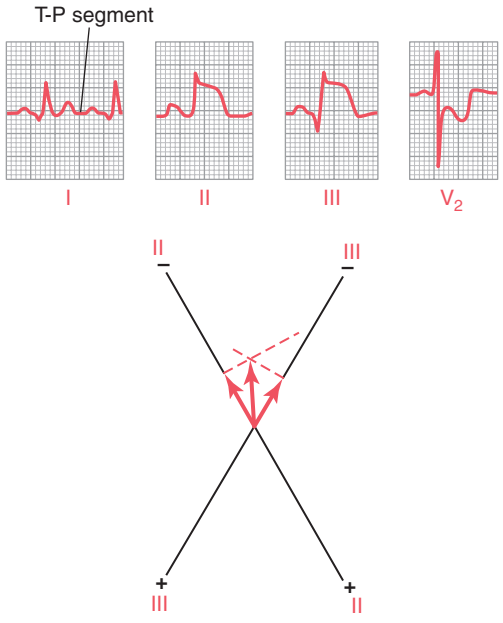

Figure 12.20 Injury potential in an *acute posterior wall, apical infarction*.

ventricle. Thus, in this ECG, the current of injury is coming mainly from the left ventricle, as well as from the anterior wall of the heart. Therefore, one would conclude that this anterior wall infarction almost certainly is caused by thrombosis of the anterior descending branch of the left coronary artery.

Posterior Wall Infarction. **Fig. 12.20** shows the three standard bipolar limb leads and one chest lead (lead V_2) from a patient with a posterior wall infarction. The major

diagnostic feature of this ECG is also in the chest lead. If a zero potential reference line is drawn through the J point of this lead, it is readily apparent that during the T-P interval, the potential of the current of injury is positive. This means that the positive end of the vector is in the direction of the anterior chest wall, and the negative end (the injured end of the vector) points away from the chest wall. In other words, the current of injury is coming from the back of the heart opposite to the anterior chest wall, which is the reason this type of ECG is the basis for diagnosing posterior wall infarction.

If one analyzes the injury potentials from leads II and III of **Fig. 12.20**, it is readily apparent that the injury potential is negative in both leads. By vectorial analysis, as shown in the figure, one finds that the resultant vector of the injury potential is about −95 degrees, with the negative end pointing downward and the positive end pointing upward. Thus, because the infarct, as indicated by the chest lead, is on the posterior wall of the heart and, as indicated by the injury potentials in leads II and III, it is in the apical portion of the heart, one would suspect that this infarct is near the apex on the posterior wall of the left ventricle.

Infarction in Other Parts of the Heart. Using the same procedures demonstrated in the preceding discussions of anterior and posterior wall infarctions, it is often possible to determine the locus of an infarcted area emitting a current of injury. In making such vectorial analyses, it should be remembered that *the positive end of the injury potential vector points toward the normal cardiac muscle, and the negative end points toward the injured portion of the heart that is emitting the current of injury.*

Progressive Changes in the Electrocardiogram During and After Acute Coronary Thrombosis. **Fig. 12.21** shows a V_3 chest lead from a patient with an acute anterior wall infarction, demonstrating changes in the ECG from the day of the attack to 1 day later, 3 weeks later and, finally, 1 year later. From this ECG, one can see that the injury potential is strong immediately after the acute attack (the T-P segment is displaced positively from the S-T segment). However, after about 1 week, the injury potential has diminished considerably and, after 3 weeks, it is gone. After that, the ECG does not change greatly during the next year. This is the usual recovery pattern after an acute myocardial infarction of moderate degree, showing that the *new collateral coronary blood flow* develops enough to reestablish appropriate nutrition to most of the infarcted area.

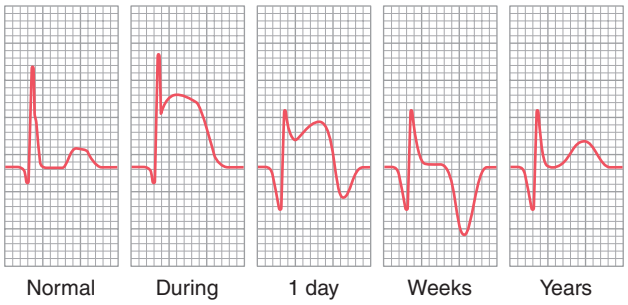

Figure 12.21 Recovery of the myocardium after *anterior wall infarction*, demonstrating the disappearance of the injury potential that is present on the first day after the infarction.

In some patients who experience myocardial infarction, the infarcted area never redevelops adequate coronary blood supply. Often, some of the heart muscle dies, but if the muscle does not die, it will continue to show an injury potential as long as the ischemia exists, particularly during bouts of exercise when the heart is overloaded.

Q Waves on an ECG Represent Old Myocardial Infarction. **Fig. 12.22** shows leads I and III after *anterior and posterior infarctions* about 1 year after the acute heart attacks. In anterior infarction a Q wave usually has developed at the beginning of the QRS complex in lead I because of the loss of muscle mass in the anterior wall of the left ventricle. However, in a posterior infarction, a Q wave has developed at the beginning of the QRS complex in lead III because of loss of muscle in the posterior apical part of the ventricle.

These configurations are not found in all cases of old myocardial infarction. Local loss of muscle and local points of cardiac signal conduction block can cause bizarre QRS patterns (e.g., especially prominent Q waves), decreased voltage, and QRS prolongation.

Angina Pectoris. The term *angina pectoris* means pain from the heart felt in the pectoral regions of the chest. This pain usually also radiates into the left neck area and down the left arm. The pain is typically caused by moderate to severe ischemia of the heart. Usually, no pain is felt as long as the person is quiet, but as soon as the heart is overworked, the pain appears.

An injury potential sometimes appears on the ECG during an attack of severe angina pectoris because the coronary insufficiency becomes great enough to prevent adequate repolarization of some areas of the heart during diastole.

ABNORMALITIES IN THE T WAVE

Earlier in the chapter, we noted that the T wave is normally positive in all the standard bipolar limb leads and that this is caused by repolarization of the apex and outer

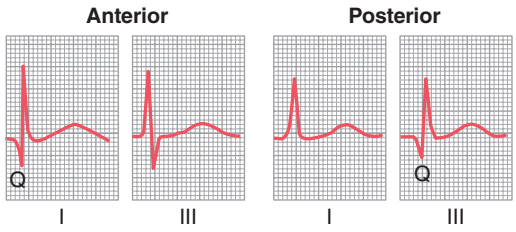

Figure 12.22 Electrocardiograms of anterior and posterior wall infarctions that occurred about 1 year previously, showing a Q wave in lead I in an anterior wall infarction and a Q wave in lead III in a *posterior wall infarction*.

surfaces of the ventricles ahead of the intraventricular surfaces. That is, the T wave becomes abnormal when the normal sequence of repolarization does not occur. Several factors, including myocardial ischemia, can change this sequence of repolarization.

EFFECT OF SLOW CONDUCTION OF THE DEPOLARIZATION WAVE ON THE CHARACTERISTICS OF THE T WAVE

Referring to **Fig. 12.14**, note that the QRS complex is considerably prolonged. The reason for this prolongation is *delayed conduction in the left ventricle* resulting from left bundle branch block. This delayed conduction causes the left ventricle to become depolarized about 0.08 second after depolarization of the right ventricle, which gives a strong mean QRS vector *to the left*. However, the refractory periods of the right and left ventricular muscle masses are not greatly different from each other. Therefore, the right ventricle begins to repolarize long before the left ventricle, which causes strong positivity in the right ventricle and negativity in the left ventricle when the T wave is developing. In other words, the mean axis of the T wave is now deviated *to the right*, which is opposite to the mean electrical axis of the QRS complex in the same ECG. Thus, when conduction of the depolarization impulse through the ventricles is greatly delayed, the T wave is almost always of opposite polarity to that of the QRS complex.

SHORTENED DEPOLARIZATION IN PORTIONS OF THE VENTRICULAR MUSCLE CAN CAUSE T-WAVE ABNORMALITIES

If the base of the ventricles should exhibit an abnormally short period of depolarization—that is, a shortened action potential—repolarization of the ventricles would not begin at the apex, as it normally does. Instead, the base of the ventricles would repolarize ahead of the apex, and the vector of repolarization would point from the apex toward the base of the heart, opposite to the standard vector of repolarization. Consequently, the T wave in all three standard leads would be negative rather than the usual positive. Thus, the simple fact that the base of the ventricles has a shortened period of depolarization is sufficient to cause marked changes in the T wave, even to the extent of changing the entire T-wave polarity, as shown in **Fig. 12.23**.

Mild ischemia is the most common cause of shortening of depolarization of cardiac muscle because this condition increases current flow through the potassium channels. When the ischemia occurs in only one area of the heart, the depolarization period of this area decreases out of proportion to that in other portions. As a result, *changes in the T-wave morphology, such as inversion or biphasic waveforms, can be evidence of myocardial ischemia*. The ischemia might result from chronic, progressive coronary stenosis (narrowing), acute coronary occlusion, coronary artery spasm, or relative coronary insufficiency that occurs during exercise or severe anemia.

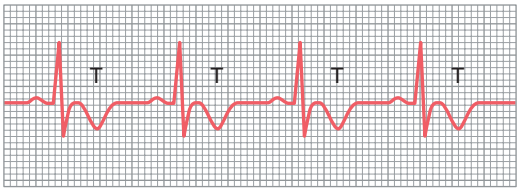

Figure 12.23 An inverted T wave resulting from mild *ischemia at the base* of the ventricles.

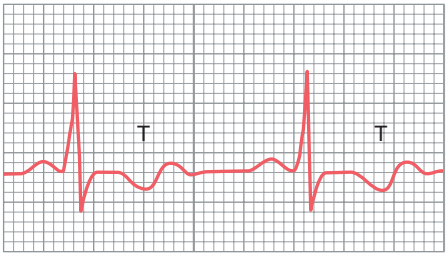

Figure 12.24 A biphasic T wave caused by *digitalis toxicity*.

Effect of Digitalis on the T Wave. As discussed in Chapter 22, digitalis is a drug that can be used during heart failure to increase the strength of cardiac muscle contraction. However, when an overdose of digitalis is given, depolarization duration in one part of the ventricles may be increased out of proportion to that of other parts. As a result, nonspecific changes, such as T-wave inversion or biphasic T waves, may occur in one or more of the electrocardiographic leads. A biphasic T wave caused by excessive administration of digitalis is shown in **Fig. 12.24**. Therefore, changes in the T wave during digitalis administration are often the earliest signs of digitalis toxicity.

CHAPTER 13

Cardiac Arrhythmias and Their Electrocardiographic Interpretation

Some of the most distressing types of heart malfunction occur because of abnormal rhythm of the heart. For example, sometimes the beat of the atria is not coordinated with the beat of the ventricles, so the atria no longer function to optimize ventricular filling.

The purpose of this chapter is to discuss the physiology of common cardiac arrhythmias and their effects on heart pumping, as well as their diagnosis by electrocardiography. The causes of the cardiac arrhythmias are usually one or a combination of the following abnormalities in the rhythmicity-conduction system of the heart:

- Abnormal rhythmicity of the pacemaker
- Shift of the pacemaker from the sinus node to another place in the heart
- Blocks at different points in the spread of the impulse through the heart
- Abnormal pathways of impulse transmission through the heart
- Spontaneous generation of spurious impulses in almost any part of the heart

ABNORMAL SINUS RHYTHMS

TACHYCARDIA

The term *tachycardia* means *fast heart rate*, which usually is defined as faster than 100 beats/min in an adult. An electrocardiogram (ECG) recorded from a patient with tachycardia is shown in **Fig. 13.1**. This ECG is normal except that the heart rate, as determined from the time intervals between QRS complexes, is about 150 beats/min instead of the normal 72 beats/min. Some causes of tachycardia include increased body temperature, dehydration, blood loss anemia, stimulation of the heart by the sympathetic nerves, and toxic conditions of the heart.

The heart rate usually increases about 10 beats/min for each degree Fahrenheit increase in body temperature (with an increase of 18 beats/min for each degree Celsius), up to a body temperature of about 105°F (40.5°C). Beyond this, the heart rate may decrease because of progressive debility of the heart muscle as a result of the fever. Fever causes tachycardia because an increased temperature increases the rate of metabolism of the sinus node, which in turn directly increases its excitability and rate of rhythm.

Many factors can cause the sympathetic nervous system to excite the heart, as discussed in this text. For example, when a patient sustains severe blood loss, sympathetic reflex stimulation of the heart may increase the heart rate to 150 to 180 beats/min. Simple weakening of the myocardium usually increases the heart rate because the weakened heart does not pump blood into the arterial tree to a normal extent, causing reductions in blood pressure and eliciting sympathetic reflexes to increase the heart rate.

BRADYCARDIA

The term *bradycardia* means a slow heart rate, usually defined as fewer than 60 beats/min. Bradycardia is shown by the ECG in **Fig. 13.2**.

Bradycardia in Athletes. The well-trained athlete's heart is often larger and considerably stronger than that of a normal person, which allows the athlete's heart to pump a large stroke volume output per beat, even during periods of rest. When the athlete is at rest, increased quantities of blood pumped into the arterial tree with each beat initiate feedback circulatory reflexes or other effects that cause bradycardia. Exercise training may also decrease intrinsic pacemaker activity of the sinus node due to downregulation of ion channels responsible for the "funny" current that, in turn, causes rhythmic depolarization, as discussed in Chapter 10.

Vagal Stimulation Causes Bradycardia. Any circulatory reflex that stimulates the vagus nerves causes release of acetylcholine at the vagal endings in the heart, resulting in a parasympathetic effect. Perhaps the most striking example of this phenomenon occurs in patients with *carotid sinus syndrome*. In these patients, the pressure receptors (baroreceptors) in the carotid sinus region of the carotid artery walls are excessively sensitive. Therefore, even mild external pressure on the neck elicits a strong baroreceptor reflex, causing intense vagal-acetylcholine effects on the heart, including extreme bradycardia. Sometimes this reflex is so powerful that it actually stops the heart for 5 to 10 seconds, leading to loss of consciousness (syncope).

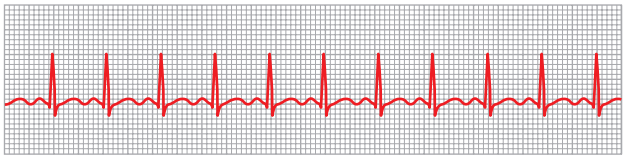

Figure 13.1 Sinus tachycardia (lead I).

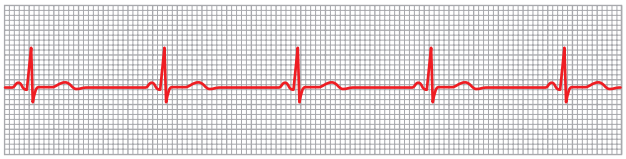

Figure 13.2 Sinus bradycardia (lead III).

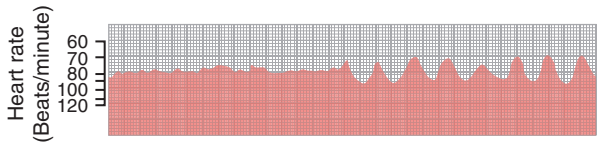

Figure 13.3 Sinus arrhythmia as recorded by a cardiotachometer. To the *left* is the record when the subject was breathing normally; to the *right*, when the subject was breathing deeply.

SINUS ARRHYTHMIA

Fig. 13.3 shows a *cardiotachometer* recording of the heart rate, at first during normal respiration and then, in the second half of the record, during deep respiration. A cardiotachometer is an instrument that records the duration of the interval between the successive QRS complexes in the ECG *by the height of successive spikes*. Note from this record that the heart rate increased and decreased no more than 5% during quiet respiration (shown on the left half of the record). Then, *during deep respiration*, the heart rate increased and decreased with each respiratory cycle by as much as 30%.

Sinus arrhythmia can result from many circulatory conditions that alter the strengths of the sympathetic and parasympathetic nerve signals to the heart sinus node. The respiratory type of sinus arrhythmia results mainly from the spillover of signals from the medullary respiratory center into the adjacent vasomotor center during inspiratory and expiratory cycles of respiration. The spillover signals cause alternate increases and decreases in the number of impulses transmitted through the sympathetic and vagus nerves to the heart.

HEART BLOCK WITHIN THE INTRACARDIAC CONDUCTION PATHWAYS

SINOATRIAL BLOCK

In rare cases, the impulse from the sinus node is blocked before it enters the atrial muscle. This phenomenon is demonstrated in **Fig. 13.4**, which shows sudden cessation

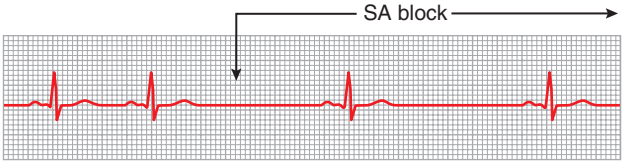

Figure 13.4 Sinoatrial (SA) nodal block, with atrioventricular nodal rhythm during the block period (lead III).

of P waves, with resultant standstill of the atria. However, the ventricles pick up a new rhythm, with the impulse usually originating spontaneously in the atrioventricular (AV) node, so the rate of the ventricular QRS-T complex is slowed but not otherwise altered. Sinoatrial block can be due to myocardial ischemia affecting the sinus node, inflammation or infection of the heart, or side effects from certain medications, and it can be observed in well-trained athletes.

ATRIOVENTRICULAR BLOCK

The only means whereby impulses ordinarily can pass from the atria into the ventricles is through the *AV bundle*, also known as the *bundle of His*. Conditions that can either decrease the rate of impulse conduction in this bundle or block the impulse entirely are as follows:

1. *Ischemia of the AV node or AV bundle fibers* often delays or blocks conduction from the atria to the ventricles. Coronary insufficiency can cause ischemia of the AV node and bundle in the same way that it can cause ischemia of the myocardium.
2. *Compression of the AV bundle* by scar tissue or by calcified portions of the heart can depress or block conduction from the atria to the ventricles.
3. *Inflammation of the AV node or AV bundle* can depress conduction from the atria to the ventricles. Inflammation results frequently from different types of endocarditis or myocarditis that are caused, for example, by diphtheria or rheumatic fever.
4. *Extreme stimulation of the heart by the vagus nerves* in rare cases blocks impulse conduction through the AV node. Such vagal excitation occasionally results from strong stimulation of the baroreceptors in people with *carotid sinus syndrome*, discussed earlier in relationship to bradycardia.
5. *Degeneration of the AV conduction system*, which is sometimes seen in older patients.
6. *Medications such as digitalis or beta-adrenergic antagonists* can, in some cases, impair AV conduction.

INCOMPLETE ATRIOVENTRICULAR BLOCK

First-Degree Block—Prolonged P-R Interval. The usual lapse of time between the *beginning* of the P wave and the *beginning* of the QRS complex is about 0.16 second when the heart is beating at a normal rate. This so-called *P-R*

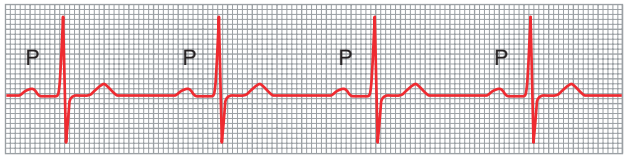

Figure 13.5 Prolonged P-R interval caused by first-degree atrioventricular heart block (lead II).

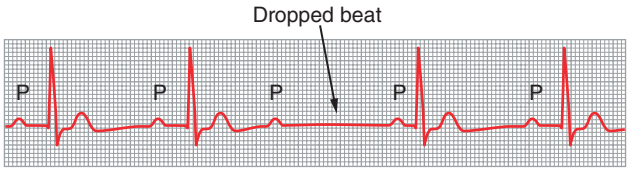

Figure 13.6 Type I second-degree atrioventricular block showing progressive P-R prolongation prior to the dropped beat.

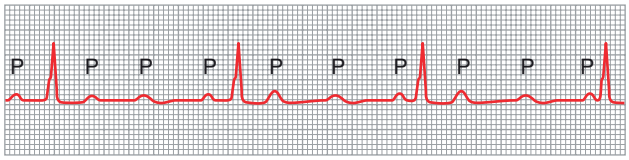

Figure 13.7 Complete atrioventricular block (lead II).

interval usually decreases in length with a faster heartbeat and increases with a slower heartbeat. In general, when the P-R interval increases to more than 0.20 second, the P-R interval is prolonged, and the patient is said to have *first-degree heart block*.

Fig. 13.5 shows an ECG with a prolonged P-R interval; the interval in this case is about 0.30 second instead of the normal 0.20 second or less. Thus, first-degree block is defined as a *delay* of conduction from the atria to the ventricles but not actual blockage of conduction. The P-R interval seldom increases above 0.35 to 0.45 second because, by that time, conduction through the AV bundle is depressed so much that conduction stops entirely. One means for determining the severity of some heart diseases, such as *acute rheumatic heart disease*, for example, is to measure the P-R interval.

Second-Degree Block. When conduction through the AV bundle is slowed enough to increase the P-R interval to 0.25 to 0.45 second, the action potential is sometimes strong enough to pass through the bundle into the ventricles and sometimes not strong enough to do so. In this case, there will be an atrial P wave but no QRS complex or T wave, and it is said that there are "dropped beats" of the ventricles. This condition is called *second-degree heart block*.

There are two types of second-degree AV block—*Mobitz type I* (also known as *Wenckebach periodicity*) and *Mobitz type II*. Type I block is characterized by progressive prolongation of the P-R interval until a ventricular beat is dropped and is then followed by resetting of the P-R interval and repeating of the abnormal cycle. A type I block is almost always caused by abnormality of the AV node. In most cases, this type of block is benign, and no specific treatment is needed.

In Mobitz type II block, there is usually a fixed number of nonconducted P waves for every QRS complex. For example, a 2:1 block implies that there are two P waves for every QRS complex. At other times, rhythms of 3:2 or 3:1 may develop. In contrast to type I block, with type II block the P-R interval does not change before the dropped beat; it remains fixed. Type II block is generally caused by an abnormality of the bundle of His–Purkinje system and may require implantation of a pacemaker to prevent progression to complete heart block and cardiac arrest.

Fig. 13.6 shows progressive P-R interval prolongation typical of type I (Wenckebach) block. Note prolongation of the P-R interval preceding the dropped beat, followed by a shortened P-R interval after the dropped beat.

Complete AV Block (Third-Degree Block). When the condition causing poor conduction in the AV node or AV bundle becomes severe, complete block of the impulse from the atria into the ventricles occurs. In this case, the ventricles spontaneously establish their own signal, usually originating in the AV node or AV bundle distal to the block. Therefore, the P waves become dissociated from the QRS and T complexes, as shown in **Fig. 13.7**. Note that the *rate of rhythm of the atria* in this ECG is about 100 beats/min, whereas the *rate of ventricular beat* is less than 40 beats/min. Furthermore, there is no relationship between the rhythm of the P waves and that of the QRS-T complexes because the ventricles have "escaped" from control by the atria and are beating at their own natural rate, controlled most often by rhythmical signals generated distal to the AV node or AV bundle where the block occurs.

Stokes-Adams Syndrome—Ventricular Escape. In some patients with AV block, the total block comes and goes; that is, impulses are conducted from the atria into the ventricles for a period of time and then, suddenly, impulses are not conducted. The duration of block may be a few seconds, a few minutes, a few hours, or even weeks or longer before conduction returns. This condition occurs in hearts with borderline ischemia of the conductive system.

Each time AV conduction ceases, the ventricles often do not start their own beating until after a delay of 5 to 30 seconds. This delay results from the phenomenon called *overdrive suppression*. Overdrive suppression means that ventricular excitability is at first suppressed because the ventricles have been driven by the atria at a rate greater than their natural rate of rhythm. However, after a few seconds, some part of the Purkinje system beyond the block, usually in the distal part of the AV node beyond the blocked point in the node, or in the AV bundle, begins discharging rhythmically at a rate of 15 to 40 times/min, acting as the pacemaker of the ventricles. This phenomenon is called *ventricular escape*.

Because the brain cannot remain active for more than 4 to 7 seconds without blood supply, most people faint

a few seconds after complete block occurs because the heart does not pump any blood for 5 to 30 seconds, until the ventricles "escape." After escape, however, the slowly beating ventricles (typically beating less than 40 beats/min) usually pump enough blood to allow rapid recovery from the faint and then to sustain the person. These periodic fainting spells (syncope) are known as the *Stokes-Adams syndrome.*

Occasionally, the interval of ventricular standstill at the onset of complete block is so long that it becomes detrimental to the patient's health or even causes death. Consequently, most of these patients are provided with an *artificial pacemaker*, a small battery-operated electrical stimulator planted beneath the skin, with electrodes usually connected to the right ventricle. The pacemaker provides continued rhythmical impulses to the ventricles and prevents the heart rate from dropping below a programmable level.

INCOMPLETE INTRAVENTRICULAR BLOCK—ELECTRICAL ALTERNANS

Most of the same factors that can cause AV block can also block impulse conduction in the peripheral ventricular Purkinje system. **Fig. 13.8** shows the condition known as *electrical alternans*, which results from partial intraventricular block every other heartbeat. This ECG also shows *tachycardia* (rapid heart rate), which is probably the reason the block has occurred. This is because when the rate of the heart is rapid, it may be impossible for some portions of the Purkinje system to recover from the previous refractory period quickly enough to respond during every succeeding heartbeat. Also, many conditions that depress the heart, such as ischemia, myocarditis, or digitalis toxicity, can cause incomplete intraventricular block, resulting in electrical alternans.

PREMATURE CONTRACTIONS

A premature contraction is a contraction of the heart before the time that normal contraction would have been expected. This condition is also called *extrasystole, premature beat*, or *ectopic beat.*

CAUSES OF PREMATURE CONTRACTIONS

Most premature contractions result from *ectopic foci* in the heart, which emit abnormal impulses at odd times during the cardiac rhythm. Possible causes of ectopic foci are as follows: (1) local areas of ischemia; (2) small calcified plaques at different points in the heart, which press against the adjacent cardiac muscle so that some of the fibers are irritated; and (3) toxic irritation of the AV node, Purkinje system, or myocardium caused by infection, drugs, nicotine, or caffeine. The mechanical initiation of premature contractions is also frequent during cardiac catheterization; large numbers of premature contractions often occur when the catheter enters the ventricle and presses against the endocardium.

PREMATURE ATRIAL CONTRACTIONS

Fig. 13.9 shows a single premature atrial contraction (PAC). The P wave of this beat occurred too soon in the heart cycle; the P-R interval is shortened, indicating that the ectopic origin of the beat is in the atria near the AV node. Also, the interval between the premature contraction and the next succeeding contraction is slightly prolonged, which is called a *compensatory pause.* One of the reasons for this compensatory pause is that the premature contraction originated in the atrium some distance from the sinus node, and the impulse had to travel through a considerable amount of atrial muscle before it discharged the sinus node. Consequently, the sinus node discharged late in the premature cycle, which made the succeeding sinus node discharge also late in appearing.

PACs occur frequently in otherwise healthy people. They often occur in athletes whose hearts are in a very healthy condition. Mild toxic conditions resulting from such factors as smoking, lack of sleep, ingestion of too much coffee, alcoholism, and use of various stimulant drugs can also initiate such contractions.

Pulse Deficit. When the heart contracts ahead of schedule, the ventricles will not have filled with blood normally, and the stroke volume output during that contraction is depressed or is almost absent. Therefore, the pulse wave passing to the peripheral arteries after a premature contraction may be so weak that it cannot be felt in the radial artery. Thus, a deficit in the number of radial pulses occurs when compared with the actual number of contractions of the heart.

AV NODAL OR AV BUNDLE PREMATURE CONTRACTIONS

Fig. 13.10 shows a premature contraction that originated in the AV node or AV bundle. The P wave is missing from the electrocardiographic record of the premature

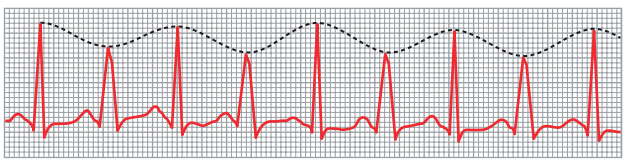

Figure 13.8 Partial intraventricular block—electrical alternans (lead I).

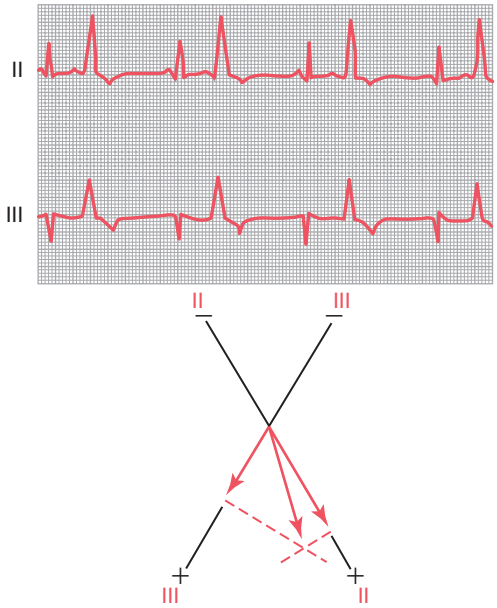

Figure 13.11 Premature ventricular contractions (PVCs) demonstrated by the large abnormal QRS-T complexes (leads II and III). The axis of the premature contractions is plotted in accordance with the principles of vectorial analysis explained in Chapter 12 and shows the origin of the PVC to be near the base of the ventricles.

contraction. Instead, the P wave is superimposed onto the QRS-T complex because the cardiac impulse traveled backward into the atria at the same time that it traveled forward into the ventricles. This P wave slightly distorts the QRS-T complex, but the P wave itself cannot be discerned. In general, AV nodal premature contractions have the same significance and causes as atrial premature contractions.

PREMATURE VENTRICULAR CONTRACTIONS

The ECG in **Fig. 13.11** shows a series of premature ventricular contractions (PVCs) alternating with normal contractions in a pattern known as *bigeminy*. PVCs cause specific effects in the ECG, as follows:

1. *The QRS complex is usually considerably prolonged.* The reason for this prolongation is that the impulse is conducted mainly through slowly conducting muscle of the ventricles rather than through the Purkinje system.
2. *The QRS complex has a high voltage.* When the normal impulse passes through the heart, it passes through both ventricles nearly simultaneously. Consequently, in the normal heart, the depolarization waves of the two sides of the heart—mainly of opposite polarity to each other—partially neutralize each other in the ECG. When a PVC occurs, the impulse almost always travels in only one direction, so there is no such neutralization effect, and one entire side or end of the ventricles is depolarized ahead of the other, which causes large electrical potentials, as shown for the PVCs in **Fig. 13.11**.
3. After almost all PVCs, the *T wave has an electrical potential polarity exactly opposite to that of the QRS complex* because the *slow conduction of the impulse* through the cardiac muscle causes the muscle fibers that depolarize first also to repolarize first.

Some PVCs are relatively benign in their effects on overall pumping by the heart as long as they are not too frequent; they can result from such factors as nicotine in tobacco products, excessive intake of caffeine, lack of sleep, various mild toxic states, and even emotional irritability. However, high PVC burden (more than 20%) has been associated with development of cardiac dilation and weakened contractile function. Many other PVCs result from stray impulses or reentrant signals that originate around the borders of infarcted, ischemic, inflamed areas of the heart.

The presence of such PVCs is not to be taken lightly. People with significant numbers of PVCs often have a higher than normal risk of developing spontaneous lethal ventricular fibrillation, presumably initiated by one of the PVCs. This development is especially true when the PVCs occur during the vulnerable period for causing fibrillation, just at the end of the T wave, when the ventricles are coming out of refractoriness, as explained later in this chapter.

Vector Analysis of the Origin of an Ectopic Premature Ventricular Contraction. In Chapter 12, the principles of vectorial analysis are explained. By applying these principles, one can determine from the ECG in **Fig. 13.11** the point of origin of the PVC, as follows. Note that the potentials of the premature contractions in leads II and III are both strongly positive. On plotting these potentials on the axes of leads II and III and solving by vectorial analysis for the mean QRS vector in the heart, one finds that the vector of this premature contraction has its negative end (origin) at the base of the heart and its positive end toward the apex. Thus, the first portion of the heart to become depolarized during this premature contraction is near the base of the ventricles, which therefore is the origin of the ectopic focus.

Disorders of Cardiac Repolarization—Long QT Syndromes. Recall that the Q wave corresponds to ventricular depolarization, whereas the T wave corresponds to ventricular repolarization. The Q-T interval is the time from the beginning of the Q wave to the end of the T wave. Disorders that delay repolarization of ventricular muscle after the action potential cause prolonged

ventricular action potentials and therefore excessively long Q-T intervals on the ECG, a condition called *long QT syndrome* (LQTS).

The major reason that LQTS is of concern is that delayed repolarization of ventricular muscle increases a person's susceptibility to developing ventricular arrhythmias called *torsades de pointes*, which literally means "twisting of the points." This type of arrhythmia has the features shown in **Fig. 13.12**. The shape of the QRS complex may change over time, with the onset of arrhythmia usually following a premature beat, a pause, and then another beat with a long Q-T interval, which may trigger arrhythmias, tachycardia, and, in some cases, ventricular fibrillation.

Disorders of cardiac repolarization that lead to LQTS may be inherited or acquired. The congenital forms of LQTS are rare disorders caused by mutations of sodium or potassium channel genes. At least 17 different mutations of these genes causing variable degrees of Q-T prolongation have been identified.

More common are the acquired forms of LQTS that are associated with plasma electrolyte disturbances, such as hypomagnesemia, hypokalemia, or hypocalcemia, or with the administration of excess amounts of antiarrhythmic drugs such as quinidine or some antibiotics such as fluoroquinolones or erythromycin, which prolong the Q-T interval.

Although some people with LQTS exhibit no major symptoms (other than the prolonged Q-T interval on the ECG), other people exhibit fainting and experience ventricular arrhythmias that may be precipitated by physical exercise, intense emotions such as fright or anger, or being startled by a noise. The ventricular arrhythmias associated with LQTS can, in some cases, deteriorate into ventricular fibrillation and sudden death.

Treatment may include magnesium sulfate for acute LQTS and antiarrhythmic medications such as beta-adrenergic blockers or surgical implantation of a cardiac defibrillator for long-term LQTS.

PAROXYSMAL TACHYCARDIA

Some abnormalities in different portions of the heart, including the atria, Purkinje system, or ventricles, can occasionally cause rapid rhythmical discharge of impulses that spread in all directions throughout the heart. This phenomenon is believed to be caused most frequently by reentrant *circus movement* feedback pathways that set up local repeated self–re-excitation. Because of the rapid rhythm in the irritable focus, this focus becomes the pacemaker of the heart.

The term *paroxysmal* means that the heart rate becomes rapid, then slows down, and then becomes rapid again, with the paroxysm beginning suddenly and lasting for a few seconds, a few minutes, a few hours, or much longer. The paroxysm usually ends as suddenly as it began, with the pacemaker of the heart instantly shifting back to the sinus node.

Paroxysmal atrial tachycardia often can be stopped by eliciting a vagal reflex. A type of vagal reflex sometimes elicited for this purpose is to press on the neck in the regions of the carotid sinuses or to perform the Valsalva maneuver, which may cause enough of a vagal reflex to stop the paroxysm. The Valsalva maneuver can be

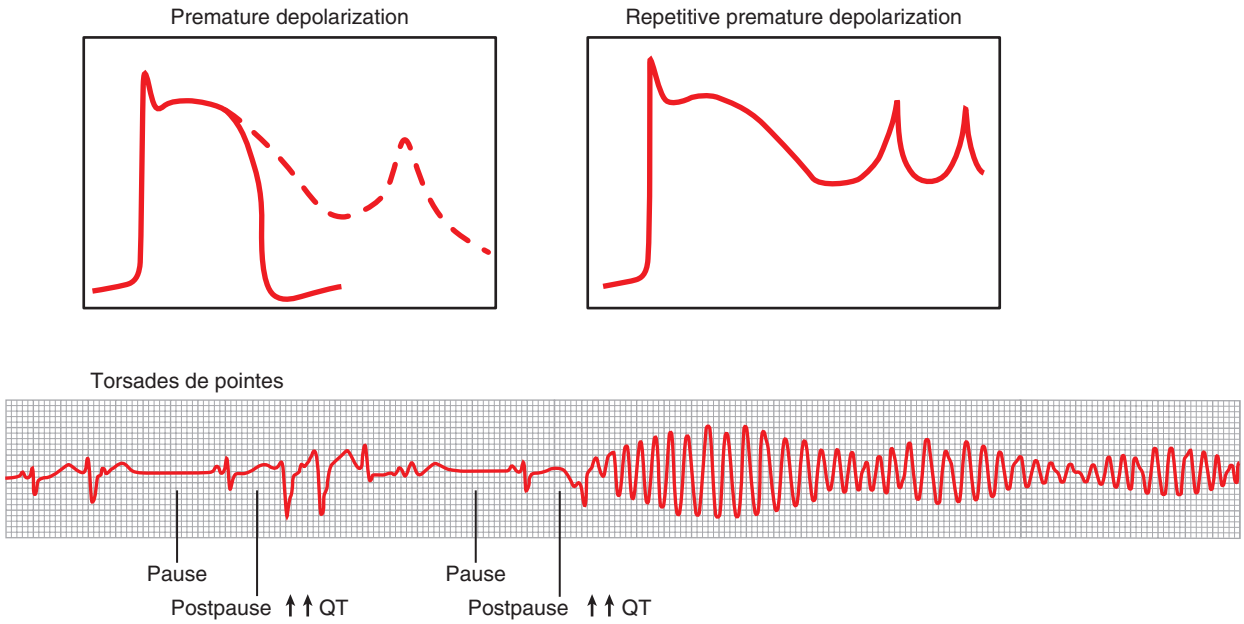

Figure 13.12 Development of arrhythmias in long QT syndrome (LQTS). When the ventricular muscle fiber action potential is prolonged as a result of delayed repolarization, a premature depolarization *(dashed line in top left figure)* may occur before complete repolarization. Repetitive premature depolarizations *(top right figure)* may lead to multiple depolarizations under certain conditions. In torsades de pointes *(bottom figure)*, premature ventricular beats often precede pauses, postpause prolongation of the Q-T interval, and arrhythmias. *(Modified from Murray KT, Roden DM: Disorders of cardiac repolarization: the long QT syndromes. In: Crawford MG, DiMarco JP [eds]:* Cardiology. *London: Mosby, 2001.)*

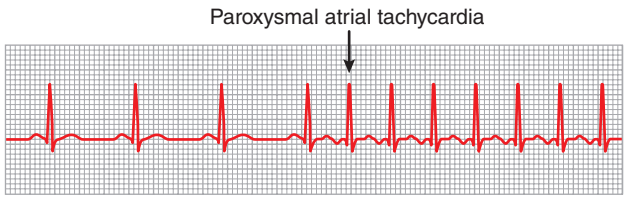

Figure 13.13 Paroxysmal atrial tachycardia—onset in the middle of the record (lead I).

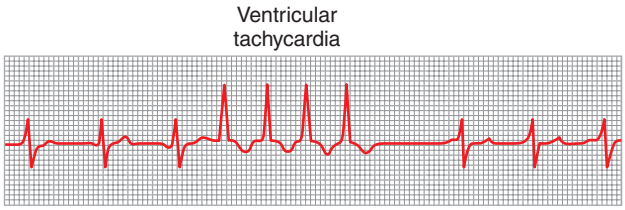

Figure 13.14 Ventricular paroxysmal tachycardia (lead III).

performed by forcefully exhaling against a closed airway (e.g., holding the nose and closing the mouth) or bearing down as though initiating a bowel movement. Antiarrhythmic drugs may also be used to slow conduction or prolong the refractory period in cardiac tissues.

PAROXYSMAL ATRIAL TACHYCARDIA

Fig. 13.13 demonstrates a sudden increase in the heart rate from about 95 to about 150 beats/min in the middle of the record. On close study of the ECG, an inverted P wave is seen during the rapid heartbeat before each QRS-T complex, and this P wave is partially superimposed onto the normal T wave of the preceding beat. This finding indicates that the origin of this paroxysmal tachycardia is in the atrium, but because the P wave is abnormal in shape, the origin is not near the sinus node.

AV Nodal Paroxysmal Tachycardia. Paroxysmal tachycardia often results from an aberrant rhythm involving the AV node that usually causes almost normal QRS-T complexes but totally missing or obscured P waves.

Atrial or AV nodal paroxysmal tachycardia, both of which are referred to as *supraventricular tachycardias*, usually occur in young, otherwise healthy people, and they often grow out of the predisposition to tachycardia after adolescence. In general, supraventricular tachycardia frightens a person tremendously and may cause weakness during the paroxysm, but it usually does not cause permanent harm from the attack.

VENTRICULAR TACHYCARDIA

Fig. 13.14 shows a typical short paroxysm of ventricular tachycardia. The ECG of ventricular tachycardia has the appearance of a series of ventricular premature beats occurring one after another, without any normal beats interspersed.

Ventricular tachycardia is usually a serious condition for two reasons. First, this type of tachycardia usually does not occur unless considerable ischemic damage is present in the ventricles. Second, *ventricular tachycardia frequently initiates the lethal condition of ventricular fibrillation* because of rapid repeated stimulation of the ventricular muscle, as discussed in the next section.

Sometimes, intoxication from the heart failure treatment drug *digitalis* causes irritable foci that lead to ventricular tachycardia. Antiarrhythmic drugs such as *amiodarone* or *lidocaine* can be used to treat ventricular tachycardia. Lidocaine depresses the normal increase in sodium permeability of the cardiac muscle membrane during generation of the action potential, often blocking the rhythmical discharge of the focal point that has been causing the paroxysmal attack. Amiodarone has multiple actions, such as prolonging the action potential and refractory period in cardiac muscle and slowing AV conduction. In some cases, *cardioversion* with an electric shock to the heart is needed for restoration of normal heart rhythm.

VENTRICULAR FIBRILLATION

The most serious of all cardiac arrhythmias is ventricular fibrillation, which is almost invariably fatal if not stopped within 1 to 3 minutes. Ventricular fibrillation results from cardiac impulses that have gone berserk within the ventricular muscle mass, stimulating first one portion of the ventricular muscle, then another portion, then another, and eventually feeding back onto itself to re-excite the same ventricular muscle over and over, never stopping. When this phenomenon occurs, many small portions of the ventricular muscle will be contracting at the same time, while equally as many other portions will be relaxing. Thus, there is never a coordinated contraction of all the ventricular muscle at once, which is required for a pumping cycle of the heart. Despite massive movement of stimulatory signals throughout the ventricles, the ventricular chambers neither enlarge nor contract but remain in an indeterminate stage of partial contraction, pumping either no blood or negligible amounts. Therefore, after ventricular fibrillation begins, unconsciousness occurs within 4 to 5 seconds because of lack of blood flow to the brain, and irretrievable death of tissues begins to occur throughout the body within a few minutes.

Multiple factors can spark the beginning of ventricular fibrillation; a person may have a normal heartbeat one moment, but 1 second later, the ventricles are in fibrillation. Especially likely to initiate fibrillation are sudden electrical shock of the heart, ischemia of the heart muscle, or ischemia of the specialized conducting system.

PHENOMENON OF REENTRY—CIRCUS MOVEMENTS AS THE BASIS FOR VENTRICULAR FIBRILLATION

When the *normal* cardiac impulse in the normal heart has traveled through the extent of the ventricles, it has no

place to go because all the ventricular muscle is refractory and cannot conduct the impulse farther. Therefore, that impulse dies, and the heart awaits a new action potential to begin in the sinus node.

Under some circumstances, however, this normal sequence of events does not occur. Therefore, the following is a more complete explanation of the background conditions that can initiate reentry and lead to what is referred to as *circus movements*, which in turn cause ventricular fibrillation.

Fig. 13.15 shows several small cardiac muscle strips cut in the form of circles. If such a strip is stimulated at the 12 o'clock position *so that the impulse travels in only one direction*, the impulse spreads progressively around the circle until it returns to the 12 o'clock position. If the originally stimulated muscle fibers are still in a refractory state, the impulse then dies out because refractory muscle cannot transmit a second impulse. However, three different conditions can cause this impulse to continue to travel around the circle, causing reentry of the impulse into muscle that has already been excited (circus movement):

1. If the *pathway around the circle is much longer than normal*, by the time the impulse returns to the 12 o'clock position, the originally stimulated muscle will no longer be refractory, and the impulse will continue around the circle again and again.
2. If the length of the pathway remains constant but the *velocity of conduction becomes decreased* enough, an increased interval of time will elapse before the impulse returns to the 12 o'clock position. By this time, the originally stimulated muscle might be out of the refractory state, and the impulse can continue around the circle again and again.
3. *The refractory period of the muscle might become greatly shortened*. In this case, the impulse could also continue around and around the circle.

All these conditions occur in different pathological states of the human heart, including (1) a long pathway, which typically occurs in dilated hearts; (2) a decreased rate of conduction, which frequently results from blockage of the Purkinje system, ischemia of the muscle, high blood potassium levels, or many other factors; and (3) a shortened refractory period, which commonly occurs in response to various drugs, such as epinephrine, or after repetitive electrical stimulation. Thus, in many cardiac disturbances, reentry can cause abnormal patterns of cardiac contraction or abnormal cardiac rhythms that ignore the pace-setting effects of the sinus node.

CHAIN REACTION MECHANISM OF FIBRILLATION

In ventricular fibrillation, one sees many separate and small contractile waves spreading at the same time in different directions over the cardiac muscle. The reentrant impulses in fibrillation are not simply a single impulse moving in a circle, as shown in **Fig. 13.15**. Instead, they have degenerated into a series of multiple wave fronts that have the appearance of a chain reaction. One of the best ways to explain this process in fibrillation is to describe the initiation of fibrillation by electric shock with a 60-cycle alternating electric current.

Fibrillation Caused By 60-Cycle Alternating Current. At a central point in the ventricles of heart A in **Fig. 13.16**, a 60-cycle electrical stimulus is applied through a stimulating electrode. The first cycle of the electrical stimulus causes a depolarization wave to spread in all directions, leaving all the muscle beneath the electrode in a refractory state. After about 0.25 second, part of this muscle begins to come out of the refractory state. Some portions come out of refractoriness before other portions. This state of events is depicted in heart A by many lighter patches, which represent excitable cardiac muscle, and dark patches, which represent muscle that is still refractory. Now, continuing 60-cycle stimuli from the electrode can cause impulses to travel only in certain directions through the heart but not in all directions. Thus, in heart A, certain impulses travel for short

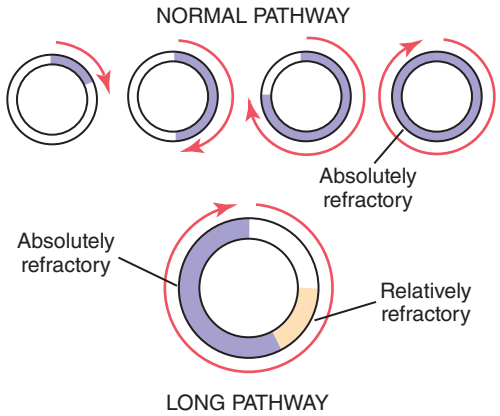

Figure 13.15 Circus movement, showing annihilation of the impulse in the normal pathway and continued propagation of the impulse in the long pathway.

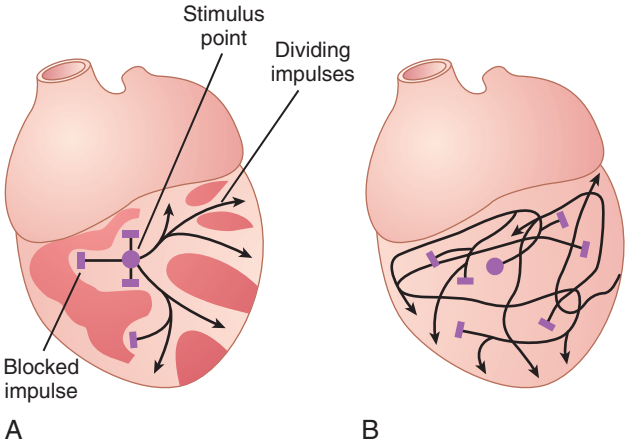

Figure 13.16 (A) Initiation of fibrillation in a heart when patches of refractory musculature are present. (B) Continued propagation of *fibrillatory impulses* in the fibrillating ventricle.

distances until they reach refractory areas of the heart, and then they are blocked. However, other impulses pass between the refractory areas and continue to travel in the excitable areas. Then, several events transpire in rapid succession, all occurring simultaneously and eventuating in a state of fibrillation.

First, block of the impulses in some directions but successful transmission in other directions creates one of the necessary conditions for a reentrant signal to develop—that is, *transmission of some of the depolarization waves around the heart in only some directions but not in other directions*.

Second, the rapid stimulation of the heart causes two changes in the cardiac muscle, both of which predispose to circus movement: (1) the *velocity of conduction through the heart muscle decreases*, which allows a longer time interval for the impulses to travel around the heart; and (2) the *refractory period of the muscle is shortened*, allowing reentry of the impulse into previously excited heart muscle within a much shorter time than normal.

Third, one of the most important features of ventricular fibrillation is the *division of impulses*, as demonstrated in heart A in **Fig. 13.16**. When a depolarization wave reaches a refractory area in the heart, it travels to both sides around the refractory area. Thus, a single impulse becomes two impulses. Then, when each of these impulses reaches another refractory area, it divides to form two more impulses. In this way, many new wave fronts are continually being formed in the heart by progressive *chain reactions* until, finally, many small depolarization waves are traveling in many directions at the same time. Furthermore, this irregular pattern of impulse travel causes *many circuitous routes for the impulses to travel, greatly lengthening the conductive pathway, which is one of the conditions that sustains the fibrillation*. It also results in a continual irregular pattern of patchy refractory areas in the heart.

One can readily see when a vicious circle has been initiated. More and more impulses are formed; these impulses cause more and more patches of refractory muscle, and the refractory patches cause more and more division of the impulses. Therefore, whenever a single area of cardiac muscle comes out of refractoriness, an impulse is close at hand to reenter the area.

Heart B in **Fig. 13.16** demonstrates the final state that develops in ventricular fibrillation. Here, one can see many impulses traveling in all directions, with some dividing and increasing the number of impulses and others blocked by refractory areas. A single electric shock during this vulnerable period frequently can lead to an odd pattern of impulses spreading multidirectionally around refractory areas of muscle, which will lead to ventricular fibrillation.

Commotio Cordis—Ventricular Fibrillation Caused By Blunt Trauma to the Chest. Commotio cordis (Latin for "agitation of the heart") is a rare, potentially fatal condition in which ventricular fibrillation and cardiac arrest may occur immediately after a hard object (e.g., a baseball or hockey puck) strikes the chest directly over the heart during the upstroke of the T wave in ventricular repolarization. A potential mechanism for commotio cordis, based on studies in experimental animals, is trauma-induced stretch of cardiomyocyte membranes, causing activation of stretch-sensitive ion channels and resulting in premature depolarization.

Blunt trauma to the chest during phases of the cardiac action potential outside of ventricular repolarization can also cause additional dysrhythmias, such as complete heart block, left bundle branch block, or ST-segment changes, although these events are usually transient.

ELECTROCARDIOGRAM IN VENTRICULAR FIBRILLATION

In ventricular fibrillation, the ECG is bizarre (**Fig. 13.17**) and ordinarily shows no tendency toward a regular rhythm of any type. During the first few seconds of ventricular fibrillation, relatively large masses of muscle contract simultaneously, which causes coarse, irregular waves in the ECG. After another few seconds, the coarse contractions of the ventricles disappear, and the ECG changes into a new pattern of low-voltage, very irregular waves. Thus, no repetitive electrocardiographic pattern can be ascribed to ventricular fibrillation. Instead, the ventricular muscle contracts at as many as 30 to 50 small patches of muscle at a time, and electrocardiographic potentials change constantly and spasmodically because the electrical currents in the heart flow first in one direction and then in another and seldom repeat any specific cycle.

The voltages of the waves in the ECG in ventricular fibrillation are usually about 0.5 millivolt when ventricular fibrillation first begins, but they decay rapidly; thus, after 20 to 30 seconds, they are usually only 0.2 to 0.3 millivolt. Minute voltages of 0.1 millivolt or less may be recorded for 10 minutes or longer after ventricular fibrillation begins. As already noted, because no pumping of blood occurs during ventricular fibrillation, this state is lethal unless stopped by successful therapy, such as an immediate electroshock (defibrillation) through the heart, as explained in the next section.

VENTRICULAR DEFIBRILLATION

Although a moderate alternating current voltage applied directly to the ventricles almost invariably throws the ventricles into fibrillation, a strong high-voltage electrical

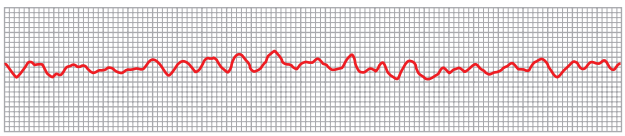

Figure 13.17 Ventricular fibrillation (lead II).

current passed through the ventricles for a fraction of a second can stop fibrillation by throwing all the ventricular muscle into refractoriness simultaneously. This is accomplished by passing intense current through large electrodes placed on two sides of the heart. The current penetrates most of the fibers of the ventricles at the same time, thus stimulating essentially all parts of the ventricles simultaneously and causing them all to become refractory. All action potentials stop, and the heart remains quiescent for 3 to 5 seconds, after which it begins to beat again, usually with the sinus node or some other part of the heart becoming the pacemaker. However, if the same reentrant focus that had originally thrown the ventricles into fibrillation is still present, fibrillation may begin again immediately.

When electrodes are applied directly to the two sides of the heart, fibrillation can usually be stopped using 200 to 1000 volts of direct current applied for a few thousandths of a second. When applied through two electrodes on the chest wall, as shown in **Fig. 13.18**, the usual procedure is to charge a large electrical capacitor up to several thousand volts and then to cause the capacitor to discharge for a few thousandths of a second through the electrodes and through the heart.

In most cases, defibrillation current is delivered to the heart in biphasic waveforms, alternating the direction of the current pulse through the heart. This form of delivery substantially reduces the energy needed for successful defibrillation, thereby decreasing the risk for burns and cardiac damage.

In patients with a high risk for ventricular fibrillation, a small, battery-powered, implantable cardioverter-defibrillator (ICD) with electrode wires lodged in the right ventricle may be implanted. The device is programmed to detect ventricular fibrillation and revert it by delivering a brief electrical impulse to the heart. Advances in electronics and batteries have permitted the development of ICDs that can deliver enough electrical current to defibrillate the heart through electrode wires implanted subcutaneously, outside the rib cage near the heart rather than in or on the heart itself. These devices can be implanted with a minor surgical procedure.

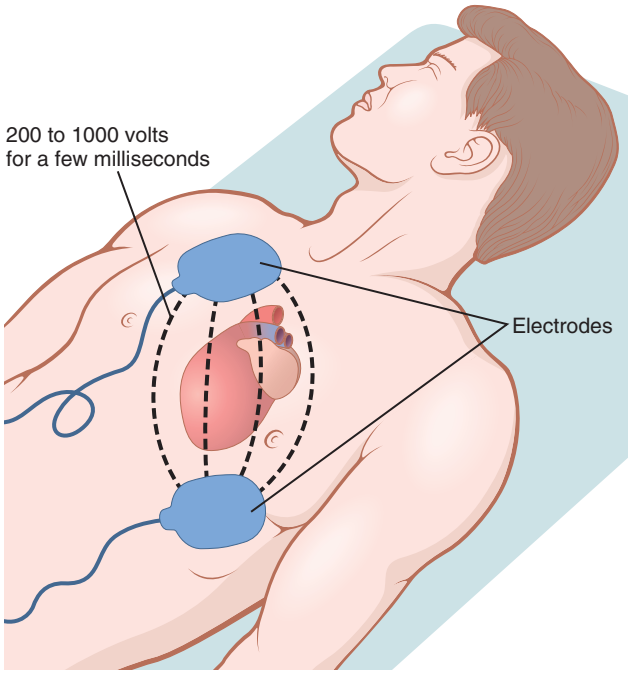

Figure 13.18 Application of electrical current to the chest to stop ventricular fibrillation.

EXTERNAL PUMPING OF THE HEART (CARDIOPULMONARY RESUSCITATION) AS AN AID TO DEFIBRILLATION

Unless defibrillated within 1 minute after ventricular fibrillation begins, the heart is usually too weak to be revived by defibrillation because of the lack of nutrition from coronary blood flow. However, it is still possible to revive the heart by preliminarily pumping the heart by hand (intermittent hand squeezing) and then defibrillating the heart later. In this way, small quantities of blood are delivered into the aorta, and a renewed coronary blood supply develops. Then, after a few minutes of hand pumping, electrical defibrillation may become possible. Fibrillating hearts have been pumped by hand for as long as 90 minutes followed by successful defibrillation.

A technique for pumping the heart without opening the chest consists of intermittent thrusts of pressure on the chest wall along with artificial respiration. This process, plus defibrillation, is called *cardiopulmonary resuscitation* (CPR).

Lack of blood flow to the brain for more than 5 to 8 minutes usually causes permanent cognitive impairment or even destruction of brain tissue. Even if the heart is revived, the person may die from the effects of brain damage or may live with permanent cognitive impairment.

ATRIAL FIBRILLATION

Remember that except for the conducting pathway through the AV bundle, the atrial muscle mass is separated from the ventricular muscle mass by fibrous tissue. Therefore, ventricular fibrillation often occurs without

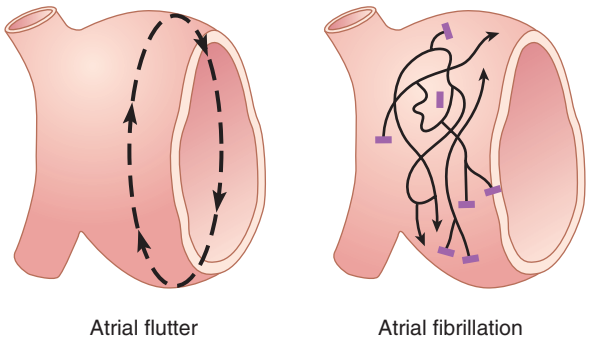

Figure 13.19 Pathways of impulses in atrial flutter and atrial fibrillation.

atrial fibrillation. Likewise, atrial fibrillation often occurs without ventricular fibrillation (shown on the right in **Fig. 13.19**).

The mechanism of atrial fibrillation is identical to that of ventricular fibrillation, except that the process occurs only in the atrial muscle mass instead of the ventricular muscle. A frequent cause of atrial fibrillation is atrial enlargement, which can result, for example, from heart valve lesions that prevent the atria from emptying adequately into the ventricles or from ventricular failure with excess damming of blood in the atria. The dilated atrial walls provide ideal conditions of a long conductive pathway, as well as slow conduction, both of which predispose to atrial fibrillation.

Atrial Fibrillation Causes Impaired Atrial Pumping. For the same reasons that the ventricles will not pump blood during ventricular fibrillation, neither do the atria pump blood in atrial fibrillation. Therefore, the atria become useless as primer pumps for the ventricles. Even so, blood flows passively through the atria into the ventricles, and the efficiency of ventricular pumping is decreased by only 20% to 30%. Therefore, in contrast to the lethality of ventricular fibrillation, a person can live for years with atrial fibrillation, although at reduced efficiency of overall heart pumping. However, due to the reduced atrial contractile function, blood can stagnate, allowing blood clots to form in the left atrial appendage. These blood clots can dislodge and travel to the brain, causing stroke, or to other parts of the body. Therefore, patients with atrial fibrillation are often placed on blood thinner medications (anticoagulants) to reduce the risk of embolism.

In patients who have high bleeding risk and cannot safely take anticoagulants, left atrial appendage occlusion devices are sometimes inserted via a catheter into the appendage where the device opens like an umbrella to prevents clots in the appendage from entering the bloodstream.

ELECTROCARDIOGRAM IN ATRIAL FIBRILLATION

Fig. 13.20 shows the ECG during atrial fibrillation. Numerous small depolarization waves spread in all directions through the atria during atrial fibrillation. Because the waves are weak, and many of them are of opposite polarity at any given time, they usually almost completely electrically neutralize one another. Therefore, in the ECG, one can see either no P waves from the atria or only a fine, high-frequency, very low voltage wave record. Conversely, the QRS-T complexes are normal unless there is some pathology of the ventricles, but their timing is irregular, as explained next.

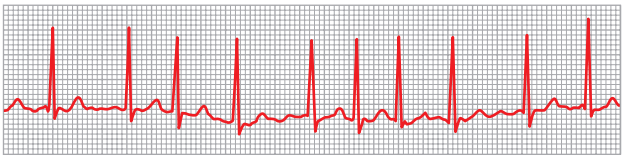

Figure 13.20 Atrial fibrillation (lead II). The waves that can be seen are ventricular QRS and T waves.

IRREGULARITY OF VENTRICULAR RHYTHM DURING ATRIAL FIBRILLATION

When the atria are fibrillating, impulses arrive from the atrial muscle at the AV node rapidly but also irregularly. Because the AV node will not pass a second impulse for about 0.35 second after a previous one, at least 0.35 second must elapse between one ventricular contraction and the next. Then, an additional but variable interval of 0 to 0.6 second occurs before one of the irregular atrial fibrillatory impulses happens to arrive at the AV node. Thus, the interval between successive ventricular contractions varies from a minimum of about 0.35 second to a maximum of about 0.95 second, causing a very irregular heartbeat. In fact, this irregularity, demonstrated by the variable spacing of the heartbeats in the ECG shown in **Fig. 13.20**, is one of the clinical findings used to diagnose the condition. Therefore, atrial fibrillation is often described as an *irregularly, irregular rhythm*. Also, because of the rapid rate of the fibrillatory impulses in the atria, the ventricle is driven at a fast heart rate, usually between 125 and 150 beats/min.

ELECTROSHOCK TREATMENT OF ATRIAL FIBRILLATION

Atrial fibrillation, similar to ventricular fibrillation, can be converted by electroshock back to normal rhythm. The procedure is similar to that for ventricular fibrillation conversion, except the single electric shock is programmed (or synchronized) to fire only during the QRS complex when the ventricles are refractory to stimulation. A normal rhythm often follows *if the heart is capable of generating a normal rhythm*. This procedure is called synchronized *cardioversion* instead of *defibrillation* in the setting of ventricular fibrillation.

ATRIAL FLUTTER

Atrial flutter is another condition caused by a circus movement in the atria. Atrial flutter is different from atrial fibrillation in that the electrical signal travels as a single large wave, always in one direction, around and around the atrial muscle mass, as shown to the left in **Fig. 13.19**. Atrial flutter causes a rapid rate of contraction of the atria, usually between 200 and 350 beats/min. However, because one side of the atria is contracting while the other side is relaxing, the amount of blood pumped by the atria is reduced. Furthermore, the signals reach the AV node too rapidly for all of them to be passed into the ventricles because the refractory periods

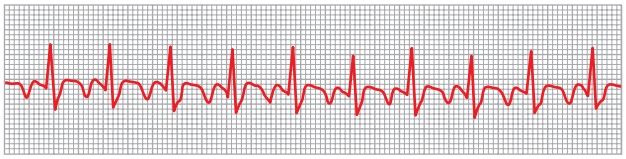

Figure 13.21 Atrial flutter at 250 beats/min with a 2:1 atrial to ventricular rhythm at 125 beats/min (lead II).

of the AV node and AV bundle are too long to pass more than a fraction of the atrial signals. Therefore, there are usually two to three beats of the atria for every single beat of the ventricles.

Fig. 13.21 shows a typical ECG *sawtooth pattern* of atrial flutter. The P waves are strong because of the contraction of semicoordinated masses of muscle. However, note that a QRS-T complex follows an atrial P wave only once for every two beats of the atria, giving a 2:1 rhythm.

CARDIAC ARREST

A final serious abnormality of the cardiac rhythmicity-conduction system is *cardiac arrest*, which results from cessation of all electrical control signals in the heart. That is, no spontaneous rhythm remains.

Cardiac arrest may occur *during deep anesthesia*, when severe hypoxia may develop because of inadequate respiration. The hypoxia prevents the muscle fibers and conductive fibers from maintaining normal electrolyte concentration differentials across their membranes, and their excitability may be so affected that the automatic rhythmicity disappears.

In many cases of cardiac arrest from anesthesia, prolonged CPR (for many minutes or even hours) may be successful in reestablishing a normal heart rhythm. In some patients, severe myocardial disease can cause permanent or semipermanent cardiac arrest, which can cause death. To treat the condition, rhythmical electrical impulses from an *implanted electronic cardiac pacemaker* have been used successfully to keep patients alive for months to years.

Overview of the Circulation: Pressure, Flow, and Resistance

The main function of the circulation is to transport nutrients, waste products, hormones, and other substances from one part of the body to another and, in general, to maintain an appropriate environment in all the tissue fluids for survival and optimal function of the cells.

The rate of blood flow through many tissues is controlled mainly in response to their need for nutrients and removal of waste products of metabolism. In some organs, such as the kidneys, the circulation serves additional functions. Blood flow to the kidney, for example, is far in excess of its metabolic requirements and is also needed for its excretory function, which requires that a large volume of blood be filtered each minute.

The heart and blood vessels, in turn, are controlled to provide the cardiac output and arterial pressure needed to supply adequate tissue blood flow. What are the mechanisms for controlling blood volume and blood flow, and how do they relate to the other functions of the circulation? These are some of the topics and questions that we discuss in this section on the circulation.

PHYSICAL CHARACTERISTICS OF THE CIRCULATION

The circulation, shown in **Fig. 14.1**, is divided into the *systemic circulation* and the *pulmonary circulation*. Because the systemic circulation supplies blood flow to all the tissues of the body except the lungs, it is also called the *peripheral circulation*.

Functional Parts of the Circulation. Before discussing the details of circulatory function, it is important to understand the role of each part of the circulation.

The function of the *arteries* is to transport blood *under high pressure* to the tissues. For this reason, the arteries have strong vascular walls, and blood flows at a high velocity in the arteries.

The *arterioles* are the last small branches of the arterial system and control blood flow into the capillaries. Arterioles have strong muscular walls that can close the arterioles completely or, by relaxing, can dilate the vessels severalfold; thus, the arterioles can vastly alter blood flow in each tissue in response to its needs.

The function of the *capillaries* is to exchange fluid, nutrients, waste products of cell metabolism, electrolytes, hormones, and other substances between the blood and interstitial fluid. To serve this role, the capillary walls are thin and have numerous minute *capillary pores* permeable to water and other small molecular substances.

The *venules* collect blood from the capillaries and gradually coalesce into progressively larger veins.

The *veins* function as conduits for transport of blood from the venules back to the heart. The veins also serve as a major reservoir of extra blood. Although pressure in the venous system is low and venous walls are thin, the veins are muscular enough to contract or expand and thereby serve as a controllable reservoir for extra blood, either a small or a large amount, depending on the needs of the circulation.

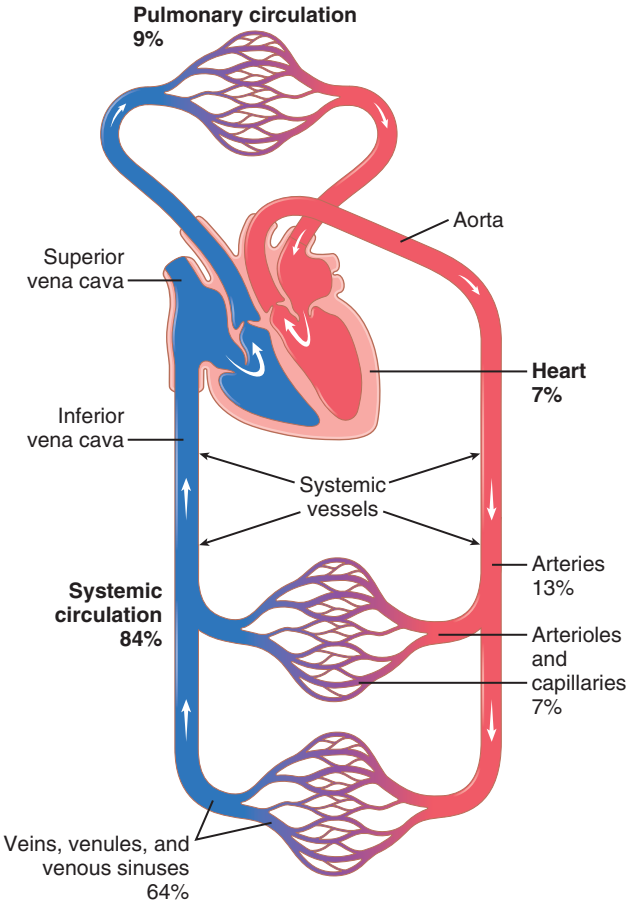

Figure 14.1 Distribution of blood (in percentage of total blood) in the different parts of the circulatory system.

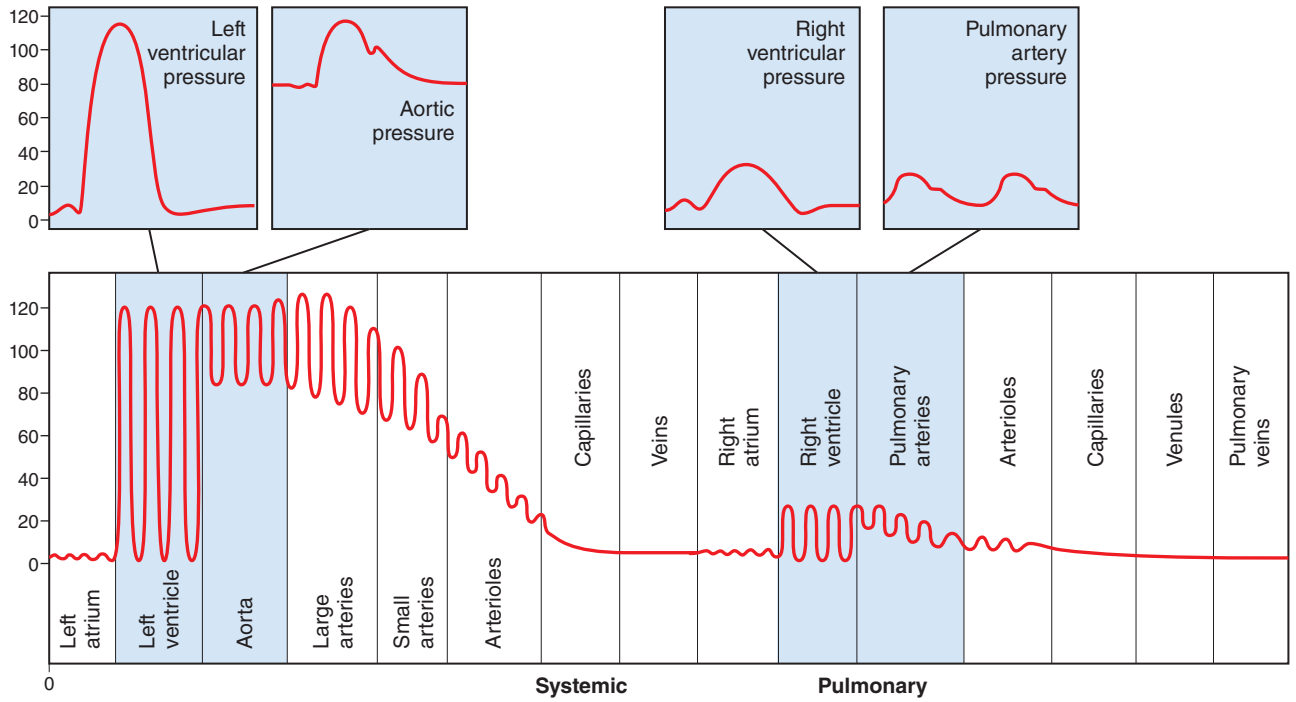

Figure 14.2 Normal blood pressures (in mm Hg) in the different portions of the circulatory system when a person is lying in the horizontal position and resting.

Volumes of Blood in Different Parts of the Circulation. Fig. 14.1 provides an overview of the circulation and lists the percentages of total blood volume in major segments of the circulation. For example, about 84% of the entire blood volume of the body is in the systemic circulation and 16% is in the heart and lungs. Of the 84% in the systemic circulation, approximately 64% is in the veins, 13% is in the arteries, and 7% is in the systemic arterioles and capillaries. The heart contains 7% of the blood and the pulmonary vessels contain 9%.

Most surprising is the low blood volume in the capillaries. It is here, however, that the most important function of the circulation occurs—diffusion of substances back and forth between the blood and tissues, as discussed in Chapter 16.

Blood Flow Velocity Is Inversely Proportional to Vascular Cross-Sectional Area. If all the *systemic vessels* of each type were put side by side, their approximate total cross-sectional areas for the average human would be as follows:

Vessel	Cross-Sectional Area (cm^2)
Aorta	2.5
Small arteries	20
Arterioles	40
Capillaries	2500
Venules	250
Small veins	80
Venae cavae	8

Note particularly that the cross-sectional areas of the veins are much larger than those of the arteries, averaging about four times those of the corresponding arteries. This difference explains the large blood storage capacity of the venous system in comparison with the arterial system.

Because the same volume of blood flow (F) must pass through each segment of the circulation each minute, the velocity of blood flow (v) is inversely proportional to the vascular cross-sectional area (A):

$$v = F/A$$

Thus, under resting conditions, the velocity averages about 33 cm/sec in the aorta but is only 1/1000 as rapid in the capillaries—about 0.3 mm/sec. However, because the capillaries have a typical length of only 0.3 to 1 millimeter, the blood remains in the capillaries for only 1 to 3 seconds, which is surprising because all diffusion of nutrient food substances and electrolytes that occurs through the capillary walls must be performed in this short time.

Pressures in the Various Portions of the Circulation. The heart pumps blood continually into the aorta and the mean pressure in the aorta is high, averaging about 100 mm Hg. Also, because heart pumping is pulsatile, the arterial pressure normally alternates between an average *systolic pressure level* of 120 mm Hg and a *diastolic pressure level* of 80 mm Hg under resting conditions, as shown on the left side of Fig. 14.2. These pressures vary considerably among different individuals and at different times of the day, depending on activity and many other factors, as well as at different stages of life. For example, systolic/diastolic pressure averages about 95/53 mm Hg

in children 1 to 2 years of age and often increases above 120/80 mm Hg in older adults.

As the blood flows through the *systemic circulation*, its mean pressure falls progressively to about 0 mm Hg by the time it reaches the termination of the superior and inferior venae cavae where they empty into the right atrium of the heart.

The pressure in many of the systemic capillaries varies from as high as 35 mm Hg near the arteriolar ends to as low as 10 mm Hg near the venous ends, but their average functional pressure in most vascular beds is about 17 mm Hg, a pressure low enough that little of the plasma leaks through the minute *pores* of the capillary walls, even though nutrients can *diffuse* easily through these same pores to the outlying tissue cells. In some capillaries, such as the glomerular capillaries of the kidneys, the pressure is considerably higher, averaging about 60 mm Hg and causing much higher rates of fluid filtration.

At the far-right side of **Fig. 14.2**, note the respective pressures in the different parts of the *pulmonary circulation*. In the pulmonary arteries, the pressure is pulsatile, just as in the aorta, but the pressure is far less; *pulmonary artery systolic pressure* averages about 25 mm Hg and *diastolic pressure* averages about 8 mm Hg, with a mean pulmonary arterial pressure of only 16 mm Hg. The mean pulmonary capillary pressure averages only 7 mm Hg. Yet, the total blood flow through the lungs each minute is the same as through the systemic circulation. The low pressures of the pulmonary system are in accord with the needs of the lungs because all that is required is to expose the blood in the pulmonary capillaries to oxygen and other gases in the pulmonary alveoli.

BASIC PRINCIPLES OF CIRCULATORY FUNCTION

Although the details of circulatory function are complex, three basic principles underlie major functions of the system.

1. *Blood flow to most tissues is controlled according to the tissue needs.* When tissues are active, they need increased supply of nutrients and therefore more blood flow than when at rest, occasionally as much as 20 to 30 times the resting level. However, the heart normally cannot increase its cardiac output more than four to seven times higher than resting levels. Therefore, it is not possible simply to increase blood flow everywhere in the body when a particular tissue demands increased flow. Instead, the microvessels of each tissue, especially the arterioles, continuously monitor tissue needs, such as the availability of oxygen and other nutrients and the accumulation of carbon dioxide and other tissue waste products. These microvessels, in turn, dilate or constrict to control local blood flow at the level required for the tissue activity. Also, nervous control of the circulation from the central nervous system and hormones provides additional help in controlling tissue blood flow.
2. *Cardiac output is the sum of all the local tissue flows.* When blood flows through a tissue, it immediately returns by way of the veins to the heart. The heart responds automatically to this increased inflow of blood by pumping it immediately back into the arteries. Thus, as long as the heart is functioning normally, it acts as an automaton, responding to the demands of the tissues. The heart, however, often needs help in the form of special nerve signals to make it pump the required amounts of blood flow.
3. *Arterial pressure regulation is generally independent of either local blood flow control or cardiac output control.* The circulatory system is provided with an extensive system for controlling the arterial blood pressure. For example, if at any time the pressure falls significantly below the normal level of about 100 mm Hg, a barrage of nervous reflexes elicits a series of circulatory changes to raise the pressure back toward normal within seconds. The nervous signals especially do the following: (a) increase the force of heart pumping; (b) cause contraction of the large venous reservoirs to provide more blood to the heart; and (c) cause generalized constriction of the arterioles in many tissues so that more blood accumulates in the large arteries to increase the arterial pressure. Then, over more prolonged periods—hours and days—the kidneys play an additional major role in pressure control by secreting pressure-controlling hormones and regulating blood volume.

Thus, the needs of the individual tissues are served specifically by the circulation. In the remainder of this chapter, we begin to discuss the basic control of tissue blood flow, cardiac output, and arterial pressure.

INTERRELATIONSHIPS OF PRESSURE, FLOW, AND RESISTANCE

Blood flow through a blood vessel is determined by two factors: (1) *pressure difference* of the blood between the two ends of the vessel, also sometimes called the *pressure gradient* along the vessel, which pushes the blood through the vessel; and (2) the impediment to blood flow through the vessel, which is called *vascular resistance*. **Fig. 14.3** illustrates these relationships in a blood vessel segment.

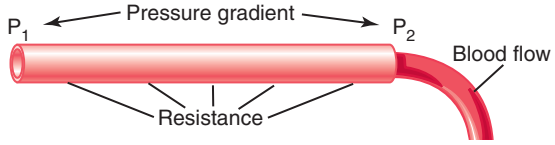

Figure 14.3 Interrelationships of pressure, resistance, and blood flow. P_1, Pressure at the origin of the vessel; P_2, pressure at the other end of the vessel.

P_1 represents the pressure at the origin of the vessel and P_2 is the pressure at the other end. Resistance occurs as a result of friction between the flowing blood and the intravascular endothelium all along the inside of the vessel. The flow through the vessel can be calculated by the following formula, which is called *Ohm's law*:

$$F = \frac{\Delta P}{R}$$

in which F is blood flow, ΔP is the pressure difference ($P_1 - P_2$) between the two ends of the vessel, and R is the resistance. This formula states that the blood flow is directly proportional to the pressure difference but inversely proportional to the resistance.

Note that it is the *difference* in pressure between the two ends of the vessel, not the absolute pressure in the vessel, that determines flow rate. For example, if the pressure at both ends of a vessel is 100 mm Hg and no difference exists between the two ends, there will be no flow, despite the presence of 100 mm Hg pressure.

Ohm's law, illustrated in the preceding formula, expresses one of the most important of all the relationships that the reader needs to understand to comprehend the hemodynamics of the circulation. Because of the extreme importance of this formula, the reader should also become familiar with its other algebraic forms:

$$\Delta P = F \times R$$

$$R = \frac{\Delta P}{F}$$

BLOOD FLOW

Blood flow rate means the quantity of blood that passes a given point in the circulation in a given period of time. Ordinarily, blood flow is expressed in *milliliters per minute* or *liters per minute*, but it can be expressed in milliliters per second or in any other units of flow and time.

The overall blood flow in the total circulation of a 70-kg adult person at rest averages about 5000 to 6000 mL/min, with considerable variation depending on activity, body weight, muscle mass, age, sex, and other factors. For example, total blood flow in the circulation under resting conditions is usually about 10% to 20% greater in men than in women, partly related to larger body mass in men. This total blood flow in the circulation is called the *cardiac output* because it is the amount of blood pumped into the aorta by the heart each minute.

Methods for Measuring Blood Flow

Mechanical and mechanoelectrical *flowmeter* devices can be inserted in series with a blood vessel or, in some cases, applied to the outside of the vessel to measure blood flow.

Electromagnetic Flowmeter. An electromagnetic flowmeter, the principles of which are illustrated in **Fig. 14.4**, can be used to measure blood flow without opening the blood vessel. **Fig. 14.4A** shows the generation of electromotive force (electrical voltage) in blood that is moving through a magnetic field. In this case, a blood vessel is placed between the poles of a strong magnet, and electrodes are placed on the two sides of the vessel perpendicular to the magnetic lines of force. When blood flows through the vessel, an electrical voltage proportional to the rate of blood flow is generated between the two electrodes, and this voltage is recorded using an appropriate voltmeter or electronic recording apparatus. **Fig. 14.4B** shows an actual probe that is placed on a large blood vessel to record its blood flow. The probe contains both the strong magnet and the electrodes.

A special advantage of the electromagnetic flowmeter is that it can record changes in flow in less than 1/100 of a second, allowing for the accurate recording of pulsatile changes in flow as well as steady flow.

Ultrasonic Doppler Flowmeter. Another type of flowmeter that can be applied to the outside of the vessel and that has many of the same advantages as the electromagnetic flowmeter is the *ultrasonic Doppler flowmeter*, as shown in **Fig. 14.5**. A minute piezoelectric crystal is mounted at one end in the wall of the transducer device. This crystal, when energized with an appropriate electronic apparatus, transmits ultrasound at a frequency of several hundred thousand cycles per second downstream along the flowing blood. A portion of the sound is reflected by the red blood cells in the flowing blood. The reflected ultrasound waves then travel backward from the blood cells toward the crystal. These reflected waves have a lower frequency than the transmitted wave because the red blood cells are moving away from the transmitter crystal. This effect is called the *Doppler effect*. (It is the same effect experienced when a train approaches and passes by while blowing its whistle. Once the whistle has passed by the person, the pitch of the sound from the whistle suddenly becomes much lower than when the train is approaching.)

For the flow transducer shown in **Fig. 14.5**, the high-frequency ultrasound wave is intermittently cut off, and the reflected wave is received back onto the crystal and greatly amplified by the electronic apparatus. Another portion of the electronic apparatus determines the frequency difference between the transmitted wave and the reflected wave, thus determining the velocity of blood flow. As long as the diameter of a blood vessel does not change, changes in blood flow in the vessel are directly related to changes in flow velocity.

A variety of noninvasive Doppler ultrasound transducers are used clinically to assess blood flow velocity in large and small blood vessels of the body. These transducers are often handheld and used to direct high-frequency sound waves through the skin to the blood vessels being tested.

Laminar Flow of Blood in Vessels. When blood flows at a steady rate through a long, smooth blood vessel, it flows in *streamlines*, with each layer of blood remaining the same distance from the vessel wall. Also, the central-most portion of the blood stays in the center of the vessel.

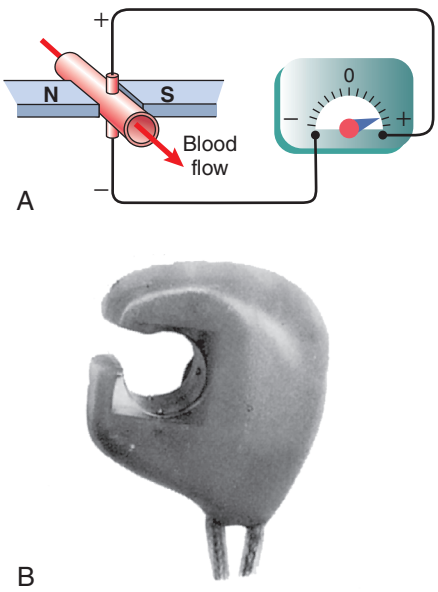

Figure 14.4 (A) Electromagnetic flowmeter showing the generation of an electrical voltage in electrodes on a blood vessel when the vessel is placed in a strong magnetic field and blood flows through the vessel. *N* and *S* refer to the magnet's north and south poles. (B) Electromagnetic flowmeter probe for chronic implantation around blood vessels.

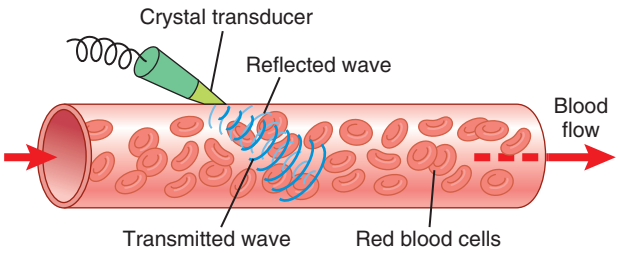

Figure 14.5 Ultrasonic Doppler flow transducer.

This type of flow is called *laminar flow* or *streamline flow*, in contrast to *turbulent flow*, which is blood flowing in all directions in the vessel and continually mixing in the vessel, as discussed subsequently.

Parabolic Velocity Profile During Laminar Flow. When laminar flow occurs, the velocity of flow in the center of the vessel is far greater than that toward the outer edges. This phenomenon is demonstrated in **Fig. 14.6**. In **Fig. 14.6A**, a vessel contains two fluids, the one at the left colored by a dye and the one at the right a clear fluid, but there is no flow in the vessel. When the fluids are made to flow, a parabolic interface develops between them, as shown 1 second later in **Fig. 14.6B**. The portion of fluid adjacent to the vessel wall has hardly moved, the portion slightly away from the wall has moved a small distance, and the portion in the center of the vessel has moved a longer distance. This effect is called the *parabolic profile for velocity of blood flow*.

The cause of the parabolic profile is as follows. The fluid molecules touching the wall move slowly because of

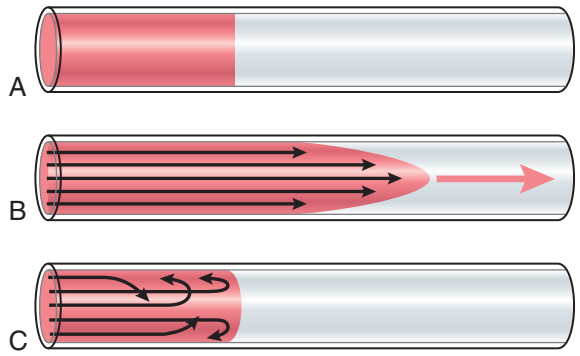

Figure 14.6 (A) Two fluids (one dyed red, and the other clear) before flow begins. (B) The same fluids 1 second after flow begins. (C) Turbulent flow, with elements of the fluid moving in a disorderly pattern.

adherence to the vessel wall. The next layer of molecules slips over these, the third layer over the second, the fourth layer over the third, and so forth. Therefore, the fluid in the middle of the vessel can move rapidly because many layers of slipping molecules exist between the middle of the vessel and the vessel wall. Thus, each layer toward the center flows progressively more rapidly than the outer layers.

Turbulent Flow of Blood Under Some Conditions. When the rate of blood flow becomes too great, when it passes by an obstruction in a vessel, when it makes a sharp turn, or when it passes over a rough surface, the flow may then become *turbulent*, or disorderly, rather than streamlined (**Fig. 14.6C**). Turbulent flow means that the blood flows crosswise in the vessel and along the vessel, usually forming whorls in the blood, called *eddy currents*. These eddy currents are similar to the whirlpools that can be seen in a rapidly flowing river at a point of obstruction. When eddy currents are present, the blood flows with much greater resistance than when the flow is streamlined because eddies add to the overall friction of flow in the vessel tremendously.

The tendency for turbulent flow increases in direct proportion to the velocity of blood flow, the diameter of the blood vessel, and the density of the blood and is inversely proportional to the viscosity of the blood, in accordance with the following equation:

$$Re = \frac{v \cdot d \cdot \rho}{\eta}$$

where *Re* is *Reynolds' number*, the measure of the tendency for turbulence to occur, v is the mean velocity of blood flow (in cm/sec), d is the vessel diameter (in centimeters), ρ is density (in grams/mL), and η is the viscosity (in poise). The viscosity of blood is normally about 1/30 poise, and the density is only slightly greater than 1. When Reynolds' number rises above 200 to 400, turbulent flow will occur at some branches of vessels but will die out along the smooth portions of the vessels. However, when Reynolds' number rises above approximately 2000, turbulence will usually occur, even in a straight, smooth vessel.

Reynolds' number for flow in the vascular system normally rises to 200 to 400, even in large arteries. As a result, there is almost always some flow turbulence at the branches of these vessels. In the proximal portions of the aorta and pulmonary artery, Reynolds' number can rise to several thousand during the rapid phase of ejection by the ventricles, which causes considerable turbulence in the proximal aorta and pulmonary artery, where many conditions are appropriate for turbulence, such as the following: (1) high velocity of blood flow; (2) pulsatile nature of the flow; (3) sudden change in vessel diameter; and (4) large vessel diameter. However, in small vessels, Reynolds' number is almost never high enough to cause turbulence.

BLOOD PRESSURE

Standard Units of Pressure. Blood pressure almost always is measured in millimeters of mercury (mm Hg) because the mercury manometer has been used as the standard reference for measuring pressure since its invention in 1846 by Poiseuille. Actually, blood pressure means the *force exerted by the blood against any unit area of the vessel wall*. If the pressure in a vessel is 100 mm Hg, this means that the force exerted is sufficient to push a column of mercury against gravity up to a level 100 millimeters high.

Occasionally, pressure is measured in *centimeters of water* (cm H_2O). A pressure of 10 cm H_2O means a pressure sufficient to raise a column of water against gravity to a height of 10 centimeters. *One millimeter of mercury pressure equals 1.36 centimeters of water pressure* because the specific gravity of mercury is 13.6 times that of water, and 1 centimeter is 10 times as great as 1 millimeter.

High-Fidelity Methods for Measuring Blood Pressure. The mercury in a manometer has so much inertia that it cannot rise and fall rapidly. For this reason, the mercury manometer, although excellent for recording steady pressures, cannot respond to pressure changes that occur more rapidly than about one cycle every 2 to 3 seconds. Whenever it is desired to record rapidly changing pressures, other types of pressure recorders are necessary. **Fig. 14.7** demonstrates the basic principles of three electronic pressure *transducers* commonly used for converting blood pressure and/or rapid changes in pressure into electrical signals and then recording the electrical signals on a high-speed electrical recorder. Each of these transducers uses a very thin, highly stretched metal membrane that forms one wall of the fluid chamber. The fluid chamber, in turn, is connected through a needle or catheter inserted into the blood vessel in which the pressure is to be measured. When the pressure is high, the membrane bulges slightly; when it is low, it returns toward its resting position.

In **Fig. 14.7A**, a thin metal plate is placed a few hundredths of a centimeter above the membrane. When the membrane bulges, the membrane comes closer to the plate, which increases the *electrical capacitance* between these two, and this change in capacitance can be recorded using an appropriate electronic system.

In **Fig. 14.7B**, a small iron slug rests on the membrane, and this slug can be displaced upward into a center space inside an electrical wire coil. Movement of the iron into the coil increases the *inductance* of the coil, and this too can be recorded electronically.

Finally, in **Fig. 14.7C**, a very thin, stretched resistance wire is connected to the membrane. When this wire is stretched greatly, its resistance increases; when it is stretched less, its resistance decreases. These changes can also be recorded by an electronic system.

The electrical signals from the transducer are sent to an amplifier and then to an appropriate recording device. With some of these high-fidelity types of recording systems, pressure cycles up to 500 cycles/sec have been recorded accurately. In common use are recorders capable of registering pressure changes that occur as rapidly as 20 to 100 cycles/sec in the manner shown on the recorder in **Fig. 14.7C**.

RESISTANCE TO BLOOD FLOW

Units of Resistance. Resistance is the impediment to blood flow in a vessel, but it cannot be measured directly. Instead, resistance must be calculated from measurements of blood flow and pressure difference between two points in the vessel. If the pressure difference between two points is 1 mm Hg and the flow is 1 mL/sec, the resistance is said to be *1 peripheral resistance unit*, usually abbreviated *PRU*.

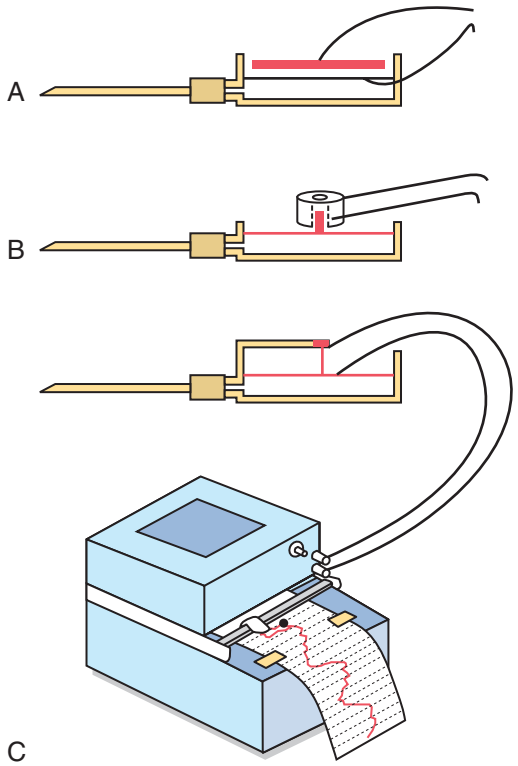

Figure 14.7 (A–C) Principles of three types of electronic transducers for recording rapidly changing blood pressures (see text).

Expression of Resistance in CGS Units. Occasionally, a basic physical unit called the CGS (centimeters, grams, seconds) unit is used to express resistance. This unit is dyne sec/cm^5. Resistance in these units can be calculated by the following formula:

$$R\left(\text{in}\,\frac{\text{dyne sec}}{\text{cm}^5}\right) = \frac{1333 \times \text{mm Hg}}{\text{mL/sec}}$$

Total Peripheral Vascular Resistance and Total Pulmonary Vascular Resistance. The rate of blood flow through the entire circulatory system is equal to the rate of blood pumping by the heart—the cardiac output. If the cardiac output averages 100 mL/sec and the pressure difference from the systemic arteries to the systemic veins is 100 mm Hg, the resistance of the entire systemic circulation, called the *total peripheral resistance*, is about 100/100, or 1 PRU.

In conditions in which all the blood vessels throughout the body become strongly constricted, the total peripheral resistance occasionally rises to as high as 4 PRU. Conversely, when the vessels become greatly dilated, the resistance can fall to as little as 0.2 PRU.

In the pulmonary system, the mean pulmonary arterial pressure averages about 16 mm Hg and the mean left atrial pressure averages 2 mm Hg, giving a net pressure difference of 14 mm. Therefore, when the cardiac output is 100 mL/sec, the *total pulmonary vascular resistance* calculates to be about 0.14 PRU (about one-seventh that in the systemic circulation).

Conductance of Blood in a Vessel Is the Reciprocal of Resistance. Conductance is a measure of the blood flow through a vessel for a given pressure difference. This measurement is generally expressed as mL/sec per mm Hg pressure, but it can also be expressed as L/sec per mm Hg or in any other units of blood flow and pressure.

It is evident that conductance is the exact reciprocal of resistance in accord with the following equation:

$$\text{Conductance} = \frac{1}{\text{Resistance}}$$

Small Changes in Vessel Diameter Markedly Change Its Conductance. Slight changes in the diameter of a blood vessel cause tremendous changes in the vessel's ability to conduct blood when the blood flow is streamlined. This phenomenon is illustrated in **Fig. 14.8A**, which shows three vessels with relative diameters of 1, 2, and 4 but with the same pressure difference of 100 mm Hg between the two ends of the vessels. Although the diameters of these vessels increase only 2-fold and 4-fold, the respective flows are 1, 16, and 256 mL/min, which is a 256-fold increase in flow. Thus, the conductance of the vessel increases in proportion to the *fourth power of the diameter*, in accordance with the following formula:

$$\text{Conductance} \propto \text{Diameter}^4$$

Poiseuille's Law. **Fig. 14.8B**, which shows cross sections of a large and small vessel, illustrates why there is a large

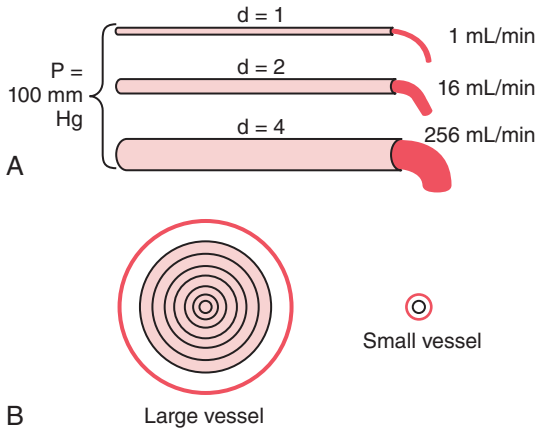

Figure 14.8 (A) Illustration of the effect of vessel diameter on blood flow. (B) Concentric rings of blood flowing at different velocities; the farther away from the vessel wall, the faster the flow. *d*, Diameter; *P*, pressure difference between the two ends of the vessels.

increase in conductance when the diameter increases. The concentric rings inside the vessels indicate that the velocity of flow in each ring is different from that in the adjacent rings because of *laminar* flow, which was discussed earlier in the chapter. That is, the blood in the ring touching the wall of the vessel is barely flowing because of its adherence to the vascular endothelium. The next ring of blood toward the center of the vessel slips past the first ring and, therefore, flows more rapidly. Likewise, the third, fourth, fifth, and sixth rings flow at progressively increasing velocities. Thus, the blood that is near the wall of the vessel flows slowly, whereas that in the middle of the vessel flows much more rapidly.

In the small vessel, essentially all the blood is near the wall, so the rapidly flowing central stream of blood does not exist. By integrating the velocities of all the concentric rings of flowing blood and multiplying them by the areas of the rings, one can derive the following formula, known as *Poiseuille's law*:

$$F = \frac{\pi \Delta P r^4}{8 \eta l}$$

in which F is the rate of blood flow, ΔP is the pressure difference between the ends of the vessel, r is the radius of the vessel, l is length of the vessel, and η is viscosity of the blood.

Note that the rate of blood flow is directly proportional to the *fourth power of the radius* of the vessel, which demonstrates once again that the diameter of a blood vessel (which is equal to twice the radius) plays the greatest role of all factors in determining the rate of blood flow through a vessel.

Importance of the Vessel Diameter Fourth Power Law in Determining Arteriolar Resistance. In the systemic circulation, the small arterioles contribute about two-thirds of the total systemic resistance to blood flow. The internal diameters of the arterioles range from as little as 4 micrometers to as much as 25 micrometers. However,

their strong vascular walls allow the internal diameters to change tremendously, often as much as 4-fold. From the fourth power law relating blood flow to diameter of the vessel, one can see that a 4-fold increase in vessel diameter can increase the flow as much as 256-fold. Thus, this fourth power law makes it possible for the arterioles, responding with only small changes in diameter to nervous signals or local tissue chemical signals, either to turn off the blood flow to the tissue almost completely or, at the other extreme, to cause a vast increase in flow. Ranges of blood flow of more than 100-fold in separate tissue areas have been recorded between the limits of maximum arteriolar constriction and maximum arteriolar dilation.

Resistance to Blood Flow in Series and Parallel Vascular Circuits. Blood pumped by the heart flows from the high-pressure part of the systemic circulation (i.e., aorta) to the low-pressure side (i.e., vena cava) through many miles of blood vessels arranged in series and in parallel. The arteries, arterioles, capillaries, venules, and veins are collectively arranged in series. When blood vessels are arranged in series, flow through each blood vessel is the same, and the total resistance to blood flow (R_{total}) is equal to the sum of the resistances of each vessel:

$$R_{total} = R_1 + R_2 + R_3 + R_4 \ldots$$

The total peripheral vascular resistance is therefore equal to the sum of resistances of the arteries, arterioles, capillaries, venules, and veins. In the example shown in **Fig. 14.9A**, the total vascular resistance is equal to the sum of R_1 and R_2.

Blood vessels branch extensively to form parallel circuits that supply blood to the many organs and tissues of the body. This parallel arrangement permits each tissue to regulate its own blood flow, to a great extent, independently of flow to other tissues.

For blood vessels arranged in parallel (**Fig. 14.9B**), the total resistance to blood flow is expressed as follows:

$$\frac{1}{R_{total}} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \frac{1}{R_4} \ldots$$

It is obvious that for a given pressure gradient, far greater amounts of blood will flow through this parallel system than through any of the individual blood vessels. Therefore, the total resistance is far less than the resistance of any single blood vessel. Flow through each of the parallel vessels in **Fig. 14.9B** is determined by the pressure gradient and its own resistance, not the resistance of the other parallel blood vessels. However, increasing the resistance of any of the blood vessels increases the total vascular resistance.

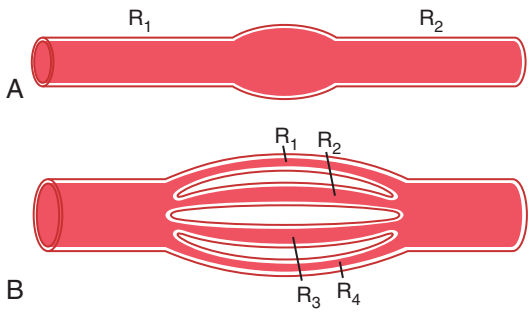

Figure 14.9 Vascular resistance (R). (A) Blood vessels in series. (B) Blood vessels in parallel.

It may seem paradoxical that adding more blood vessels to a circuit reduces the total vascular resistance. Many parallel blood vessels, however, make it easier for blood to flow through the circuit because each parallel vessel provides another pathway, or *conductance*, for blood flow. The total conductance (C_{total}) for blood flow is the sum of the conductance of each parallel pathway:

$$C_{total} = C_1 + C_2 + C_3 + C_4 \ldots$$

For example, brain, kidney, muscle, gastrointestinal, skin, and coronary circulations are arranged in parallel, and each tissue contributes to the overall conductance of the systemic circulation. Blood flow through each tissue is a fraction of the total blood flow (cardiac output) and is determined by the resistance (the reciprocal of conductance) for blood flow in the tissue, as well as the pressure gradient. Therefore, amputation of a limb or surgical removal of a kidney also removes a parallel circuit and reduces the total vascular conductance and total blood flow (i.e., cardiac output) while increasing the total peripheral vascular resistance. Thus, changes in cardiac output are usually determined mainly by the various factors that control blood flow in the body's tissues (see Chapter 20 for further discussion).

Effect of Blood Hematocrit and Blood Viscosity on Vascular Resistance and Blood Flow

Another important factor in Poiseuille's equation is the viscosity of the blood. The greater the viscosity, the lower the flow in a vessel if all other factors are constant. Furthermore, *the viscosity of normal blood is about three times as great as the viscosity of water*.

What makes the blood so viscous? It is mainly the large numbers of suspended red cells in the blood, each of which exerts frictional drag against adjacent cells and against the wall of the blood vessel.

Hematocrit—the Proportion of Blood That Is Red Blood Cells. If a person has a hematocrit of 40, this means that 40% of the blood volume is red blood cells, and the remainder is mostly plasma with white blood cells and platelets comprising only about 1%. The hematocrit of adult men averages about 42, whereas that of women averages about 38. These values can vary greatly, depending on whether the person has anemia, the degree of bodily activity, and the altitude at which the person resides. These changes in hematocrit are discussed in relationship to the red blood cells and their oxygen transport function in Chapter 33.

Hematocrit is determined by centrifuging blood in a calibrated tube, as shown in **Fig. 14.10**. The calibration allows direct reading of the percentage of cells.

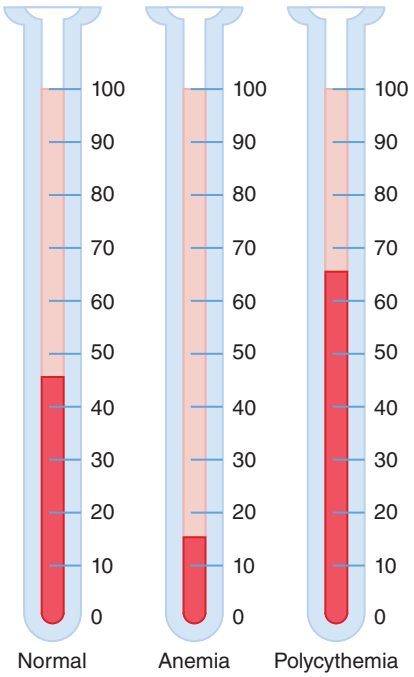

Figure 14.10 Hematocrit values in a healthy (normal) person and in patients with anemia and polycythemia. The numbers refer to the percentage of the blood composed of red blood cells.

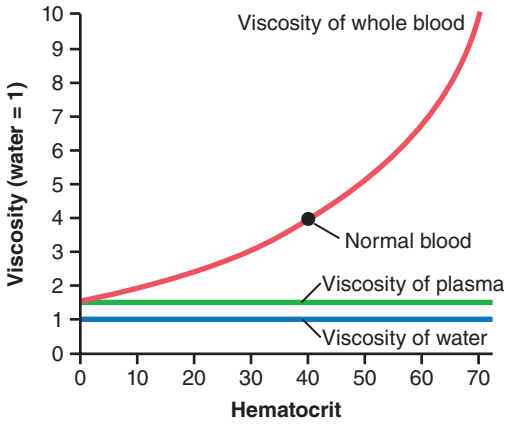

Figure 14.11 Effect of hematocrit on blood viscosity (water viscosity = 1).

Increasing Hematocrit Markedly Increases Blood Viscosity. The viscosity of blood increases markedly as the hematocrit increases, as shown in **Fig. 14.11**. The viscosity of whole blood at a normal hematocrit is about 3 to 4, which means that three to four times as much pressure is required to force whole blood as to force water through the same blood vessel. When the hematocrit rises to 60 or 70, which it often does in persons with *polycythemia*, the blood viscosity can become as great as 10 times that of water, and its flow through blood vessels is greatly retarded.

Other factors that affect blood viscosity are the plasma protein concentration and types of proteins in the plasma, but these effects are so much less than the effect of hematocrit that they are not significant considerations in most hemodynamic studies. The viscosity of blood plasma is about 1.5 times that of water.

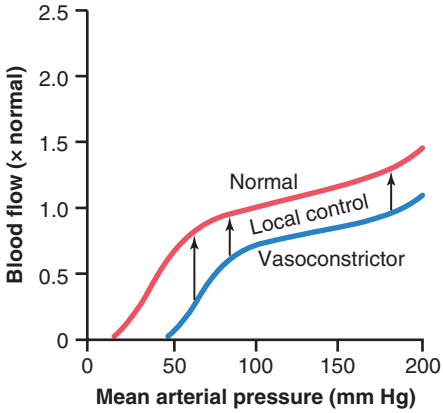

Figure 14.12 Effect of changes in arterial pressure over a period of several minutes on blood flow in a tissue such as skeletal muscle. Note that between pressures of 70 and 175 mm Hg, blood flow is autoregulated. The *blue line* shows the effect of vasoconstriction (e.g., due to sympathetic stimulation) on this relationship. Reduced tissue blood flow is rarely maintained for more than a few hours because of the activation of local autoregulatory mechanisms that eventually return blood flow toward normal.

EFFECTS OF PRESSURE ON VASCULAR RESISTANCE AND TISSUE BLOOD FLOW

Autoregulation Attenuates the Effect of Arterial Pressure on Tissue Blood Flow. From the discussion thus far, one might expect an increase in arterial pressure to cause a proportionate increase in blood flow through the body's tissues. However, the effect of arterial pressure on blood flow in many tissues is usually far less than one might expect, as shown in **Fig. 14.12**. This is because an increase in arterial pressure not only increases the force that pushes blood through the vessels but also initiates compensatory increases in vascular resistance within a few seconds through activation of the local control mechanisms, discussed in Chapter 17. Conversely, with reductions in arterial pressure, vascular resistance is promptly reduced in most tissues, and blood flow is maintained at a relatively constant rate. The ability of each tissue to adjust its vascular resistance and to maintain normal blood flow during changes in arterial pressure between approximately 70 and 175 mm Hg is called *blood flow autoregulation*.

Note in **Fig. 14.12** that changes in blood flow can be caused by strong sympathetic stimulation, which *constricts* the blood vessels. Likewise, hormonal vasoconstrictors, such as *norepinephrine, angiotensin II, vasopressin*, or *endothelin*, can also reduce blood flow, at least transiently.

Blood flow changes rarely last for more than a few hours in most tissues, even when increases in arterial pressure or increased levels of vasoconstrictors are sustained. The reason for the relative constancy of blood flow is that each tissue's local autoregulatory mechanisms eventually override most of the effects of vasoconstrictors to provide a blood flow that is appropriate for the needs of the tissue.

Pressure-Flow Relationship in Passive Vascular Beds. In isolated blood vessels or in tissues that do not

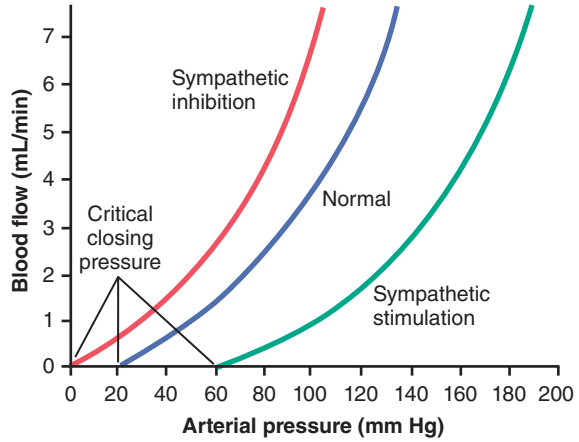

Figure 14.13 Effect of arterial pressure on blood flow through a *passive* blood vessel at different degrees of vascular tone caused by increased or decreased sympathetic stimulation of the vessel.

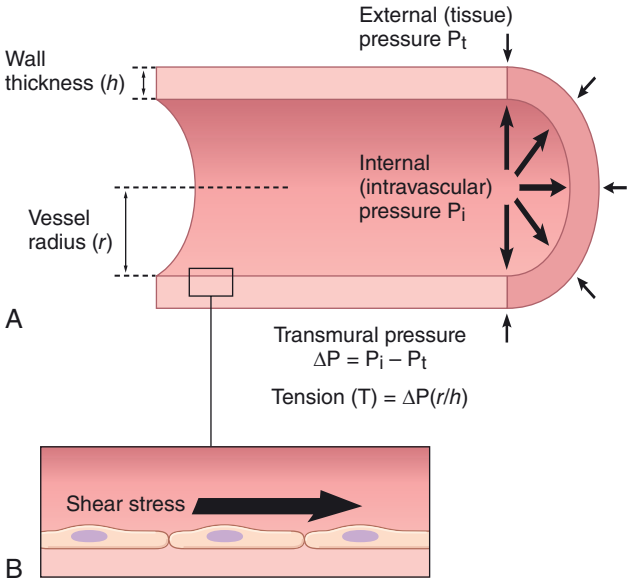

Figure 14.14 Illustration of the effects of vessel wall tension and shear stress on blood vessels. (A) Wall tension develops in response to transmural pressure gradients and causes stretch of endothelial and vascular smooth muscle cells in all directions. (B) Shear stress is the frictional force or drag on endothelial cells caused by flowing blood. Shear stress results in unidirectional endothelial cell deformation.

exhibit autoregulation, changes in arterial pressure may have important effects on blood flow. The effect of pressure on blood flow may, in some cases, be even greater than that predicted by Poiseuille's equation, as shown by the upward curving lines in **Fig. 14.13**. The reason for this is that increased arterial pressure not only increases the force that pushes blood through the vessels but also distends the elastic vessels, actually *decreasing* vascular resistance. Conversely, decreased arterial pressure in passive blood vessels increases resistance as the elastic vessels gradually collapse due to reduced distending pressure. When pressure falls below a critical level, called the *critical closing pressure*, flow ceases because the blood vessels are completely collapsed.

Sympathetic stimulation and other vasoconstrictors can alter the passive pressure-flow relationship shown in **Fig. 14.13**. Thus, *inhibition of* sympathetic activity *greatly dilates* the vessels and can increase the blood flow 2-fold or more. Conversely, very strong sympathetic stimulation *can constrict* the vessels so much that blood flow occasionally decreases to as low as zero for a few seconds, despite high arterial pressure.

In reality, there are few physiological conditions in which tissues display the passive pressure-flow relationship shown in **Fig. 14.13**. Even in tissues that do not effectively autoregulate blood flow during acute changes in arterial pressure, blood flow is regulated according to the needs of the tissue when the pressure changes are sustained, as discussed in Chapter 17.

Vascular Wall Tension. Tension on the blood vessel wall develops in response to transmural pressure gradients and causes vascular smooth muscle and endothelial cells to stretch in all directions (**Fig. 14.14A**). According to the *law of Laplace*, wall tension (T) for a thin-walled tube is proportional to the transmural pressure gradient (ΔP) times the radius (r) of the blood vessel divided by its wall thickness (h):

$$T = \Delta P \times (r/h)$$

Thus, larger blood vessels exposed to high pressures, such as the aorta, must have stronger walls to withstand higher levels of tension and are generally reinforced with fibrous bands of collagen. In contrast, capillaries have a much smaller radii and therefore are exposed to much lower wall tension, permitting them to withstand pressures as high as 65 to 70 mm Hg in some organs such as the kidneys. As discussed in Chapter 17, chronic changes in blood pressure lead to remodeling of blood vessels to accommodate the associated changes in wall tension.

Vascular Shear Stress. As blood flows it creates a frictional force, or drag, on the endothelial cells lining the blood vessels (**Fig. 14.14B**). This force, called *shear stress*, is proportional to the flow velocity and viscosity of the blood, inversely related to the radius cubed, and generally is expressed in force/unit area (e.g., dynes/cm^2). In clinical practice, there is no single commonly used method for measuring shear stress. However, despite its relatively low magnitude compared to contractile forces or wall stretch from blood pressure, shear stress is important in the development and adaptation of the vascular system to accommodate tissue blood flow requirements. Endothelial cells contain multiple proteins that together serve as mechanical sensors and regulate signaling pathways that shape the vasculature during embryonic development and continue altering blood vessel morphology to optimize delivery of blood to tissues in adult life, as discussed further in Chapter 17.

See the Bibliography for Chapter 15.

Vascular Distensibility and Functions of the Arterial and Venous Systems

VASCULAR DISTENSIBILITY

A valuable characteristic of the vascular system is that all blood vessels are *distensible*. The distensibility of arteries allows them to accommodate the pulsatile output of the heart and to average out the pressure pulsations. This capability provides smooth continuous flow of blood through the very small blood vessels of the tissues.

The veins are the most distensible of all the blood vessels. Even slight increases in venous pressure cause the veins to store 0.5 to 1.0 liter of extra blood. Therefore, *the veins provide a reservoir* for storing large quantities of extra blood that can be called into use whenever blood is required elsewhere in the circulation.

Units of Vascular Distensibility. Vascular distensibility normally is expressed as the fractional increase in volume for each millimeter of mercury rise in pressure, in accordance with the following formula:

$$\text{Vascular distensibility} = \frac{\text{Increase in volume}}{\text{Increase in pressure} \times \text{Original volume}}$$

That is, if 1 mm Hg increase in pressure causes a vessel that originally contained 10 mL of blood to increase its volume by 1 mL, the distensibility would be 0.1 per mm Hg, or 10% per mm Hg.

The Veins Are Much More Distensible Than the Arteries. The walls of the arteries are thicker and far stronger than those of the veins. Consequently, the veins, on average, are about eight times more distensible than the arteries. Thus, a given increase in pressure causes about eight times as much increase in blood in veins as in arteries of comparable size.

In the pulmonary circulation, the pulmonary vein distensibilities are similar to those of the systemic circulation. However, the pulmonary arteries normally operate under pressures about one-sixth of those in the systemic arterial system, and their distensibilities are correspondingly greater—about six times the distensibility of systemic arteries.

Vascular Compliance (or Vascular Capacitance)

The *total quantity of blood* that can be stored in a given portion of the circulation for each mm Hg pressure rise is called the *compliance* or *capacitance* of the respective vascular bed and is calculated by the following equation:

$$\text{Vascular compliance} = \frac{\text{Increase in volume}}{\text{Increase in pressure}}$$

Compliance and distensibility are quite different. A highly distensible vessel that has a small volume may have far less compliance than a much less distensible vessel that has a large volume because *compliance is equal to distensibility times volume*.

The compliance of a systemic vein is about 24 times that of its corresponding artery because it is about 8 times as distensible and has a volume about 3 times as great ($8 \times 3 = 24$).

Volume-Pressure Curves of the Arterial and Venous Circulations

A convenient method for expressing the relationship of pressure to volume in a vessel or in any portion of the circulation is to use a *volume-pressure curve*. The red and blue solid curves in **Fig. 15.1** represent, respectively, the volume-pressure curves of the normal systemic arterial system and venous system, showing that when the arterial system of the average adult person (including all the large arteries, small arteries, and arterioles) is filled with about 700 mL of blood, the mean arterial pressure is 100 mm Hg, but when it is filled with only 400 mL of blood, the pressure falls to zero.

In the entire systemic venous system, the volume normally ranges from 2000 to 3500 mL, and a change of several hundred milliliters in this volume is required to change the venous pressure by only 3 to 5 mm Hg. This characteristic mainly explains why as much as one-half liter of blood can be transfused into a healthy person in only a few minutes without greatly altering the function of the circulation.

Effect of Sympathetic Stimulation or Sympathetic Inhibition on the Volume-Pressure Relationships of the Arterial and Venous Systems. Also shown in **Fig. 15.1** are the effects on the volume-pressure curves when the vascular sympathetic nerves are excited or inhibited. An increase in vascular smooth muscle tone caused by sympathetic stimulation increases the pressure at each volume of the arteries or veins, whereas sympathetic inhibition decreases the pressure at each volume.

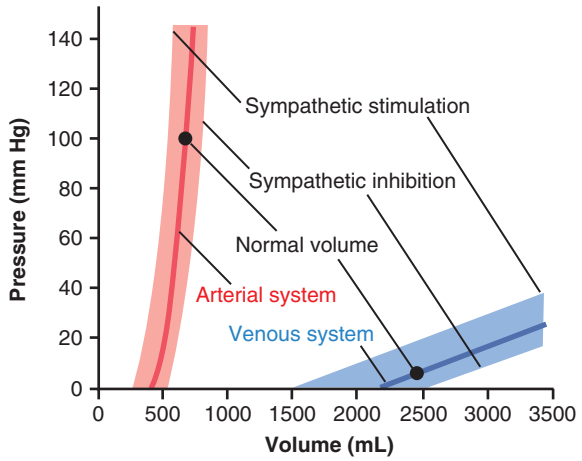

Figure 15.1 Volume-pressure curves of the systemic arterial and venous systems, showing the effects of stimulation or inhibition of the sympathetic nerves to the circulatory system.

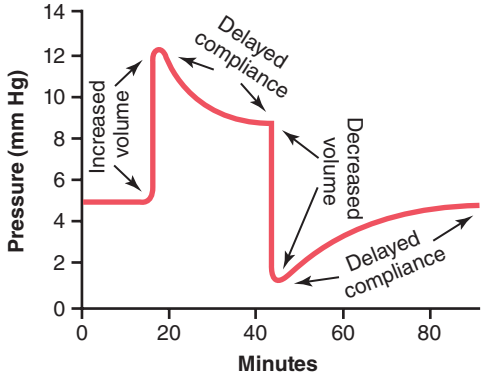

Figure 15.2 Effect on the intravascular pressure of injecting a volume of blood into a venous segment and later removing the excess blood, demonstrating the principle of *delayed compliance*.

Control of the vessels by the sympathetic nervous system in this manner is valuable for diminishing the dimensions of one segment of the circulation, thus transferring blood to other segments. For example, an increase in vascular tone throughout the systemic circulation can cause large volumes of blood to shift into the heart, which is one of the principal methods that the body uses to rapidly increase heart pumping.

Sympathetic control of vascular capacitance is highly important when there is reduced blood volume, such as occurs after hemorrhage. Enhancement of sympathetic tone, especially to the veins, reduces the vessel sizes enough that the circulation continues to operate almost normally, even when as much as 25% of the total blood volume has been lost.

Delayed Compliance (Stress-Relaxation) of Vessels. The term *delayed compliance* means that a vessel exposed to increased volume initially exhibits a large increase in pressure, but progressive delayed stretching of smooth muscle in the vessel wall allows the pressure to return toward normal over a period of minutes to hours. This effect is shown in **Fig. 15.2**. In this figure, the pressure is recorded in a small segment of a vein that is occluded at both ends. An extra volume of blood is suddenly injected until the pressure rises from 5 to 12 mm Hg. Even though none of the blood is removed after it is injected, the pressure rapidly begins to decrease and approaches about 9 mm Hg after several minutes. Thus, the volume of blood injected causes immediate *elastic* distention of the vein, but then the smooth muscle fibers of the vein begin to creep to longer lengths, and their tensions correspondingly decrease. This effect is a characteristic of all smooth muscle and is called *stress-relaxation*, as explained in Chapter 8.

Delayed compliance is a valuable mechanism for the circulation to accommodate extra blood when necessary, such as after a large transfusion. Delayed compliance in the reverse direction is one way in which the circulation automatically adjusts itself over a period of minutes or hours to diminished blood volume after serious hemorrhage.

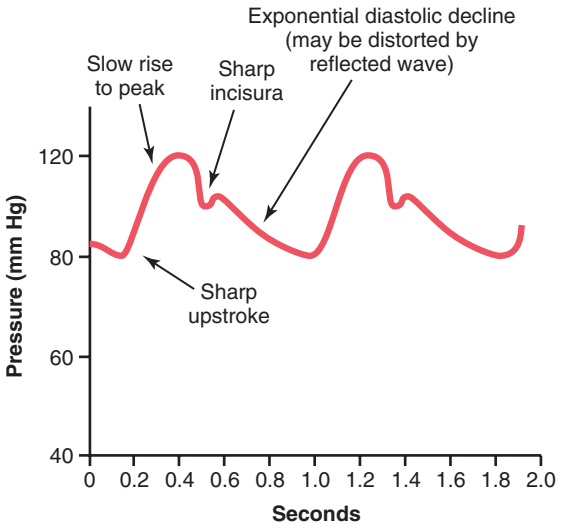

Figure 15.3 Pressure pulse contour in the ascending aorta.

ARTERIAL PRESSURE PULSATIONS

With each beat of the heart, a new surge of blood fills the arteries. Were it not for distensibility of the arterial system, all this new blood would flow through the peripheral blood vessels almost instantaneously, only during cardiac systole, and no flow would occur during diastole. However, the compliance of the arterial tree normally reduces the pressure pulsations to almost no pulsations by the time the blood reaches the capillaries; therefore, tissue blood flow is mainly continuous with very little pulsation.

The *pressure pulsations* at the root of the aorta are illustrated in **Fig. 15.3**. In a healthy young adult, the pressure at the top of each pulse, called the *systolic pressure*, is about 120 mm Hg. At the lowest point of each pulse, called the *diastolic pressure*, it is about 80 mm Hg. The difference between these two pressures, about 40 mm Hg, is called the *pulse pressure*.

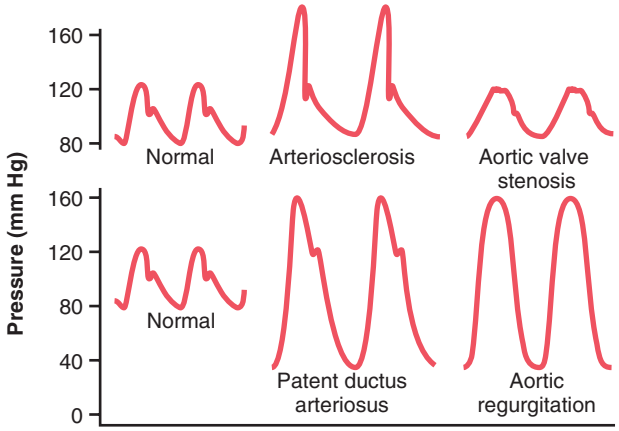

Figure 15.4 Aortic pressure pulse contours in arteriosclerosis, aortic valve stenosis, patent ductus arteriosus, and aortic regurgitation.

Two major factors affect the pulse pressure: (1) the *stroke volume output* of the heart; and (2) the *compliance (total distensibility)* of the arterial tree.

In general, the greater the stroke volume output, the greater the amount of blood that must be accommodated in the arterial tree with each heartbeat and, therefore, the greater the pressure rise and fall during systole and diastole, thus causing a greater pulse pressure. Conversely, the less the compliance of the arterial system, the greater the rise in pressure for a given stroke volume of blood pumped into the arteries. For example, as demonstrated by the middle top curves in **Fig. 15.4**, the pulse pressure sometimes rises to twice normal when the arteries have stiffened with *arteriosclerosis* and therefore are relatively noncompliant.

In effect, pulse pressure is determined approximately by the *ratio of stroke volume output to compliance of the arterial tree*. Any condition of the circulation that affects either of these two factors also affects the pulse pressure:

$$\text{Pulse pressure} \approx \text{Stroke volume/arterial compliance}$$

ABNORMAL PRESSURE PULSE CONTOURS

Some pathophysiological conditions of the circulation cause *abnormal contours of the pressure pulse wave* in addition to altering the pulse pressure. Especially distinctive among these conditions are aortic stenosis, patent ductus arteriosus, and aortic regurgitation, each of which is shown in **Fig. 15.4**.

In persons with *aortic valve stenosis*, the diameter of the aortic valve opening is reduced significantly, and the aortic pressure pulse is decreased significantly because of diminished blood flow outward through the stenotic valve.

In persons with *patent ductus arteriosus*, 50% or more of the blood pumped into the aorta by the left ventricle flows immediately backward through the wide open ductus into the pulmonary artery and lung blood vessels, thus allowing the diastolic pressure to fall very low before the next heartbeat and increasing the pulse pressure.

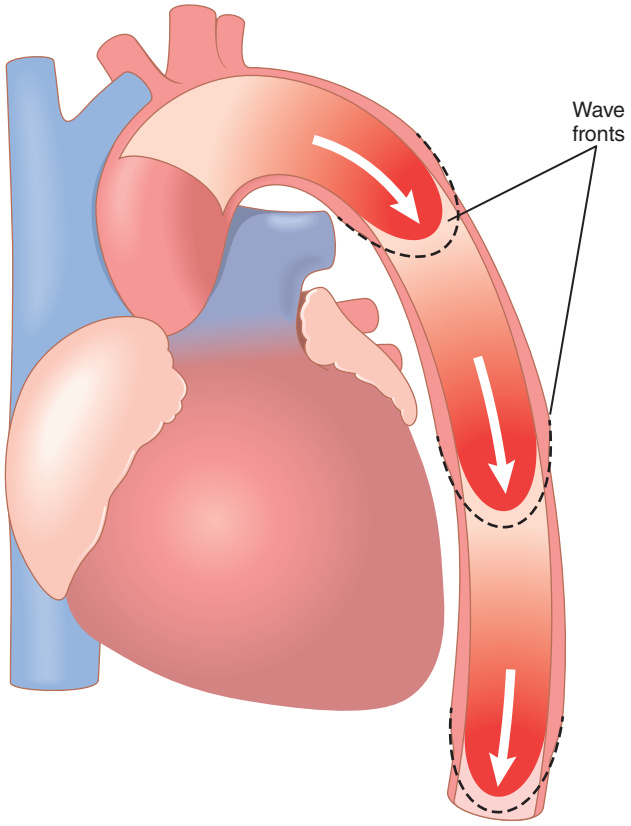

Figure 15.5 Progressive stages in transmission of the pressure pulse along the aorta.

In persons with *aortic regurgitation*, the aortic valve is absent or does not close completely. Therefore, after each heartbeat, the blood that has just been pumped into the aorta flows immediately backward into the left ventricle. As a result, the aortic pressure can fall all the way to zero between heartbeats. Also, there is no incisura in the aortic pulse contour because there is no aortic valve to close.

TRANSMISSION OF PRESSURE PULSES TO THE PERIPHERAL ARTERIES

When the heart ejects blood into the aorta during systole, only the proximal portion of the aorta initially becomes distended because the inertia of the blood prevents sudden blood movement all the way to the periphery. However, the rising pressure in the proximal aorta rapidly overcomes this inertia, and the wavefront of distention spreads farther and farther along the aorta, as shown in **Fig. 15.5**. This phenomenon is called *transmission of the pressure pulse* in the arteries.

The velocity of pressure pulse transmission is 3 to 5 m/sec in the normal aorta, 7 to 10 m/sec in the large arterial branches, and 15 to 35 m/sec in the small arteries. In general, the greater the compliance of each vascular segment, the slower the velocity, which explains the slower transmission in the aorta and the much faster transmission in the much less compliant small distal arteries. In the aorta, the velocity of transmission of the pressure pulse

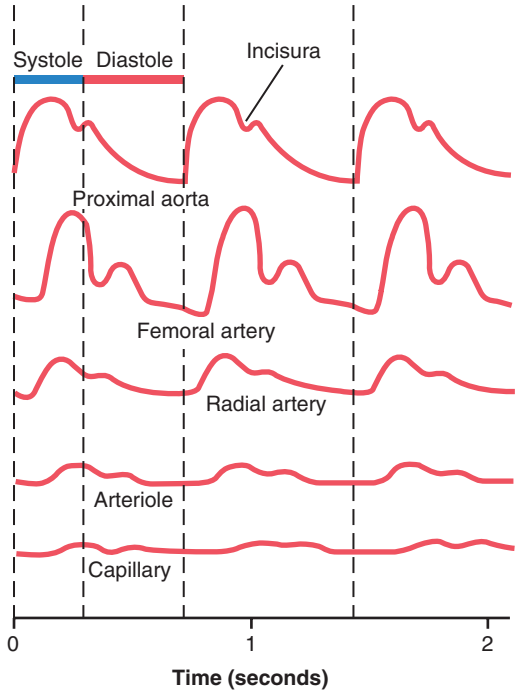

Figure 15.6 Changes in the pulse pressure contour as the pulse wave travels toward the smaller vessels.

is 15 or more times the velocity of blood flow because the pressure pulse is simply a moving wave of *pressure* that involves little forward total movement of blood volume.

Pressure Pulses Are Damped in the Smaller Arteries, Arterioles, and Capillaries. Fig. 15.6 shows typical changes in the pressure pulse contours as the pulse travels into the peripheral vessels. Note especially in the three lower curves that the intensity of pulsation becomes progressively less in the smaller arteries, arterioles, and especially the capillaries. In fact, only when aortic pulsations are extremely large or the arterioles are greatly dilated can pulsations be observed in most capillaries.

The causes of this progressive *damping of the pressure pulses* in the periphery are 2-fold: (1) resistance to blood movement in the vessels; and (2) compliance of the vessels. The resistance damps the pulsations because a small amount of blood must flow forward at the pulse wave front to distend the next segment of the vessel; the greater the resistance, the more difficult it is for blood flow to occur. The compliance damps the pulsations because the more compliant a vessel, the greater the quantity of blood required at the pulse wave front to cause an increase in pressure. Therefore, *the degree of damping is almost directly proportional to the product of resistance times compliance.*

CLINICAL METHODS FOR MEASURING SYSTOLIC AND DIASTOLIC PRESSURES

It is not practical to use pressure recorders that require needle or catheter insertion into an artery for making routine arterial pressure measurements in human patients, although these types of recorders are used on occasion when special studies are necessary. Instead, the clinician determines systolic and diastolic pressures through indirect means, usually by *auscultatory or oscillatory methods.*

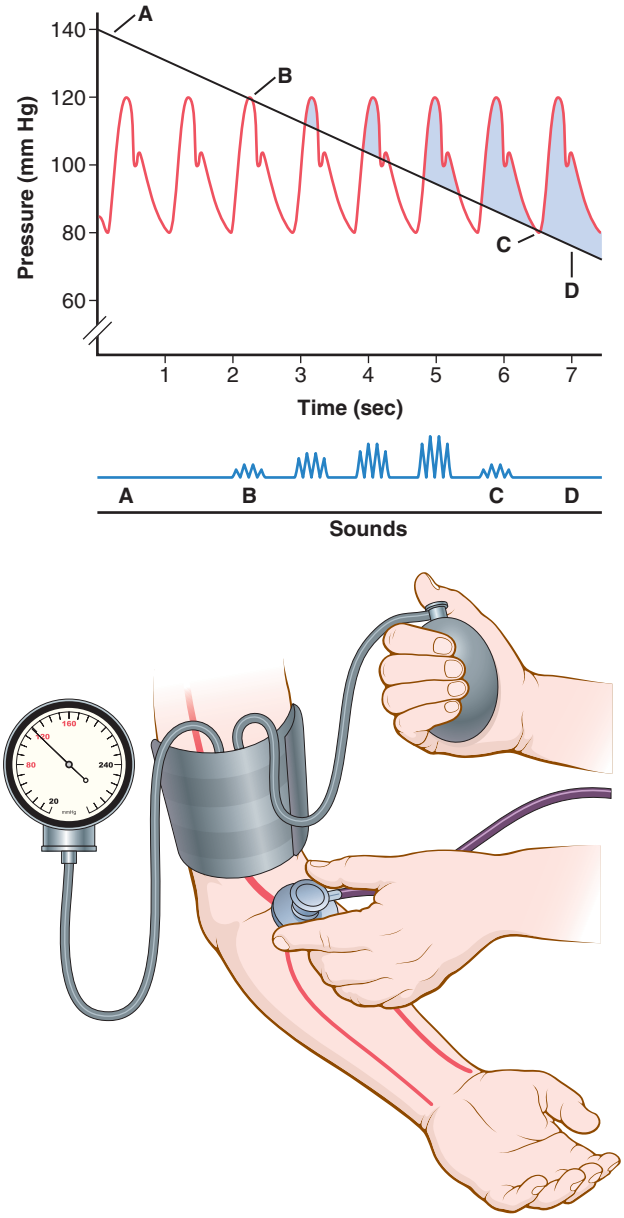

Figure 15.7 Auscultatory method for measuring systolic and diastolic arterial pressures.

Auscultatory Method. Fig. 15.7 illustrates the auscultatory method for determining systolic and diastolic arterial pressures. A stethoscope is placed over the brachial artery at the antecubital space, and a blood pressure cuff is inflated around the upper arm to a level higher than the arterial pressure. As long as the cuff compresses the arm with enough pressure to completely close the brachial artery, no sounds are heard from the artery with the stethoscope. The cuff pressure is then slowly reduced. At the point where systolic arterial pressure exceeds the cuff pressure,

blood begins to jet through the partially constricted artery and a sound is heard with each pulsation. These sounds are called *Korotkoff sounds*, named after Nikolai Korotkoff, a Russian physician, who described them in 1905.

Korotkoff sounds are believed to be caused mainly by blood jetting through the partly occluded vessel and by vibrations of the vessel wall. The jet causes turbulence in the vessel beyond the cuff, and this turbulence sets up the vibrations heard through the stethoscope. The laminar blood flow that normally occurs in arteries produces little vibration of the arterial wall; therefore, no sounds are heard with a stethoscope when the artery is wide open and blood is flowing freely.

In determining blood pressure by the auscultatory method, the pressure in the cuff is first elevated well above arterial systolic pressure. As long as this cuff pressure is higher than systolic pressure, the brachial artery remains collapsed so that no blood jets into the lower artery during any part of the pressure cycle. Therefore, no Korotkoff sounds are heard in the lower artery. Then the cuff pressure is slowly reduced. Just as soon as the pressure in the cuff falls below systolic pressure (point B, **Fig. 15.7**), blood begins to flow through the artery beneath the cuff during the peak of systolic pressure, and one begins to hear *tapping* sounds from the brachial artery in synchrony with the heartbeat. As soon as these sounds begin to be heard, the pressure level indicated by the manometer connected to the cuff is about equal to the systolic pressure.

As the pressure in the cuff is lowered further, the Korotkoff sounds change in quality, having less of the tapping quality and more of a rhythmical and harsher quality. Then, finally, when the pressure in the cuff falls near diastolic pressure, the sounds suddenly change to a muffled quality (point C, **Fig. 15.7**). One notes the manometer pressure when the Korotkoff sounds change to the muffled quality, and this pressure is about equal to the diastolic pressure, although it slightly overestimates the diastolic pressure determined by direct intraarterial catheter. As the cuff pressure falls a few mm Hg further, the artery no longer closes during diastole, which means that the basic factor causing the sounds (the jetting of blood through a squeezed artery) is no longer present. Therefore, the sounds disappear entirely.

Many clinicians believe that the pressure at which the Korotkoff sounds completely disappear should be used as the diastolic pressure, except in situations in which the disappearance of sounds cannot reliably be determined because sounds are audible, even after complete deflation of the cuff. For example, in patients with arterial-venous fistulas for hemodialysis or with aortic insufficiency, Korotkoff sounds may be heard after complete deflation of the cuff.

The auscultatory method for determining systolic and diastolic pressures is not entirely accurate, but it usually gives values within 10% of those determined by direct catheter measurement from inside the arteries.

Automated Oscillometric Method. Systolic and diastolic arterial pressures are often measured using automated oscillometric devices. These devices use a sphygmomanometer cuff, like the auscultatory method, but with an electronic pressure sensor to detect cuff pressure oscillations that occur when blood flows through an artery, often the brachial artery. Oscillometric arterial pressure devices use specific electronic algorithms to inflate and deflate the cuff automatically and interpret the cuff pressure oscillations. When the cuff is inflated, and its pressure exceeds systolic pressure, there is no blood flow in the artery and no oscillation of the cuff pressure. As the cuff is slowly deflated, blood begins to spurt through the artery, and the cuff pressure then oscillates in synchrony with the cyclic expansion and contraction of the artery. As the cuff pressure declines further, the oscillations increase in amplitude to a maximum, which corresponds to the mean arterial pressure. The oscillation amplitude then declines as the cuff pressure falls below the patient's diastolic pressure and blood flows smoothly through the artery. Using device-specific algorithms, the cuff pressure oscillations are automatically converted into digital systolic and diastolic pressure signals, as well as heart rate, and displayed.

Oscillometric arterial pressure monitors require less skill than the auscultatory technique and can be used by the patient at home, avoiding the so-called *white-coat effect* that raises blood pressure in some patients when a health care professional is present. These devices, however, must be calibrated for accuracy and can yield unreliable measurements in patients when the cuff size is inappropriate or in some abnormal circulatory conditions, such as severe arteriosclerosis, which increases stiffness of the artery wall.

Normal Arterial Pressures as Measured By the Auscultatory and Oscillatory Methods. **Fig. 15.8** shows the approximate normal systolic and diastolic arterial pressures at different ages. The progressive increase in pressure with age results from the effects of aging on the blood pressure control mechanisms. We shall see in Chapter 19 that the kidneys are primarily responsible for

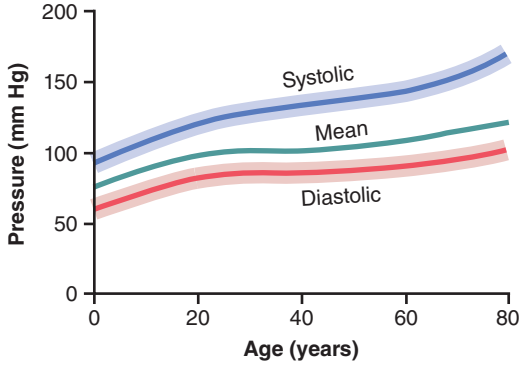

Figure 15.8 Changes in systolic, diastolic, and mean arterial pressures with age. The *shaded areas* show the approximate normal ranges.

this long-term regulation of arterial pressure; it is well known that the kidneys exhibit declining function with age, especially after the age of 50 years.

Systolic and diastolic blood pressures are, on average, a few millimeters of mercury higher in men than in women until age 45 to 55, when women undergo menopause and blood pressure increases to about the same level as found in men of the same age.

A slight extra increase in *systolic* pressure in men and women usually occurs beyond the age of 60 years. This increase results partly from decreasing distensibility, or hardening, of the arteries, which is often a result of *atherosclerosis*. The final effect is a higher systolic pressure with considerable increase in pulse pressure, as previously explained.

Mean Arterial Pressure. The mean arterial pressure is the average of the arterial pressures measured millisecond by millisecond over a period of time. It is not equal to the average of the systolic and diastolic pressures because at normal heart rates, a greater fraction of the cardiac cycle is spent in diastole than in systole. Thus, the arterial pressure remains closer to diastolic pressure than to systolic pressure during the greater part of the cardiac cycle. At the usual heart rate, the mean arterial pressure is determined about 60% by the diastolic pressure and 40% by the systolic pressure. Note in **Fig. 15.8** that the mean pressure (*solid green line*) at all ages is nearer to the diastolic pressure than to the systolic pressure. However, at very high heart rates, diastole comprises a smaller fraction of the cardiac cycle, and the mean arterial pressure is more closely approximated as the average of systolic and diastolic pressures.

VEINS AND THEIR FUNCTIONS

The veins provide passageways for flow of blood to the heart, but they also perform other functions that are necessary for operation of the circulation. Of special importance is that they are capable of constricting and enlarging and thereby storing small or large quantities of blood and making this blood available when required by the remainder of the circulation. The peripheral veins can also propel blood forward by means of a so-called *venous pump*, and they even help regulate cardiac output, an exceedingly important function described in detail in Chapter 20.

VENOUS PRESSURES—RIGHT ATRIAL PRESSURE (CENTRAL VENOUS PRESSURE) AND PERIPHERAL VENOUS PRESSURES

Blood from all the systemic veins flows into the right atrium of the heart. Therefore, the pressure in the right atrium is called the *central venous pressure*.

Right atrial pressure is regulated by a balance between (1) the ability of the heart to pump blood out of the right atrium and ventricle into the lungs and (2) the flow of blood from the peripheral veins into the right atrium. If the right heart is pumping strongly, the right atrial pressure decreases. Conversely, weakness of the heart elevates the right atrial pressure. Also, any effect that causes rapid inflow of blood into the right atrium from the peripheral veins elevates the right atrial pressure. Some factors that can increase this venous return and thereby increase the right atrial pressure are as follows: (1) increased blood volume; (2) increased large vessel tone throughout the body with resultant increased peripheral venous pressures; and (3) dilation of the arterioles, which decreases the peripheral resistance and allows rapid flow of blood from the arteries into the veins.

The same factors that regulate right atrial pressure also contribute to the regulation of cardiac output because the amount of blood pumped by the heart depends on both the ability of the heart to pump and the tendency for blood to flow into the heart from the peripheral vessels. In Chapter 20 we discuss regulation of right atrial pressure in much more depth in connection with cardiac output regulation.

The *normal right atrial pressure* is about 0 mm Hg, which is equal to the atmospheric pressure around the body. It can increase to 20 to 30 mm Hg under very abnormal conditions, such as the following: (1) serious heart failure; or (2) after massive transfusion of blood, which greatly increases the total blood volume and causes increased quantities of blood to flow into the heart from the peripheral vessels.

The lower limit to the right atrial pressure is usually about –3 to –5 mm Hg below atmospheric pressure, which is also the pressure in the chest cavity that surrounds the heart. The right atrial pressure approaches these low values when the heart pumps with exceptional vigor or when blood flow into the heart from the peripheral vessels is greatly depressed, such as after severe hemorrhage.

Venous Resistance and Peripheral Venous Pressure

Large veins have so little resistance to blood flow *when they are distended* that the resistance then is almost zero. However, as shown in **Fig. 15.9**, most of the large veins that enter the thorax are compressed at many points by the surrounding tissues so that blood flow is impeded at these points. For example, the veins from the arms are compressed by their sharp angulations over the first rib. Also, the pressure in the neck veins often falls so low that the atmospheric pressure on the outside of the neck causes these veins to collapse. Finally, veins coursing through the abdomen are often compressed by different organs and by the intraabdominal pressure, so they usually are at least partially collapsed to an ovoid or slitlike state. For these reasons, the *large veins do usually offer some resistance to blood flow*, and thus the pressure in the more peripheral small veins in a person lying down is usually +4 to +6 mm Hg greater than the right atrial pressure.

High Right Atrial Pressure Increases Peripheral Venous Pressure. When the right atrial pressure rises

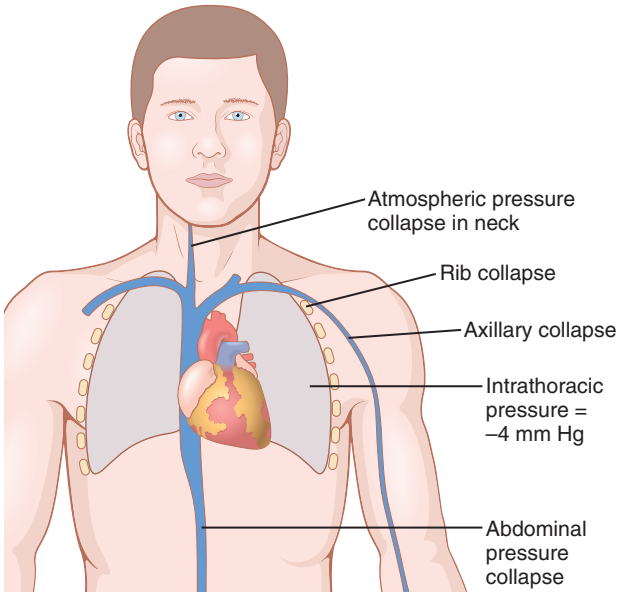

Figure 15.9 Compression points that tend to collapse the veins entering the thorax.

above its normal value of 0 mm Hg, blood begins to back up in the large veins. This backup of blood enlarges the veins, and even the collapse points in the veins open up when the right atrial pressure rises above +4 to +6 mm Hg. Then, as the right atrial pressure rises further, the additional increase causes a corresponding rise in peripheral venous pressure in the limbs and elsewhere. Because heart function must be impaired significantly to cause a rise in right atrial pressure as high as +4 to +6 mm Hg, the peripheral venous pressure is not noticeably elevated, even in the early stages of heart failure, as long as the person is at rest.

Increased Intraabdominal Pressure Raises Venous Pressures of the Leg. The pressure in the abdominal cavity of a recumbent person normally averages about +6 mm Hg, but it can rise to +15 to +30 mm Hg as a result of pregnancy, large tumors, abdominal obesity, or excessive fluid (called *ascites*) in the abdominal cavity. When the intraabdominal pressure rises, the pressure in the veins of the legs must rise *above* the abdominal pressure before the abdominal veins will open and allow the blood to flow from the legs to the heart. Thus, if the intraabdominal pressure is +20 mm Hg, the lowest possible pressure in the femoral veins is also about +20 mm Hg.

Effect of Gravitational Pressure on Venous Pressure

In any body of water that is exposed to air, the pressure at the surface of the water is equal to atmospheric pressure, but the pressure rises 1 mm Hg for each 13.6 millimeters of distance below the surface. This pressure results from the weight of the water and therefore is called *gravitational pressure* or *hydrostatic pressure*.

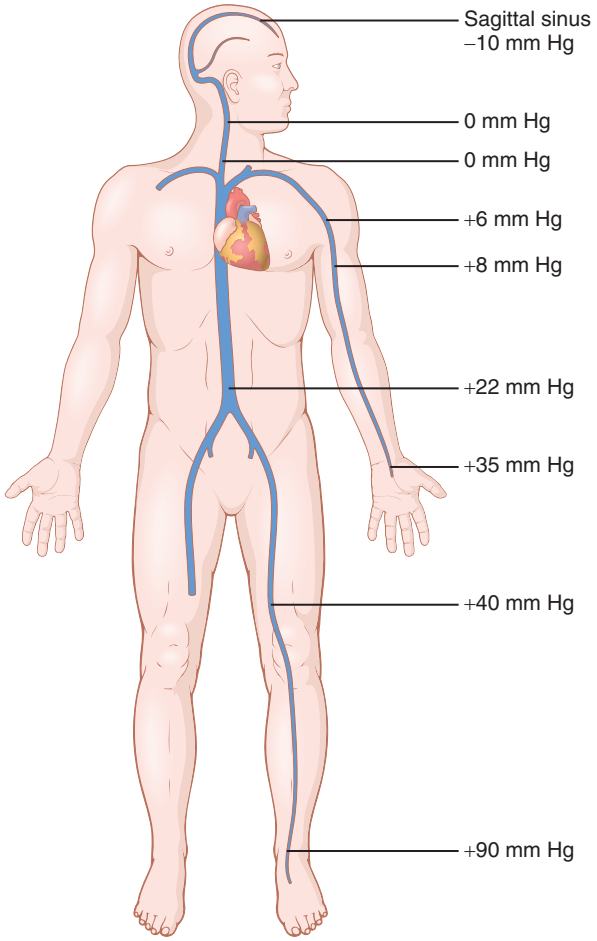

Figure 15.10 Effect of gravitational pressure on the venous pressures throughout the body in the standing person.

Gravitational pressure also occurs in the vascular system because of the weight of the blood in the vessels, as shown in **Fig. 15.10**. When a person is standing, the pressure in the right atrium remains about 0 mm Hg because the heart pumps any excess blood that attempts to accumulate at this point into the arteries. However, in an adult *who is standing absolutely still*, the pressure in the veins of the feet is about +90 mm Hg because of the gravitational weight of the blood in the veins between the heart and the feet. The venous pressures at other levels of the body are proportionately between 0 and 90 mm Hg.

In the arm veins, the pressure at the level of the top rib is usually about +6 mm Hg because of compression of the subclavian vein as it passes over this rib. The gravitational pressure down the length of the arm is then determined by the distance below the level of this rib. Thus, if the gravitational difference between the level of the rib and the hand is +29 mm Hg, this gravitational pressure is added to the +6 mm Hg pressure caused by compression of the vein as it crosses the rib, making a total of +35 mm Hg pressure in the veins of the hand.

The neck veins of a person standing upright collapse almost completely all the way to the skull because of

atmospheric pressure on the outside of the neck. This collapse causes the pressure in these veins to remain at zero along their entire extent. Any tendency for the pressure to rise above this level opens the veins and allows the pressure to fall back to zero because of flow of the blood. Conversely, any tendency for the neck vein pressure to fall below zero further collapses the veins, which further increases their resistance and again returns the pressure back to zero.

The veins inside the skull, on the other hand, are in a chamber (the skull cavity) that cannot collapse. Consequently, *negative pressure can exist in the dural sinuses of the head;* in the standing position, the venous pressure in the sagittal sinus at the top of the brain is about −10 mm Hg because of the hydrostatic "suction" between the top of the skull and the base of the skull. Therefore, if the sagittal sinus is opened during surgery, air can be sucked immediately into the venous system; the air may even pass downward to cause air embolism in the heart and death.

Effect of the Gravitational Factor on Arterial and Other Pressures. The gravitational factor also affects pressures in the peripheral arteries and capillaries. For example, a standing person who has a mean arterial pressure of 100 mm Hg at the level of the heart has an arterial pressure in the feet of about 190 mm Hg. Therefore, when the arterial pressure is stated to be 100 mm Hg, this generally means that 100 mm Hg is the pressure at the gravitational level of the heart but not necessarily elsewhere in the arterial vessels.

Venous Valves and the Venous Pump: Their Effects on Venous Pressure

Were it not for valves in the veins, the gravitational pressure effect would cause the venous pressure in the feet always to be about +90 mm Hg in a standing adult. However, every time the legs move, the muscles tighten and compress the veins in or adjacent to the muscles, which squeezes the blood out of the veins. However, the valves in the veins, shown in **Fig. 15.11**, are arranged so that the direction of venous blood flow can only be toward the heart. Consequently, every time a person moves the legs or even tenses the leg muscles, a certain amount of venous blood is propelled toward the heart. This pumping system is known as the *venous pump* or *muscle pump*, and it is efficient enough that under ordinary circumstances, the venous pressure in the feet of a walking adult remains less than +20 mm Hg.

If a person stands perfectly still, the venous pump does not work, and the venous pressures in the lower legs increase to the full gravitational value of 90 mm Hg in about 30 seconds. The pressures in the capillaries also increase greatly, causing fluid to leak from the circulatory system into the tissue spaces. As a result, the legs swell, and the blood volume diminishes. As much as 10% to 20% of the blood volume can be lost from the circulatory

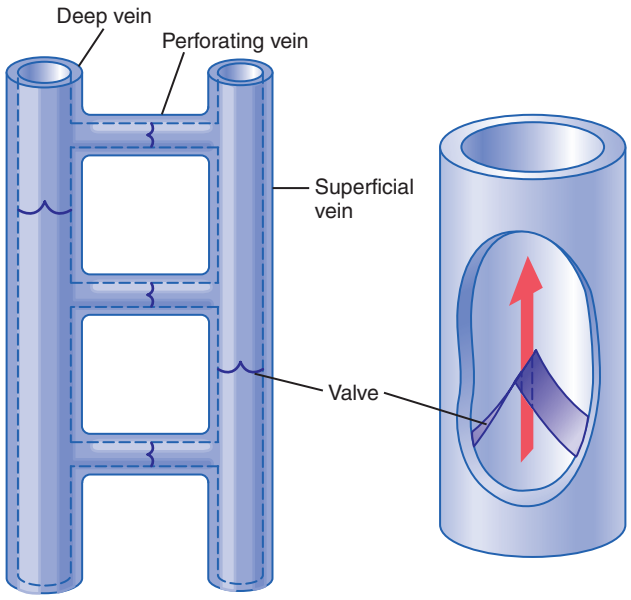

Figure 15.11 Venous valves of the leg.

system within the 15 to 30 minutes of standing absolutely still, which may lead to fainting, as sometimes occurs when a soldier is made to stand at attention. This situation can be avoided by simply flexing the leg muscles periodically and slightly bending the knees, thus permitting the venous pump to work.

Venous Valve Incompetence Causes Varicose Veins. The valves of the venous system may become incompetent or even destroyed when the veins have been overstretched by excess venous pressure lasting weeks or months, which can occur in pregnancy or when a person stands most of the time. Stretching the veins increases their cross-sectional areas, but the leaflets of the valves do not increase in size. Therefore, the leaflets of the valves no longer close completely. With this lack of complete closure, the pressure in the veins of the legs increases greatly because of failure of the venous pump, which further increases the sizes of the veins and finally destroys the function of the valves entirely. Thus, the person develops what are called *varicose veins*, which are characterized by large bulbous protrusions of the veins beneath the skin of the entire leg, particularly the lower leg.

Whenever people with varicose veins stand for more than a few minutes, the venous and capillary pressures become very high, and leakage of fluid from the capillaries causes edema in the legs. The edema, in turn, prevents adequate diffusion of nutritional materials from the capillaries to the muscle and skin cells, so the muscles become painful and weak, and the skin may even become gangrenous and ulcerate. The best treatment for such a condition is continual elevation of the legs to a level at least as high as the heart. Tight binders or long compression stockings on the legs also can assist in preventing edema and its sequelae.

Clinical Estimation of Venous Pressure. Venous pressure often can be estimated by simply observing the degree of distention of the peripheral veins, especially of the neck veins. For example, in the sitting position, the neck veins are normally never distended in a quietly resting person. However, when the right atrial pressure increases to about +10 mm Hg, the lower veins of the neck begin to protrude and, at +15 mm Hg atrial pressure, essentially all the veins in the neck become distended.

Direct Measurement of Venous Pressure and Right Atrial Pressure. Venous pressure can be measured easily by inserting a needle directly into a vein and connecting it to a pressure recorder. The only means whereby *right atrial pressure* can be measured accurately is by inserting a catheter through the peripheral veins and into the right atrium. Pressures measured through such *central venous catheters* are often used in some types of hospitalized cardiac patients to provide a constant assessment of the heart-pumping ability.

Pressure Reference Level for Measuring Venous and Other Circulatory Pressures. Although we have discussed right atrial pressure as being 0 mm Hg and arterial pressure as being 100 mm Hg, we have not stated the gravitational level in the circulatory system to which this pressure is referred. There is one point in the circulatory system at which gravitational pressure factors caused by changes in body position of a healthy person usually do not affect the pressure measurement by more than 1 to 2 mm Hg. This is at or near the level of the tricuspid valve, as shown by the crossed axes in **Fig. 15.12**. Therefore, all circulatory pressure measurements discussed in this text are referred to this level, which is called the *reference level for pressure measurement*.

The reason for the lack of gravitational effects at the tricuspid valve is that the heart automatically prevents significant gravitational changes in pressure at this point in the following way. If the pressure at the tricuspid valve rises slightly above normal, the right ventricle fills to a greater extent than usual, causing the heart to pump blood more rapidly and therefore decreasing the pressure at the tricuspid valve back toward the normal mean value. Conversely, if the pressure falls, the right ventricle fails to fill adequately, its pumping decreases, and blood dams up in the venous system until the pressure at the tricuspid level again rises to the normal value. In other words, *the heart acts as a feedback regulator of pressure* at the tricuspid valve.

When a person is lying on their back, the tricuspid valve is located at almost exactly 60% of the chest thickness in front of the back. This is the *zero pressure reference level* for a person lying down.

BLOOD RESERVOIR FUNCTION OF THE VEINS

We indicated in Chapter 14 that more than 60% of all the blood in the circulatory system is usually in the veins. For this reason, and also because the veins are so compliant, the venous system serves as a *blood reservoir* for the circulation.

When blood is lost from the body and the arterial pressure begins to fall, nervous signals are elicited from the carotid sinuses and other pressure-sensitive areas of the circulation, as discussed in Chapter 18. These signals, in turn, elicit nerve signals from the brain and spinal cord, mainly through sympathetic nerves to the veins, causing them to constrict. This process takes up much of the slack in the circulatory system caused by the lost blood. Even after as much as 20% of the total blood volume has been lost, the circulatory system often functions almost normally because of this variable reservoir function of the veins.

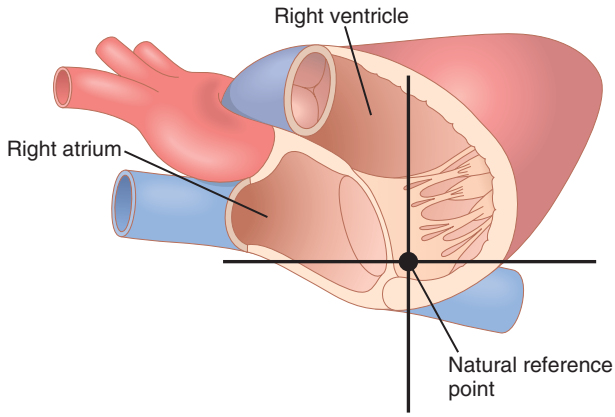

Figure 15.12 Reference point for circulatory pressure measurement (located near the tricuspid valve).

SPECIFIC BLOOD RESERVOIRS

Certain portions of the circulatory system are so extensive and/or so compliant that they are called *specific blood reservoirs*. These reservoirs include the following: (1) the *spleen*, which sometimes can decrease in size sufficiently to release as much as 100 mL of blood into other areas of the circulation; (2) the *liver*, the sinuses of which can release several hundred milliliters of blood into the remainder of the circulation; (3) the *large abdominal veins*, which can contribute as much as 300 mL; and (4) the *venous plexus beneath the skin*, which also can contribute several hundred milliliters. The *heart* and *lungs*, although not parts of the systemic venous reservoir system, may also be considered blood reservoirs. The heart, for example, shrinks during sympathetic stimulation and in this way can contribute some 50 to 100 mL of blood; the lungs can contribute another 100 to 200 mL when pulmonary pressures decrease to low values.

THE SPLEEN IS A RESERVOIR FOR RED BLOOD CELLS

Fig. 15.13 shows that the spleen has two separate areas for storing blood, the *venous sinuses* and the *pulp*. The sinuses can swell in the same way as any other part of the venous system and store whole blood.

In the splenic pulp, the capillaries are so permeable that whole blood, including the red blood cells, oozes

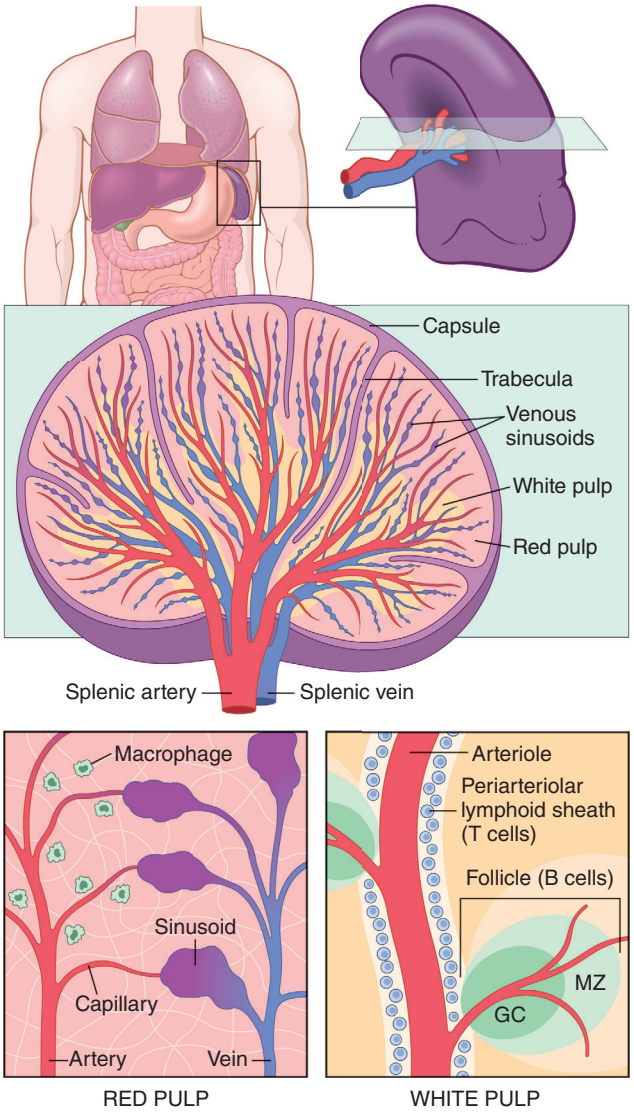

Figure 15.13 Functional structures of the spleen. *MZ*, Marginal zone; *GZ*, germinal center (B lymphocytes).

through the capillary walls into a trabecular mesh, forming the *red pulp*. The red cells are trapped by the trabeculae while the plasma flows into the venous sinuses and then into the general circulation. As a consequence, the red pulp of the spleen is a *special reservoir that contains large quantities of concentrated red blood cells*. These concentrated red blood cells can then be expelled into the general circulation whenever the sympathetic nervous system becomes excited and causes the spleen and its vessels to contract. As much as 50 mL of concentrated red blood cells can be released into the circulation, raising the hematocrit by 1% to 2%.

Other areas of the splenic pulp contain islands of white blood cells, which collectively are called the *white pulp*. Here, lymphoid cells are manufactured that are similar to those manufactured in the lymph nodes. They are part of the body's immune system, described in Chapter 35.

The Spleen Removes Old Red Blood Cells. Blood cells passing through the splenic pulp before entering the sinuses undergo thorough squeezing. Older fragile red blood cells do not withstand this trauma and are destroyed in the spleen. After the cells rupture, the released hemoglobin and cell stroma are digested by the reticuloendothelial cells of the spleen, and the products of digestion are mainly reused by the body as nutrients, often for making new blood cells.

Reticuloendothelial Cells of the Spleen Function as a Blood Cleansing System. The pulp of the spleen contains many large phagocytic reticuloendothelial cells, and the venous sinuses are lined with similar cells. These cells function as part of a cleansing system for the blood, acting in concert with a similar system of reticuloendothelial cells in the venous sinuses of the liver. When the blood is invaded by infectious agents, the reticuloendothelial cells of the spleen rapidly remove substances such as debris, bacteria, and parasites. Also, in many chronic infections, the spleen enlarges in the same manner as lymph nodes and then performs its cleansing function even more avidly.

The absence of a spleen (asplenia) or reduced function of the spleen (hyposplenism) is associated with multiple disorders, including increased susceptibility to severe invasive infections as well as autoimmune and gastrointestinal disorders. The importance of the spleen in resistance of the body to infection is further discussed in Chapter 34.

CHAPTER 16

The Microcirculation and Lymphatic System: Capillary Fluid Exchange, Interstitial Fluid, and Lymph Flow

The microcirculation is responsible for *transporting nutrients to the tissues* and *removing cell excreta*. The small arterioles control blood flow to each tissue, and local conditions in the tissues, in turn, control the diameters of the arterioles. In most cases, each tissue controls its own blood flow according to its individual needs, as discussed in Chapter 17.

The walls of the capillaries are thin and constructed of single-layer, highly permeable endothelial cells. Therefore, water, cell nutrients, and cell excreta can all interchange quickly and efficiently between the tissues and circulating blood.

The peripheral circulation of the entire body has about 10 billion capillaries, with a total surface area estimated to be 500 to 700 square meters (about one-eighth the surface area of a football field). It is rare that any single functional cell of the body is more than 20 to 30 micrometers away from a capillary.

STRUCTURE OF THE MICROCIRCULATION AND CAPILLARY SYSTEM

The microcirculation is organized to serve each organ's specific needs. In general, each nutrient artery entering an organ branches six to eight times before the arteries become small enough to be called *arterioles*, which generally have internal diameters of only 10 to 15 micrometers. Then, the arterioles branch two to five times, reaching diameters of 5 to 9 micrometers at their ends, where they supply blood to the capillaries.

The arterioles are highly muscular, and their diameters can change markedly. The metarterioles (the terminal arterioles) do not have a continuous muscular coat, but smooth muscle fibers encircle the vessel at intermittent points, as shown in **Fig. 16.1**.

At the point where each true capillary originates from a metarteriole, a smooth muscle fiber called the *precapillary sphincter* often encircles the capillary. This sphincter can open and close the entrance to the capillary.

Many capillaries, including those of the brain and kidneys, have *pericytes* that wrap around the endothelial cells at intervals along the capillary walls. Although pericytes are not smooth muscle cells, they contain contractile proteins and secrete factors that help to regulate capillary growth and tissue perfusion. In the brain, the high density of pericytes around the capillaries contributes to maintenance of the *blood-brain barrier*, which restricts entry of pathogens and large molecules into the central nervous system.

The *venules* are larger than the arterioles and have a much weaker muscular coat. Yet, the pressure in the venules is much less than that in the arterioles, so the venules can still contract considerably, despite the weak muscle.

This typical arrangement of the capillary bed is not found in all parts of the body, although a similar arrangement may serve the same purposes. Importantly, the metarterioles and precapillary sphincters are in close contact with the tissues they serve. Therefore, the local conditions of the tissues—such as the concentrations of nutrients, end products of metabolism, and hydrogen ions—can cause direct effects on the vessels to control local blood flow in each small tissue area.

Structure of the Capillary Wall. **Fig. 16.2** shows the ultramicroscopic structure of typical endothelial cells in the capillary wall as found in most tissues and organs of the body, especially in muscles and connective tissue. Note that the wall is composed of a unicellular layer of endothelial cells and is surrounded by a thin basement membrane on the outside of the capillary. The total thickness of the capillary wall is only about 0.5 micrometer. The internal diameter of the capillary is 4 to 9 micrometers, barely large enough for red blood cells and other blood cells to squeeze through.

Pores in the Capillary Membrane. **Fig. 16.2** shows two small passageways connecting the interior of the capillary with the exterior. One of these passageways is an *intercellular cleft*, which is the thin-slitted, curving channel that lies between adjacent endothelial cells. Each cleft is interrupted periodically by short ridges of protein attachments that hold the endothelial cells together but, between these ridges, fluid can percolate freely through the cleft. The cleft normally has a uniform spacing, with a width of about 6 to 7 nanometers (60 to 70 angstroms [Å]), which is slightly smaller than the diameter of an albumin protein molecule.

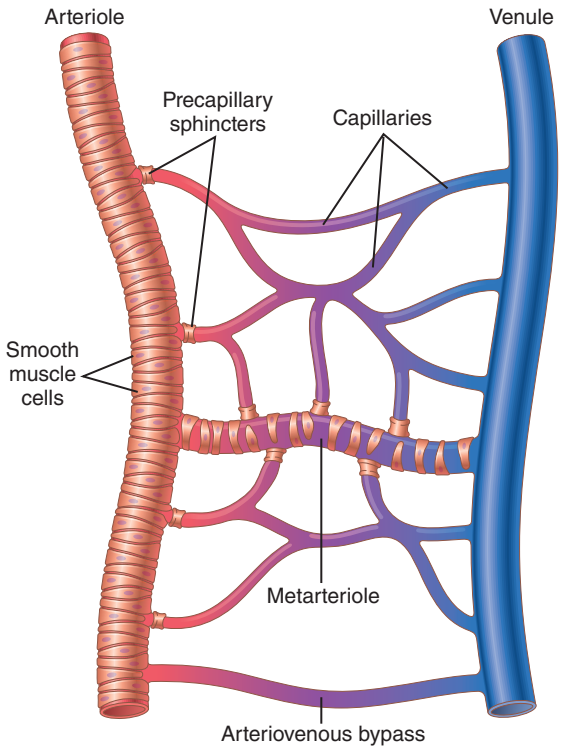

Figure 16.1 Components of the microcirculation.

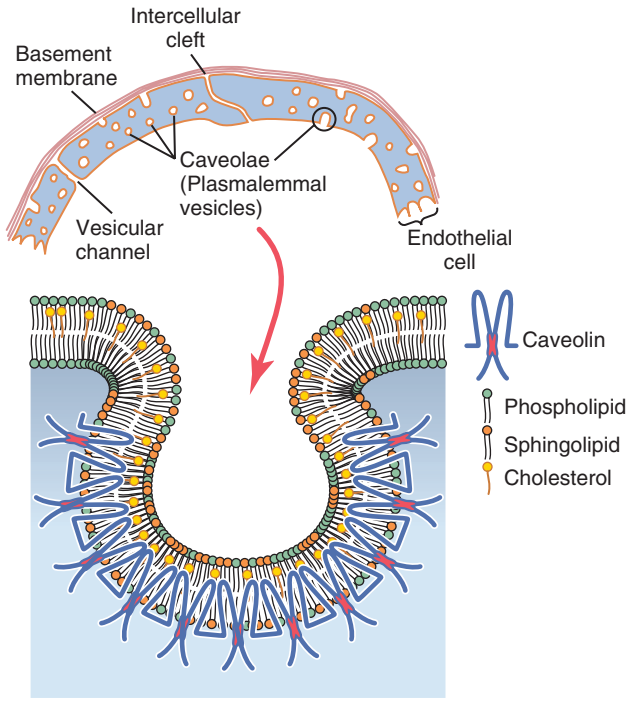

Figure 16.2 Structure of the capillary wall. Note especially the *intercellular cleft* at the junction between adjacent endothelial cells. It is believed that most water-soluble substances diffuse through the capillary membrane along the clefts. Small membrane invaginations, called *caveolae*, are believed to play a role in transporting macromolecules across the cell membrane. Caveolae contain caveolins, which are proteins that interact with cholesterol and polymerize to form the caveolae.

Because the intercellular clefts are located only at the edges of the endothelial cells, they usually represent no more than 1/1000 of the total surface area of the capillary wall. Nevertheless, the rate of thermal motion of water molecules, as well as most water-soluble ions and small solutes, is so rapid that all these substances diffuse with ease between the interior and exterior of the capillaries through these *slit pores*, the intercellular clefts.

Endothelial cells contain many minute *plasmalemmal vesicles*, also called *caveolae* (small caves). These plasmalemmal vesicles derive from oligomers of proteins called *caveolins* that are associated with molecules of *cholesterol* and *sphingolipids*. Caveolae play a role in *endocytosis* (the process whereby the cell engulfs material from outside the cell) and *transcytosis* of macromolecules across the interior of the endothelial cells. The caveolae at the surface of the cell imbibe small packets of plasma or extracellular fluid that contain plasma proteins. These vesicles can then move slowly through the endothelial cell. Some of these vesicles may coalesce to form *vesicular channels* all the way through the endothelial cell, as shown in **Fig. 16.2**.

Special Types of Pores in Capillaries of Certain Organs. The pores in capillaries of some organs have special characteristics to meet the specific needs of the organs. Some of these characteristics are as follows:

1. In the *brain*, the junctions between the capillary endothelial cells are mainly *tight junctions* that allow only small molecules such as water, oxygen, and carbon dioxide to freely pass into or out of the brain tissues.
2. In the *liver*, the clefts between the capillary endothelial cells are nearly wide open so that almost all dissolved substances of the plasma, including the plasma proteins, can pass from the blood into the liver tissues.
3. The intercellular clefts of the *gastrointestinal capillary membranes* are midway in size between those of the muscles and liver.
4. In the *glomerular capillaries of the kidney*, numerous small oval windows called *fenestrae* penetrate all the way through the middle of the endothelial cells so that large amounts of small molecular and ionic substances (but not the large plasma proteins) can filter through the glomeruli without having to pass through the clefts between the endothelial cells.

VASOMOTION CAUSES INTERMITTENT CAPILLARY BLOOD FLOW

Blood usually does not flow continuously through the capillaries. Instead, it flows intermittently, turning on and off every few seconds or minutes. This flow intermittency is caused by intermittent contraction of the metarterioles and precapillary sphincters (and sometimes even the very small arterioles), a phenomenon called *vasomotion*.

Regulation of Vasomotion. The most important factor affecting the degree of opening and closing of the metarterioles and precapillary sphincters that has been found

thus far is the concentration of *oxygen* in the tissues. When the rate of oxygen usage by the tissue is great—so that tissue oxygen concentration decreases below normal—the periods of capillary blood flow occur more often and the duration of each period of flow lasts longer, thereby allowing the capillary blood to carry increased quantities of oxygen (as well as other nutrients) to the tissues. This effect, along with multiple other factors that control local tissue blood flow, is discussed in Chapter 17.

Average Function of the Capillary System. Despite the fact that blood flow through each capillary is intermittent, so many capillaries are present in the tissues that their overall function becomes averaged. That is, there is an *average rate of blood flow* through each tissue capillary bed, an *average capillary pressure* within the capillaries, and an *average rate of transfer of substances* between the blood of the capillaries and the surrounding interstitial fluid. In the remainder of this chapter, we discuss these averages, although the average functions are, in reality, the functions of billions of individual capillaries, each operating intermittently in response to local conditions in the tissues.

EXCHANGE OF SUBSTANCES BETWEEN THE BLOOD AND INTERSTITIAL FLUID

Diffusion Through the Capillary Membrane Is the Most Important Means of Transferring Substances Between Plasma and Interstitial Fluid. Fig. 16.3 illustrates that as the blood flows along the lumen of the capillary, tremendous numbers of water molecules and dissolved particles diffuse back and forth through the capillary wall. This rapid diffusion provides continual mixing between the interstitial fluid and plasma and makes these dissolved substances readily available to the cells. Electrolytes, nutrients, and waste products of cell metabolism all diffuse easily through the capillary membrane. The proteins are the only dissolved constituents in the plasma and interstitial fluids that do not readily pass through the capillary membrane.

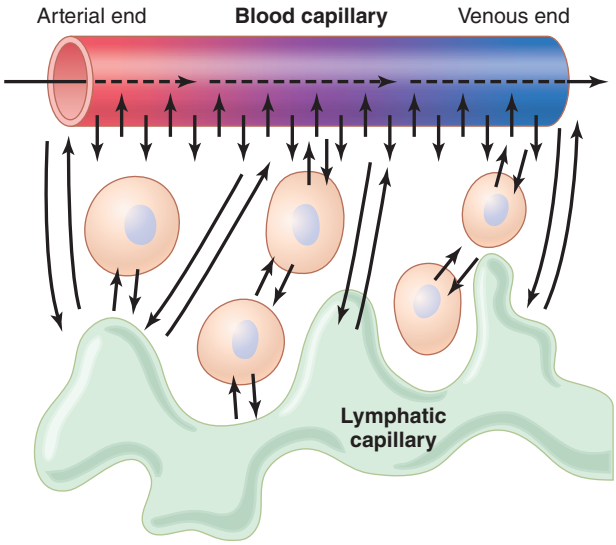

Figure 16.3 Diffusion of fluid molecules and dissolved substances between the capillary and interstitial fluid spaces.

Lipid-Soluble Substances Diffuse Directly Through the Capillary Endothelial Cell Membranes. Lipid-soluble substances, such as *oxygen* and *carbon dioxide*, can diffuse directly through the cell membranes of the capillary without having to go through the pores. Because these substances can permeate all areas of the capillary membrane, their rates of transport through the capillary membrane are many times faster than the rates for lipid-insoluble substances, such as sodium ions and glucose, which can go only through the pores.

Water-Soluble, Non–Lipid-Soluble Substances Diffuse Through Intercellular Pores in the Capillary Membrane. Many substances needed by the tissues are soluble in water but cannot pass through the lipid membranes of the endothelial cells; these include *water molecules*, *sodium ions*, *chloride ions*, and *glucose*. Although only 1/1000 of the surface area of the capillaries is represented by the intercellular clefts between the endothelial cells, the velocity of thermal molecular motion in the clefts is so great that even this small area allows tremendous diffusion of water and water-soluble substances through these cleft pores. To give an idea of the rapidity with which these substances diffuse, *the rate at which water molecules diffuse through the capillary membrane is about 80 times greater than the rate at which plasma itself flows linearly along the capillary*. That is, the water of the plasma is exchanged with the water of the interstitial fluid 80 times before the plasma can flow the entire distance through the capillary.

Effect of Molecular Size on Passage Through the Pores. The width of the capillary intercellular cleft pores, 6 to 7 nanometers, is about 20 times the diameter of the water molecule, which is the smallest molecule that normally passes through the capillary pores. The diameters of plasma protein molecules, however, are slightly greater than the width of the pores. Other substances, such as sodium ions, chloride ions, glucose, and urea, have intermediate diameters. Therefore, the permeability of the capillary pores for different substances varies according to their molecular diameters.

Table 16.1 lists the relative permeabilities of the capillary pores in skeletal muscle for various substances, demonstrating, for example, that the permeability for glucose molecules is 0.6 times that for water molecules, whereas the permeability for albumin molecules is very slight—only one 1/1000 that for water molecules.

Capillaries in Various Tissues Have Extreme Differences in Their Permeabilities. The membranes of the liver capillary sinusoids are so permeable that even plasma proteins pass through these walls, almost as easily as water and other substances. Also, the permeability of

Table 16.1 Relative Permeability of Skeletal Muscle Capillary Pores to Different-Sized Molecules

Substance	Molecular Weight	Permeability
Water	18	1.00
NaCl	58.5	0.96
Urea	60	0.8
Glucose	180	0.6
Sucrose	342	0.4
Inulin	5000	0.2
Myoglobin	17,600	0.03
Hemoglobin	68,000	0.01
Albumin	69,000	0.001

Data from Pappenheimer JR. Passage of molecules through capillary walls. *Physiol Rev*. 1953;33:387.

the renal glomerular membrane for water and electrolytes is about 500 times the permeability of the muscle capillaries, but this is not true for the plasma proteins. For these proteins, the capillary permeabilities are very slight, as in other tissues and organs.

When we study these different organs later in this text, it should become clear why some tissues require greater degrees of capillary permeability than other tissues. For example, greater degrees of capillary permeability are required for the liver to transfer large amounts of nutrients between the blood and liver parenchymal cells and for the kidneys to allow filtration of large quantities of fluid for the formation of urine.

Diffusion Through Capillary Membranes Is Proportional to the Concentration Difference Between the Two Sides of the Membrane. The greater the concentration difference of any given substance on the two sides of the capillary membrane, the greater the net movement of the substance in one direction through the membrane. For example, the concentration of oxygen in capillary blood is normally greater than in the interstitial fluid. Therefore, large quantities of oxygen normally move from the blood toward the tissues. Conversely, the concentration of carbon dioxide is greater in the tissues than in the blood, which causes excess carbon dioxide to move into the blood and to be carried away from the tissues.

The rates of diffusion through the capillary membranes of most nutritionally important substances are so great that only slight concentration differences cause more than adequate transport between the plasma and interstitial fluid. For example, the concentration of oxygen in the interstitial fluid immediately outside the capillary is no more than a few percent less than its concentration in the plasma of the blood. However, this slight difference causes enough oxygen to move from the blood into the interstitial spaces to provide all the oxygen required for tissue metabolism—often as much as several liters of oxygen per minute during very active states of the body.

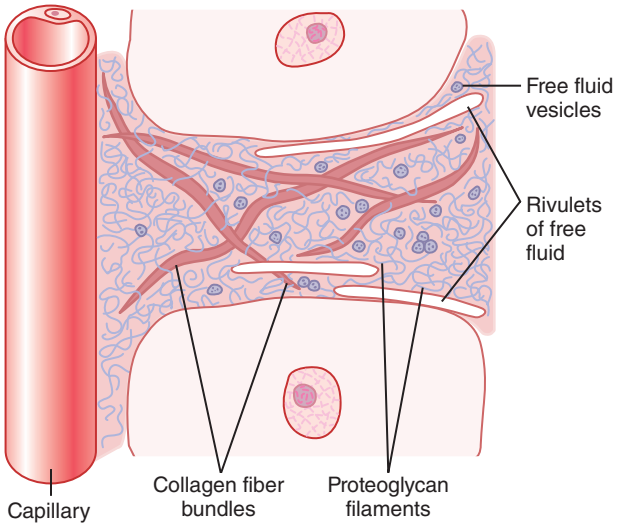

Figure 16.4 Structure of the interstitium. Proteoglycan filaments are everywhere in the spaces between the collagen fiber bundles. Free fluid vesicles and small amounts of free fluid in the form of rivulets occasionally also occur.

INTERSTITIUM AND INTERSTITIAL FLUID

About one-sixth of the total volume of the body consists of spaces between cells, which collectively are called the *interstitium*. The fluid in these spaces is called the *interstitial fluid*.

The structure of the interstitium is illustrated in **Fig. 16.4**. It contains two major types of solid structures: (1) *collagen fiber bundles*; and (2) *proteoglycan filaments*. The collagen fiber bundles extend long distances in the interstitium. They are extremely strong and provide most of the tensional strength of the tissues. The proteoglycan filaments, however, are extremely thin, coiled or twisted molecules composed of about 98% *hyaluronic acid* and 2% protein. These molecules are so thin that they cannot be seen with a light microscope and are difficult to demonstrate, even with the electron microscope. Nevertheless, they form a mat of very fine reticular filaments aptly described as a *brush pile*.

Gel in the Interstitium Is a Combination of Proteoglycan Filaments and Entrapped Fluid. The fluid in the interstitium is derived by filtration and diffusion from the capillaries. It contains almost the same constituents as plasma except for much lower concentrations of proteins because proteins do not easily pass outward through the pores of the capillaries. The interstitial fluid is entrapped mainly in the minute spaces among the proteoglycan filaments. This combination of proteoglycan filaments and fluid entrapped within them has the characteristics of a *gel*; it is therefore called *tissue gel*.

Because of the large number of proteoglycan filaments, it is *difficult for fluid to flow easily* through the tissue gel. Instead, *fluid mainly diffuses* through the gel; that is, it moves molecule by molecule from one place to another

by kinetic thermal motion rather than by large numbers of molecules moving together.

Diffusion through the gel occurs about 95% to 99% as rapidly as it does through free fluid. For the short distances between the capillaries and tissue cells, this diffusion allows for rapid transport through the interstitium, not only of water molecules but also of substances such as electrolytes, low-molecular-weight nutrients, cellular excreta, oxygen, and carbon dioxide.

Small Amounts of Free Fluid Are Normally Present in the Interstitium. Although almost all the fluid in the interstitium normally is entrapped within the tissue gel, occasionally small *rivulets of free fluid* and *small free fluid vesicles* are also present, which means fluid that is free of the proteoglycan molecules and therefore can flow freely. When a dye is injected into the circulating blood, it often can be seen to flow through the interstitium in the small rivulets, usually coursing along the surfaces of collagen fibers or surfaces of cells.

The amount of free fluid present in most *normal* tissues is slight, usually less than 1%. Conversely, when the tissues develop *edema, these small pockets and rivulets of free fluid expand tremendously* until one-half or more of the edema fluid becomes free-flowing fluid, independent of the proteoglycan filaments.

FLUID FILTRATION ACROSS CAPILLARIES

The hydrostatic pressure in the capillaries tends to force fluid and its dissolved substances through the capillary pores into the interstitial spaces. Conversely, osmotic pressure caused by the plasma proteins (called *colloid osmotic pressure*) tends to cause fluid movement by osmosis from the interstitial spaces into the blood. This osmotic pressure exerted by the plasma proteins normally prevents significant loss of fluid volume from the blood into the interstitial spaces.

Also important is the *lymphatic system*, which returns to the circulation the small amounts of excess protein and fluid that leak from the blood into the interstitial spaces. In the remainder of this chapter, we discuss the mechanisms that control capillary filtration and lymph flow function together to regulate the respective volumes of the plasma and interstitial fluid.

Hydrostatic and Colloid Osmotic Forces Determine Fluid Movement Through the Capillary Membrane. Fig. 16.5 shows the four primary forces that determine whether fluid will move out of the blood into the interstitial fluid or in the opposite direction. These forces, called *Starling forces*, were named after the physiologist Ernest Starling, who first demonstrated their importance:

1. The *capillary hydrostatic pressure* (Pc), which tends to force fluid *outward* through the capillary membrane

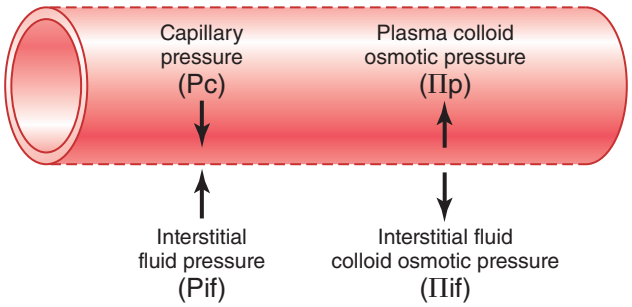

Figure 16.5 Fluid pressure and colloid osmotic pressure forces operate at the capillary membrane and tend to move fluid outward or inward through the membrane pores.

2. The *interstitial fluid hydrostatic pressure* (Pif), which tends to force fluid *inward* through the capillary membrane when Pif is positive but outward when Pif is negative
3. The capillary *plasma colloid osmotic pressure* (ΠP), which tends to cause osmosis of fluid *inward* through the capillary membrane
4. The *interstitial fluid colloid osmotic pressure* (Πif), which tends to cause osmosis of fluid *outward* through the capillary membrane

If the sum of these forces—the *net filtration pressure*—is positive, there will be a net *fluid filtration* across the capillaries. If the sum of the Starling forces is negative, there will be a net *fluid absorption* from the interstitial spaces into the capillaries. The net filtration pressure (NFP) is calculated as follows:

$$NFP = Pc - Pif - \Pi p + \Pi if$$

As discussed later, the NFP is slightly positive under normal conditions, resulting in a net filtration of fluid across the capillaries into the interstitial space in most organs. The rate of fluid filtration in a tissue is also determined by the number and size of the pores in each capillary, as well as the number of capillaries in which blood is flowing. These factors are usually expressed together as the *capillary filtration coefficient* (K_f). The K_f is therefore a measure of the capacity of the capillary membranes to filter water for a given NFP and is usually expressed as mL/min per mm Hg NFP.

The rate of capillary fluid filtration is therefore determined as follows:

$$Filtration = K_f \times NFP$$

In the following sections, we discuss each of the forces that determine the rate of capillary fluid filtration.

CAPILLARY HYDROSTATIC PRESSURE

Various methods have been used to estimate the capillary hydrostatic pressure, including: (1) *direct micropipette cannulation of the capillaries*, which gives an average capillary pressure of about 25 mm Hg in some tissues, such as the skeletal muscle and gut, and (2) *indirect functional*

measurement of the capillary pressure, which gives a capillary pressure averaging about 17 mm Hg in these tissues.

Using microscopic glass pipettes inserted directly into capillaries, pressures have been measured in capillaries of exposed tissues in experimental animals and in large capillary loops of the eponychium at the base of the fingernail in humans. These measurements have given pressures of 30 to 40 mm Hg in the arterial ends of the capillaries, 10 to 15 mm Hg in the venous ends, and about 25 mm Hg in the middle.

In some capillaries, such as the *glomerular capillaries* of the kidneys, the pressures measured are much higher, averaging about 60 mm Hg. The *peritubular capillaries* of the kidneys, in contrast, have a hydrostatic pressure that averages only about 13 mm Hg. Thus, capillary hydrostatic pressures in different tissues are highly variable, depending on the particular tissue and the physiological conditions.

INTERSTITIAL FLUID HYDROSTATIC PRESSURE

There are several methods for measuring interstitial fluid hydrostatic pressure, each of which gives slightly different values, depending on the method used and the tissue in which the pressure is measured. In loose subcutaneous tissue, interstitial fluid pressure measured by the different methods is usually a few millimeters of mercury less than atmospheric pressure; that is, the values are called *negative interstitial fluid pressure*. In other tissues that are surrounded by capsules, such as the kidneys, the interstitial pressure is generally *positive* (i.e., greater than atmospheric pressure). The methods most widely used have been: (1) measurement of the pressure with a micropipette inserted into the tissues; (2) measurement of the pressure from implanted perforated capsules; and (3) measurement of the pressure from a cotton wick inserted into the tissue. These different methods provide different values for interstitial hydrostatic pressure, even in the same tissues.

Measurement of Interstitial Fluid Pressure Using Micropipettes. The same type of micropipette used for measuring capillary pressure can also be used in some tissues for measuring interstitial fluid pressure. The tip of the micropipette is about 1 micrometer in diameter, but even this is 20 or more times larger than the sizes of the spaces between the proteoglycan filaments of the interstitium. Therefore, the pressure that is measured is probably the pressure in a free fluid pocket.

Pressures measured using the micropipette method range from −2 to +2 mm Hg in *loose* tissues, such as skin, but in most cases they average slightly less than atmospheric pressure.

Measurement of Interstitial Free Fluid Pressure in Implanted Perforated Hollow Capsules. Interstitial free fluid pressure measured when using 2-centimeter diameter capsules in normal *loose* subcutaneous tissue averages about −6 mm Hg, but with smaller capsules the values are not greatly different from the −2 mm Hg measured by the micropipette.

Although various methods give slightly different values for interstitial fluid pressure, the interstitial fluid pressure in *loose* subcutaneous tissue averages about −3 mm Hg in normal conditions.

Interstitial Fluid Pressures in Tightly Encased Tissues. Some tissues of the body are surrounded by tight encasements, such as the cranial vault around the brain, the strong fibrous capsule around the kidney, the fibrous sheaths around the muscles, and the sclera around the eye. In most of these tissues, regardless of the method used for measurement, the interstitial fluid pressures are positive. However, these interstitial fluid pressures almost invariably are still less than the pressures exerted on the outsides of the tissues by their encasements. For example, the cerebrospinal fluid pressure surrounding the brain of an animal lying on its side averages about +10 mm Hg, whereas the *brain interstitial fluid pressure* averages about +4 to +6 mm Hg. In the kidneys, the capsular pressure surrounding the kidney averages about +13 mm Hg, whereas *renal interstitial fluid pressure* averages about +6 mm Hg. Thus, if one remembers that the pressure exerted on the skin is atmospheric pressure, which is considered to be zero pressure, one might formulate a general rule that the normal interstitial fluid pressure is usually several millimeters of mercury negative with respect to the pressure that surrounds each tissue.

In most natural cavities of the body, where there is free fluid in dynamic equilibrium with the surrounding interstitial fluids, the pressures that have been measured have been negative. Some of these cavities and pressure measurements are as follows:

- Intrapleural space: −8 mm Hg
- Joint synovial spaces: −4 to −6 mm Hg
- Epidural space: −4 to −6 mm Hg

Pumping By the Lymphatic System Is the Basic Cause of the Negative Interstitial Fluid Pressure. The lymphatic system is discussed later in the chapter, but first we should understand the basic role that this system plays in determining interstitial fluid pressure. The lymphatic system removes excess fluid, excess protein molecules, debris, and other matter from the tissue spaces. Normally, when fluid enters the terminal lymphatic capillaries, the lymph vessel walls automatically contract for a few seconds and pump the fluid into the blood circulation. This overall process creates the slight negative pressure that has been measured for fluid in the interstitial spaces.

PLASMA COLLOID OSMOTIC PRESSURE

Plasma Proteins Exert Colloid Osmotic Pressure. As discussed in Chapter 4, only the molecules or ions that fail to pass through the pores of a semipermeable membrane

exert osmotic pressure. Because the proteins are the only dissolved constituents in the plasma and interstitial fluids that do not readily pass through the capillary pores, the proteins of the plasma and interstitial fluids are responsible for the osmotic pressures on the two sides of the capillary membrane. To distinguish this osmotic pressure from that which occurs at the cell membrane, it is called *colloid osmotic pressure* or *oncotic pressure*. The term *colloid osmotic pressure* is derived from the fact that a protein solution resembles a colloidal solution, despite the fact that it is actually a true molecular solution.

Normal Values for Plasma Colloid Osmotic Pressure. The colloid osmotic pressure of normal human plasma averages about 28 mm Hg; 19 mm of this pressure is caused by molecular effects of the dissolved protein, and 9 mm is caused by the *Donnan effect*—that is, extra osmotic pressure caused by sodium, potassium, and the other cations bound to the plasma proteins.

Effect of the Different Plasma Proteins on Colloid Osmotic Pressure. The plasma proteins are a mixture that contains albumin, globulins, and fibrinogen, with an average molecular weight of 69,000, 140,000, and 400,000, respectively. Thus, 1 gram of globulin contains only half as many molecules as 1 gram of albumin, and 1 gram of fibrinogen contains only one-sixth as many molecules as 1 gram of albumin. As discussed in Chapter 4, osmotic pressure is determined by the *number of molecules* dissolved in a fluid rather than by the mass of these molecules. The following chart gives both the relative mass concentrations (g/dL) of the different types of proteins in normal plasma and their normal contributions to the total plasma colloid osmotic pressure (Πp). These values include the Donnan effect of ions bound to the plasma proteins:

	g/dL	Πp (mm Hg)
Albumin	4.5	21.8
Globulins	2.5	6.0
Fibrinogen	0.3	0.2
Total	**7.3**	**28.0**

Thus, about 80% of the total colloid osmotic pressure of the plasma normally results from the albumin, 20% from the globulins, and almost none from fibrinogen. Therefore, from the point of view of capillary and tissue fluid dynamics, it is mainly albumin that is important.

INTERSTITIAL FLUID COLLOID OSMOTIC PRESSURE

Although the size of the usual capillary pore is smaller than the molecular sizes of the plasma proteins, this is not true of all the pores. Therefore, small amounts of plasma proteins do leak into the interstitial spaces through pores and by transcytosis in small vesicles.

The total quantity of protein in the entire 11 to 12 liters of interstitial fluid of the body is slightly greater than the total quantity of protein in the plasma, but because this volume is nearly four times the volume of plasma, the average protein *concentration* of the interstitial fluid of most tissues is usually only 40% of that in plasma, or about 3 g/dL. Quantitatively, the average interstitial fluid colloid osmotic pressure for this concentration of proteins is about 8 mm Hg. In some tissues, such as the kidneys, the interstitial fluid colloid osmotic pressure is substantially higher, averaging about 15 mm Hg due to a higher permeability of the capillaries for plasma proteins.

FLUID VOLUME EXCHANGE THROUGH THE CAPILLARY MEMBRANE

The different factors affecting fluid movement through the capillary membrane have been discussed, so we can put all these factors together to see how the capillary system maintains normal fluid volume distribution between the plasma and interstitial fluid.

The average capillary pressure at the arterial ends of the capillaries is 15 to 25 mm Hg greater than at the venous ends. Because of this difference, fluid filters out of the capillaries at their arterial ends, but at their venous ends fluid is reabsorbed back into the capillaries (see **Fig. 16.3**). Thus, a small amount of fluid actually "flows" through the tissues from the arterial ends of the capillaries to the venous ends.

Analysis of the Forces Causing Filtration at the Arterial End of the Capillary. The approximate average forces operative at the *arterial end* of the capillary that cause movement through the capillary membrane are shown as follows:

	mm Hg
Forces Tending to Move Fluid Outward	
Capillary hydrostatic pressure (arterial end of capillary)	30
Negative interstitial fluid hydrostatic pressure	3
Interstitial fluid colloid osmotic pressure	8
TOTAL OUTWARD FORCE	41
Forces Tending to Move Fluid Inward	
Plasma colloid osmotic pressure	28
TOTAL INWARD FORCE	28
Summation of Forces	
Outward	41
Inward	28
NET OUTWARD FORCE (AT ARTERIAL END)	13

Thus, the summation of forces at the arterial end of the capillary shows a net *filtration pressure* of 13 mm Hg, tending to move fluid outward through the capillary pores. This 13 mm Hg filtration pressure causes, on average, about 0.5% of the plasma in the flowing blood to filter out of the arterial ends of the capillaries into the interstitial spaces each time the blood passes through the capillaries.

Analysis of Reabsorption at the Venous End of the Capillary. The low blood pressure at the venous end of the capillary changes the balance of forces in favor of absorption as follows:

	mm Hg
Forces Tending to Move Fluid Inward	
Plasma colloid osmotic pressure	28
TOTAL INWARD FORCE	28
Forces Tending to Move Fluid Outward	
Capillary hydrostatic pressure (venous end of capillary)	10
Negative interstitial fluid hydrostatic pressure	3
Interstitial fluid colloid osmotic pressure	8
TOTAL OUTWARD FORCE	21
Summation of Forces	
Inward	28
Outward	21
NET INWARD FORCE	7

Thus, there is a *net reabsorption pressure* of 7 mm Hg at the venous ends of the capillaries. This reabsorption pressure is considerably less than the filtration pressure at the capillary arterial ends, but remember that the venous capillaries are more numerous and more permeable than the arterial capillaries. Thus, less reabsorption pressure is required to cause inward movement of fluid.

The reabsorption pressure causes about 90% of the fluid that has filtered out of the arterial ends of the capillaries to be reabsorbed at the venous ends. The remaining 10% flows into the lymph vessels and returns to the circulating blood.

STARLING EQUILIBRIUM FOR CAPILLARY EXCHANGE

Ernest Starling pointed out more than a century ago that under normal conditions, a state of near-equilibrium exists in most capillaries. That is, the amount of fluid filtering outward from the arterial ends of capillaries almost exactly equals the fluid returned to the circulation by absorption. The slight disequilibrium that does occur accounts for the fluid that is eventually returned to the circulation by way of the lymphatics.

The following chart shows the principles of the Starling equilibrium. For this chart, the pressures in the arterial and venous capillaries are averaged to calculate the mean *functional* capillary pressure for the entire length of the capillary. This mean functional capillary pressure is calculated to be 17.3 mm Hg.

	mm Hg
Mean Forces Tending to Move Fluid Outward	
Mean capillary pressure	17.3
Negative interstitial fluid hydrostatic pressure	3.0
Interstitial fluid colloid osmotic pressure	8.0
TOTAL OUTWARD FORCE	28.3
Mean Forces Tending to Move Fluid Inward	
Plasma colloid osmotic pressure	28.0
TOTAL INWARD FORCE	28.0
Summation of Mean Forces	
Outward	28.3
Inward	28.0
NET OUTWARD FORCE	0.3

Thus, for the total capillary circulation, we find a near-equilibrium between the total outward forces, 28.3 mm Hg, and the total inward force, 28.0 mm Hg. This slight imbalance of forces, 0.3 mm Hg, causes slightly more filtration of fluid into the interstitial spaces than reabsorption. This slight excess of filtration is called *net filtration*, and it is the fluid that must be returned to the circulation through the lymphatics. The normal rate of net filtration *in the entire body*, not including the kidneys, is only about 2 mL/min.

CAPILLARY FILTRATION COEFFICIENT

In the previous example, an average net imbalance of forces at the capillary membranes of 0.3 mm Hg causes net fluid filtration in the entire body of 2 mL/min. Expressing the net fluid filtration rate for each mm Hg imbalance, one finds a net filtration rate of 6.67 mL/min of fluid per mm Hg for the entire body. This value is called the whole body *capillary filtration coefficient*.

The filtration coefficient can also be expressed for separate parts of the body in terms of the rate of filtration per minute per mm Hg per 100 grams of tissue. On this basis, the capillary filtration coefficient of the average tissue is about 0.01 mL/min per mm Hg per 100 g of tissue. However, because of extreme differences in permeabilities and surface areas of the capillary systems in different tissues, this coefficient varies more than 100-fold among the different tissues. It is very small in brain and muscle, moderately large in subcutaneous tissue, large in the intestine, and extremely large in the liver and glomeruli of the kidney, where the capillary surface is large, and the pores are numerous or wide open. By the same token, the permeation of proteins through the capillary membranes also varies greatly. The concentration of protein in the interstitial fluid of muscles is about 1.5 g/dL; in subcutaneous tissue, it is 2 g/dL; in the intestine, it is 4 g/dL; and, in the liver, it is 6 g/dL.

Effect of Abnormal Imbalance of Forces at the Capillary Membrane. If the mean capillary pressure rises significantly above the average value of 17 mm Hg, the net force tending to cause filtration of fluid into the tissue spaces rises. Thus, a 20-mm Hg rise in mean capillary

pressure causes an increase in net filtration pressure from 0.3 to 20.3 mm Hg, which results in 68 times as much net filtration of fluid into the interstitial spaces as normally occurs. To prevent accumulation of excess fluid in these spaces would require 68 times the normal flow of fluid into the lymphatic system, an amount that is 2 to 5 times too much for the lymphatics to carry away. As a result, fluid will begin to accumulate in the interstitial spaces and edema will result.

Conversely, if the capillary pressure falls very low, net reabsorption of fluid into the capillaries will occur instead of net filtration, and the blood volume will increase at the expense of the interstitial fluid volume. These effects of imbalance at the capillary membrane in relationship to the development of edema are discussed in Chapter 25.

LYMPHATIC SYSTEM

The lymphatic system represents an accessory route through which fluid can flow from the interstitial spaces into the blood. Most importantly, the lymphatics can carry away from the tissue spaces proteins and large particulate matter that cannot be removed by absorption directly into the blood capillaries. This return of proteins to the blood from the interstitial spaces is an essential function, without which we would die within about 24 hours.

LYMPH CHANNELS OF THE BODY

Almost all tissues of the body have special lymph channels that drain excess fluid directly from the interstitial spaces (**Fig. 16.6**). The exceptions include the superficial portions of the skin, endomysium of muscles, and bones. However, even these tissues have minute interstitial channels called *prelymphatics* through which interstitial fluid can flow; this fluid eventually empties into lymphatic vessels.

Lymph Vessels and Clearance of Large Molecules From the Central Nervous System. In the central nervous system, true lymphatic vessels have been found only in the *meninges*, the membranes that cover and protect the brain and spinal cord (**Fig. 16.7**). However, another potential mechanism that may help explain how the deeper brain tissue clears large molecules and waste products from the interstitial fluid is the *glial-lymphatic (glymphatic) system*. Cerebrospinal fluid (discussed in Chapter 62) flows into small *perivascular spaces* formed by *glial cells* around the cerebral blood vessels. These spaces form channels that allow cerebrospinal fluid to flow into the brain parenchyma along periarterial spaces, exiting via a perivenous route and transporting interstitial fluid and accumulated substances into the meningeal lymphatics. Together, the meningeal lymphatics and the

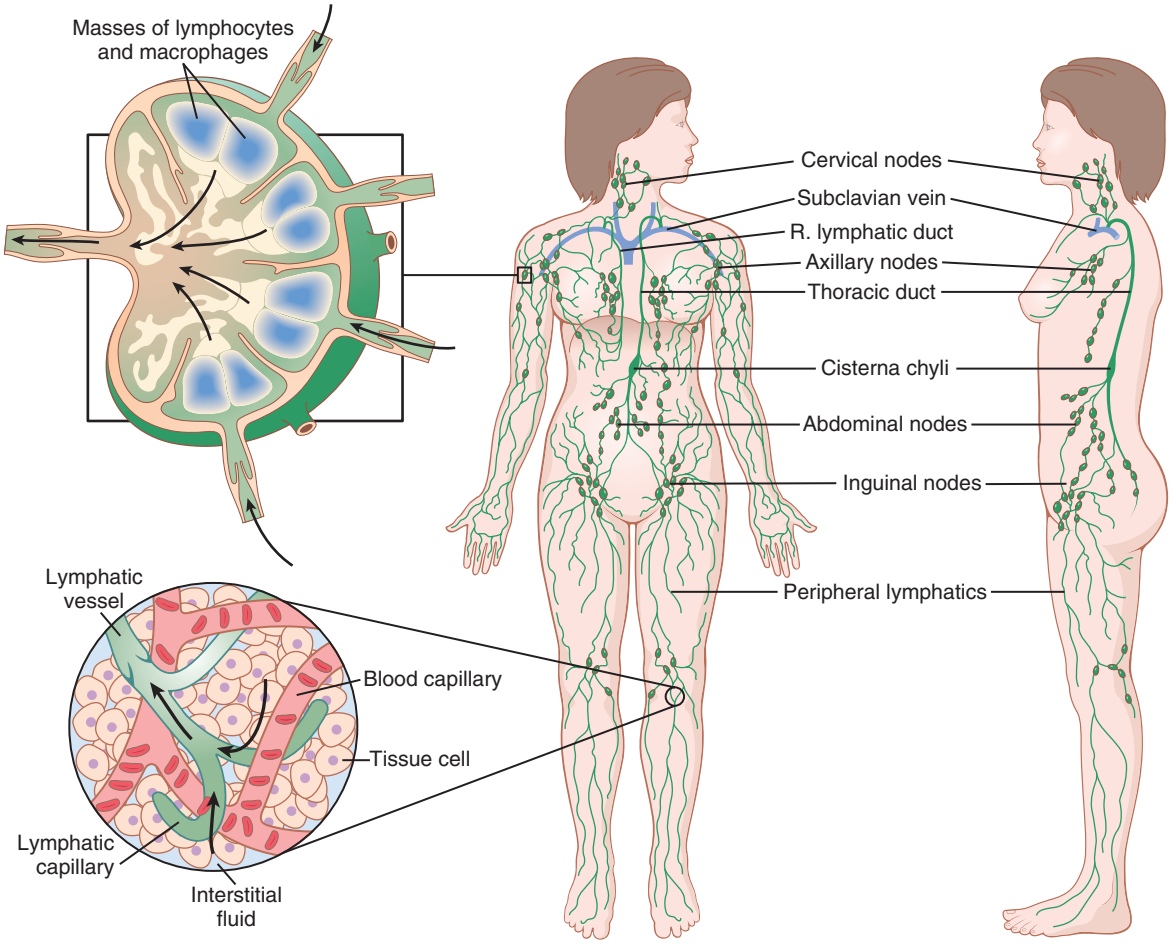

Figure 16.6 The lymphatic system.

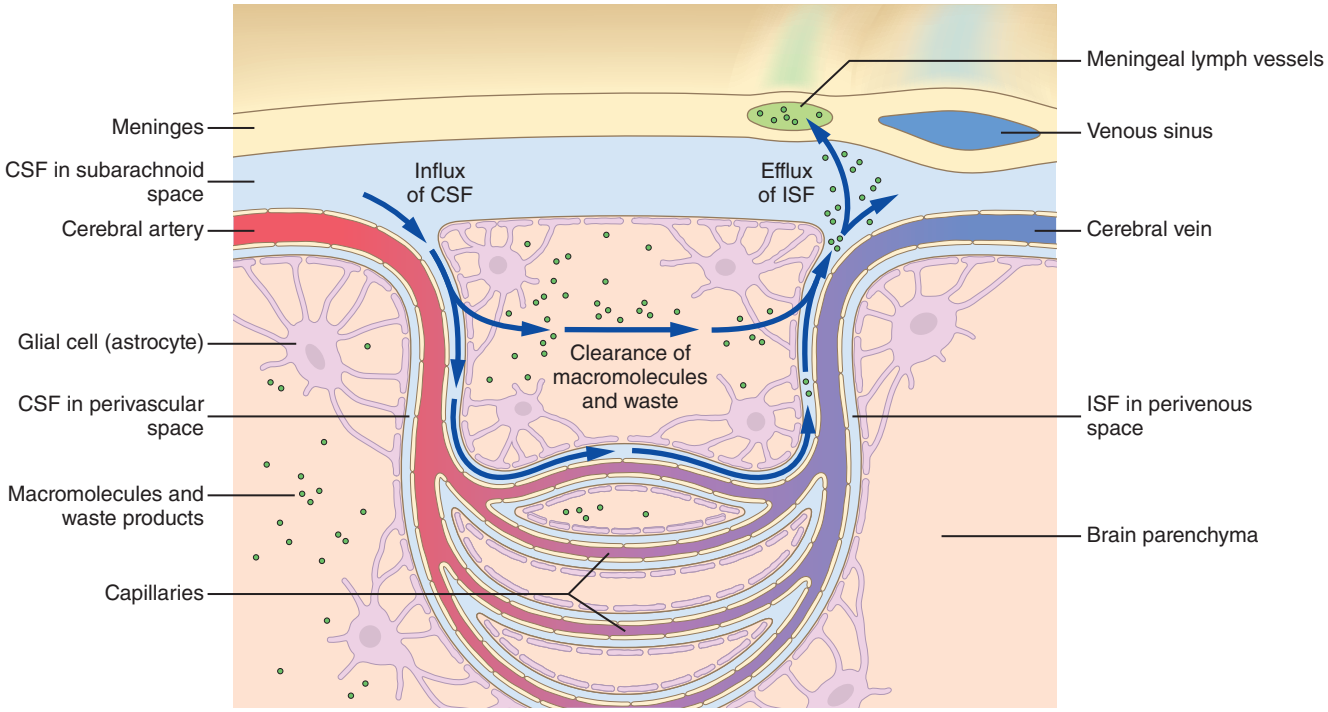

Figure 16.7 Lymph vessels in the meninges drain components of the cerebrospinal fluid (CSF) that fills the subarachnoid space. Perivascular spaces are filled with CSF that flows into deeper brain regions, along the arterioles and capillaries, and diffuses through the glia cells via aquaporins (water channels) into the parenchyma. Efflux of interstitial fluid (ISF) and waste products of tissue metabolism (including macromolecules that may accumulate) occurs through perivenous spaces back into the subarachnoid CSF, which is drained by the meningeal lymphatics. *(Adapted from Da Mesquita S, Fu Z, Kipnis J. The meningeal lymphatic system: a new player in neurophysiology.* Neuron. *2018;100:375-388.)*

glymphatic system may provide a pathway for extracellular proteins, excess fluid, waste products, and immune cells to be cleared from the brain tissue and cerebrospinal fluid into the blood.

The Thoracic Lymph Duct and Right Lymph Duct Carry Most of the Body's Lymph Into the Blood Venous System. Essentially all the lymph vessels from the lower part of the body eventually empty into the *thoracic duct*, which in turn empties into the blood venous system at the juncture of the *left* internal jugular vein and left subclavian vein, as shown in **Fig. 16.6**.

Lymph from the left side of the head, left arm, and parts of the chest region also enters the thoracic duct before it empties into the veins.

Lymph from the right side of the neck and head, right arm, and parts of the right thorax enters the *right lymph duct* (much smaller than the thoracic duct), which empties into the blood venous system at the juncture of the *right* subclavian vein and internal jugular vein.

Terminal Lymphatic Capillaries and Their Permeability. Most of the fluid filtering from the *arterial ends* of *blood capillaries* flows among the cells and finally is reabsorbed back into the *venous ends* of the *blood capillaries*, but, on average, about 10% of the fluid instead enters the *lymphatic capillaries* and returns to the blood through the lymphatic system rather than through the venous capillaries. The total quantity of all this lymph is normally only 2 to 3 L/day.

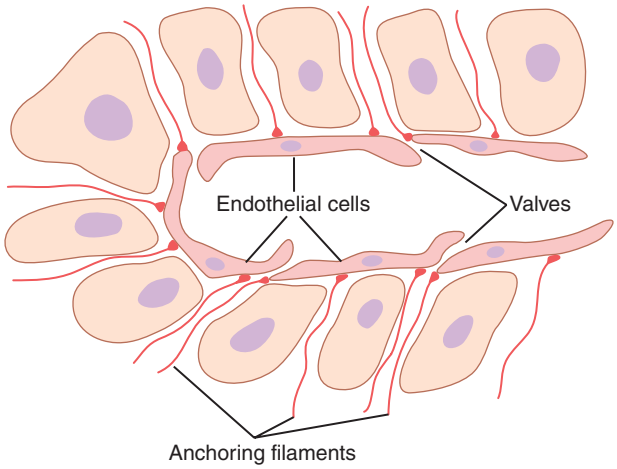

Figure 16.8 Special structure of the lymphatic capillaries that permits passage of substances of high molecular weight into the lymph.

The fluid that returns to the circulation via the lymphatics is extremely important because substances of high molecular weight, such as proteins, cannot be absorbed from the tissues in any other way, although they can enter the lymphatic capillaries almost unimpeded.

Fig. 16.8 shows the endothelial cells of the lymphatic capillary attached by *anchoring filaments* to the surrounding connective tissue. At the junctions of adjacent endothelial cells, the edge of one endothelial cell overlaps the edge of the adjacent cell in such a way that the overlapping edge is free to flap inward, thus forming a minute valve

that opens to the interior of the lymphatic capillary. Interstitial fluid, along with its suspended particles, can push the valve open and flow directly into the lymphatic capillary. However, this fluid has difficulty leaving the capillary once it has entered because any backflow closes the flap valve. Thus, the lymphatics have valves at the very tips of the terminal lymphatic capillaries, as well as valves along their larger vessels, up to the point where they empty into the blood circulation.

FORMATION OF LYMPH

Lymph is derived from interstitial fluid that flows into the lymphatics. Therefore, lymph as it first enters the terminal lymphatics has almost the same composition as the interstitial fluid.

The protein concentration in the interstitial fluid of most tissues averages about 2 g/dL, and the protein concentration of lymph flowing from these tissues is near this value. Lymph formed in the liver has a protein concentration as high as 6 g/dL, and lymph formed in the intestines has a protein concentration as high as 3 to 4 g/dL. Because about two-thirds of all lymph normally is derived from the liver and intestines, the thoracic duct lymph, which is a mixture of lymph from all areas of the body, usually has a protein concentration of 3 to 5 g/dL.

The lymphatic system is also one of the major routes for absorption of nutrients from the gastrointestinal tract, especially for absorption of virtually all fats in food, as discussed in Chapter 66. After a fatty meal, thoracic duct lymph sometimes contains as much as 1% to 2% fat.

Finally, even large particles, such as bacteria, can push their way between the endothelial cells of the lymphatic capillaries and in this way enter the lymph. As the lymph passes through the lymph nodes, these particles are almost entirely removed and destroyed, as discussed in Chapter 34.

RATE OF LYMPH FLOW

About 100 mL/hr of lymph flows through the *thoracic duct* of a resting human, and approximately another 20 mL flows into the circulation each hour through other channels, making a total estimated lymph flow of about 120 mL/hr or nearly 3 L/day.

Increased Interstitial Fluid Pressure Increases Lymph Flow. **Fig. 16.9** shows the effect of different levels of interstitial fluid hydrostatic pressure on lymph flow, as measured in animals. Note that normal lymph flow is very little at interstitial fluid pressures more negative than the normal value of −6 mm Hg. Then, as the pressure rises to 0 mm Hg (atmospheric pressure), flow increases more than 20-fold. Therefore, any factor that increases capillary filtration also increases interstitial fluid pressure, which then increases lymph flow if the lymph vessels are functioning normally. Such factors include the following:

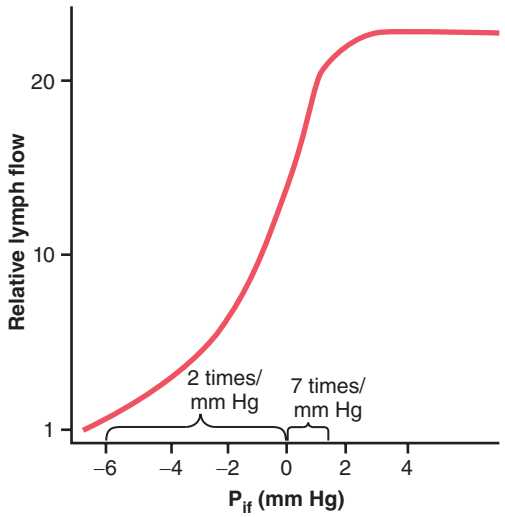

Figure 16.9 Relationship between interstitial fluid pressure and lymph flow in the leg of a dog. Note that lymph flow reaches a maximum when the interstitial pressure (P_{if}) rises slightly above atmospheric pressure (0 mm Hg). *(Courtesy Dr. Harry Gibson and Dr. Aubrey Taylor.)*

- Elevated capillary hydrostatic pressure
- Decreased plasma colloid osmotic pressure
- Increased interstitial fluid colloid osmotic pressure
- Increased permeability of the capillaries

All these factors favor net fluid movement into the interstitium, thus increasing interstitial fluid volume, interstitial fluid pressure, and lymph flow all at the same time.

However, note in **Fig. 16.9** that when the interstitial fluid hydrostatic pressure becomes 1 or 2 mm Hg greater than atmospheric pressure (>0 mm Hg), lymph flow fails to rise any further at still higher pressures. This results from the fact that the increasing tissue pressure not only increases entry of fluid into the lymphatic capillaries but also compresses the outside surfaces of the thin-walled lymphatics, thus impeding lymph flow. At the higher pressures, these two factors balance each other, so lymph flow reaches a maximum flow rate. This maximum flow rate is illustrated by the upper level plateau in **Fig. 16.9**.

Lymphatic Pump Increases Lymph Flow. Valves exist in all lymph channels. **Fig. 16.10** shows typical valves for collecting lymphatics into which the lymphatic capillaries empty.

Videos of exposed lymph vessels in animals and in humans have shown that when a collecting lymphatic or larger lymph vessel becomes stretched with fluid, the smooth muscle in the wall of the vessel automatically contracts. Furthermore, each segment of the lymph vessel between successive valves functions as a separate automatic pump. That is, even slight filling of a segment causes it to contract, and the fluid is pumped through the next valve into the next lymphatic segment. This fluid fills the subsequent segment, and a few seconds later it also contracts, with the process continuing all along the lymph vessel until the fluid is finally emptied into the blood circulation. In a very large lymph vessel, such as the thoracic

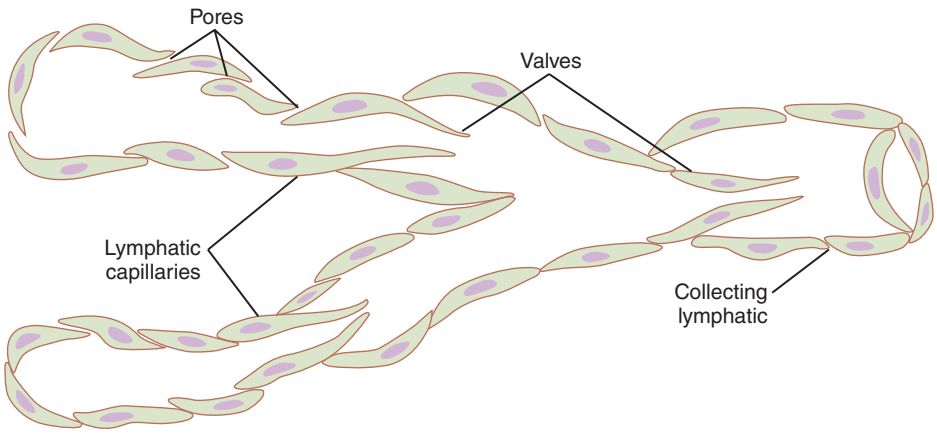

Figure 16.10 Structure of lymphatic capillaries and a collecting lymphatic, with the lymphatic valves also shown.

duct, this lymphatic pump can generate pressure as high as 50 to 100 mm Hg.

Pumping Caused By External Intermittent Compression of the Lymphatics. In addition to the pumping caused by intrinsic intermittent contraction of the lymph vessel walls, any external factor that intermittently compresses the lymph vessel can also cause pumping. In order of their importance, such factors are as follows:

- Contraction of surrounding skeletal muscles
- Movement of the parts of the body
- Pulsations of arteries adjacent to the lymphatics
- Compression of the tissues by objects outside the body

The lymphatic pump becomes very active during exercise, often increasing lymph flow 10- to 30-fold. Conversely, during periods of rest, lymph flow is sluggish (almost zero).

Lymphatic Capillary Pump. In addition to pumping by larger lymph vessels, terminal lymphatic capillaries can also pump lymph. As explained earlier in the chapter, the anchoring filaments on the walls of the lymphatic capillaries tightly adhere to the surrounding tissue cells. Therefore, each time excess fluid enters the tissue and causes the tissue to swell, the anchoring filaments pull on the wall of the lymphatic capillary, and fluid flows into the terminal lymphatic capillary through the junctions between the endothelial cells. Then, when the tissue is compressed, the pressure inside the capillary increases and causes the overlapping edges of the endothelial cells to close like valves. Therefore, the pressure pushes the lymph forward into the collecting lymphatic instead of backward through the cell junctions.

Lymphatic capillary endothelial cells also contain a few contractile actomyosin filaments. In some tissues, these filaments may cause rhythmical contraction of the lymphatic capillaries in the same rhythmic way that many of the small blood vessels and larger lymphatic vessels contract. Therefore, at least part of lymph pumping results from lymph capillary endothelial cell contraction in addition to contraction of the larger muscular lymphatics.

Summary of Factors That Determine Lymph Flow. From the previous discussion, one can see that the two primary factors that determine lymph flow are (1) the interstitial fluid pressure and (2) the activity of the lymphatic pump. Therefore, one can state that, roughly, *the rate of lymph flow is determined by the product of interstitial fluid pressure times the activity of the lymphatic pump*.

Lymphatic System Plays a Key Role in Controlling Interstitial Fluid Protein Concentration, Volume, and Pressure

It is already clear that the lymphatic system functions as an overflow mechanism to return excess proteins and excess fluid volume from the tissue spaces to the circulation. Therefore, the lymphatic system also plays a central role in controlling the following: (1) concentration of proteins in the interstitial fluids; (2) volume of interstitial fluid; and (3) interstitial fluid pressure. Here is an explanation of how these factors interact.

1. Remember that small amounts of proteins leak continuously out of the blood capillaries into the interstitium. Only minute amounts, if any, of the leaked proteins return to the circulation by way of the venous ends of the blood capillaries. Therefore, these proteins tend to accumulate in the interstitial fluid, which in turn increases the colloid osmotic pressure of the interstitial fluids.
2. The increasing colloid osmotic pressure in the interstitial fluid shifts the balance of forces at the blood capillary membranes in favor of fluid filtration into the interstitium. Therefore, in effect, fluid is translocated osmotically outward through the capillary wall by the proteins and into the interstitium, thus increasing both interstitial fluid volume and interstitial fluid pressure.
3. The increasing interstitial fluid pressure greatly increases the rate of lymph flow, which carries away the excess interstitial fluid volume and excess protein that has accumulated in the spaces.

Thus, once the interstitial fluid protein concentration reaches a certain level and causes comparable increases in

interstitial fluid volume and pressure, the return of protein and fluid by way of the lymphatic system becomes great enough to balance the rate of leakage of these into the interstitium from the blood capillaries. Therefore, the quantitative values of all these factors reach a steady state, and they remain balanced at these steady-state levels until some factor changes the rate of leakage of proteins and fluid from the blood capillaries.

CHAPTER 17

Local and Humoral Control of Tissue Blood Flow

LOCAL BLOOD FLOW IS CONTROLLED IN RESPONSE TO TISSUE NEEDS

A fundamental principle of circulatory function is that most tissues have the ability to control their own local blood flow in proportion to their specific metabolic needs. Some of the specific needs of the tissues for blood flow include the following:

1. Delivery of oxygen to the tissues
2. Delivery of other nutrients such as glucose, amino acids, and fatty acids
3. Removal of carbon dioxide from the tissues
4. Removal of hydrogen ions from the tissues
5. Maintenance of proper concentrations of ions in the tissues
6. Transport of various hormones and other substances to the different tissues.

Certain organs have special requirements. For example, blood flow to the skin determines heat loss from the body and, in this way, helps control body temperature. Also, delivery of adequate quantities of blood plasma to the kidneys allows the kidneys to filter and excrete the waste products of the body and to regulate body fluid volumes and electrolytes.

Variations in Blood Flow in Different Tissues and Organs. Note the very large blood flows listed in **Table 17.1** for some organs—for example, several hundred milliliters per minute per 100 grams of thyroid or adrenal gland tissue and a total blood flow of 1350 mL/min in the liver, which is 95 mL/min/100 g of liver tissue.

Also note the extremely large blood flow through the kidneys—1100 mL/min. This large amount of flow, about 22% of the cardiac output, is required for the kidneys to perform their function of cleansing the blood of waste products and regulating composition of the body fluids precisely.

Conversely, all the *inactive* skeletal muscles of the body together have a blood flow of only about 750 mL/min even though the muscles constitute 30% to 40% of the total body mass. In the resting state, the metabolic activity of the muscles is low, as is the blood flow—only 4 mL/min/100 g. Yet, during heavy exercise, muscle metabolic activity can increase more than 60-fold and the blood flow as much as 20-fold, increasing to as high as 16,000 mL/min in the body's total muscle vascular bed (or 80 mL/min/100 g of muscle).

Importance of Blood Flow Control By the Local Tissues. Experiments have shown that the blood flow to each tissue usually is normally regulated at the minimal level that will supply the tissue's requirements—no more, no less. For example, in tissues for which the most important requirement is delivery of oxygen, the blood flow is controlled at a level only slightly more than that required to maintain full tissue oxygenation but no more than this. By controlling local blood flow in such an exact way, the tissues rarely experience oxygen nutritional deficiency, and the workload on the heart is kept at a minimum.

MECHANISMS OF LOCAL BLOOD FLOW CONTROL

Local blood flow control can be divided into two phases, acute control and long-term control. *Acute control* is achieved by rapid changes (within seconds to minutes) in local vasodilation or vasoconstriction of the arterioles, metarterioles, and precapillary sphincters that maintain appropriate local tissue blood flow. *Long-term control* means slow, controlled changes in flow over a period of days, weeks, or even months. In general, these long-term changes provide even better control of the flow in proportion to the needs of the tissues. These changes result from increases or decreases in the physical sizes and numbers of blood vessels supplying the tissues.

ACUTE CONTROL OF LOCAL BLOOD FLOW

Increases in Tissue Metabolism Increase Tissue Blood Flow

Fig. 17.1 shows the approximate acute effect on blood flow of increasing the rate of metabolism in a tissue such as in a skeletal muscle. Note that an increase in metabolism up to eight times normal increases the blood flow acutely about 4-fold.

Reduced Oxygen Availability Increases Tissue Blood Flow. One of the most essential metabolic nutrients is oxygen. Whenever the availability of oxygen to the tissues decreases, blood flow through the tissues increases

Table 17.1 Approximate Blood Flow to Different Organs and Tissues in a 70-kg Human Under Basal Conditions

	Percentage of Cardiac Output	mL/min	mL/min/100 g of Tissue Weight
Brain	14	700	50
Heart	4	200	70
Bronchi	2	100	25
Kidneys	22	1100	360
Liver	27	1350	95
• Portal	(21)	(1050)	
• Arterial	(6)	(300)	
Muscle (inactive state)	15	750	4
Bone	5	250	3
Skin (cool weather)	6	300	3
Thyroid gland	1	50	160
Adrenal glands	0.5	25	300
Other tissues	3.5	175	1.3
Total	**100.0**	**5000**	

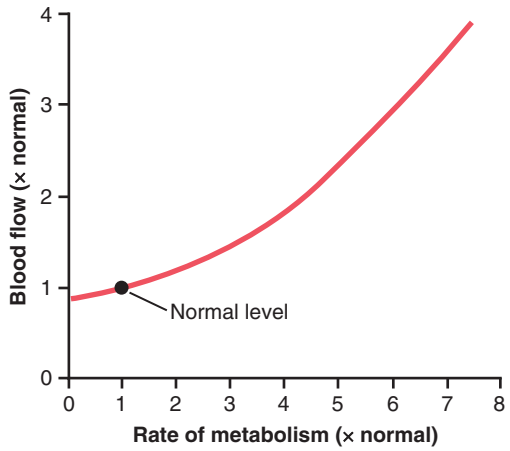

Figure 17.1 Effect of increasing rate of metabolism on tissue blood flow.

markedly. For example, each of the following conditions decreases oxygen availability to the tissues and causes a compensatory increase in tissue blood flow: (1) high altitude at the top of a high mountain; (2) pneumonia; (3) carbon monoxide poisoning (which poisons the ability of hemoglobin to transport oxygen); or (4) cyanide poisoning (which poisons the ability of the tissues to use oxygen).

Fig. 17.2 shows that as the arterial oxygen saturation decreases to about 25% of normal, the blood flow through an isolated leg increases about 3-fold; that is, the blood flow increases almost enough, but not quite enough, to make up for the decreased amount of oxygen in the blood, thus almost maintaining a relatively constant supply of oxygen to the tissues.

Total cyanide poisoning of oxygen usage by a local tissue area can cause local blood flow to increase as much as

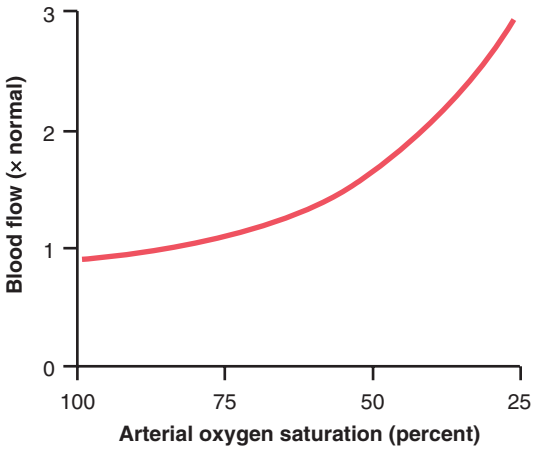

Figure 17.2 Effect of decreasing arterial oxygen saturation on blood flow through an isolated dog leg.

7-fold, demonstrating the extreme effect of oxygen deficiency to increase blood flow. Two main theories— the *vasodilator theory* and the *oxygen demand theory*— have been proposed to explain how changes in tissue metabolism or oxygen availability alter tissue blood flow.

Vasodilator Theory for Acute Local Blood Flow Regulation—Possible Role of Adenosine. According to the vasodilator theory, a greater rate of metabolism or a reduced availability of oxygen or other nutrients to a tissue causes increased formation of *vasodilator substances* in the tissue cells. The vasodilator substances are believed to diffuse through the tissues to the precapillary sphincters, metarterioles, and arterioles to cause dilation. Some of the different vasodilator substances that have been suggested are *adenosine, carbon dioxide, adenosine phosphate compounds, histamine, potassium ions*, and *hydrogen ions*.

Vasodilator substances may be released from the tissue in response to oxygen deficiency. For example, decreased oxygen availability can cause adenosine and lactic acid (containing hydrogen ions) to be released into the interstitial spaces between the tissue cells; these substances then cause intense acute vasodilation and are responsible, or partially responsible, for the local blood flow regulation. Other vasodilator substances, such as carbon dioxide, lactic acid, and potassium ions, also tend to increase in the tissues when blood flow is reduced and cell metabolism continues at the same rate, or when cell metabolism is suddenly increased. Increased concentration of vasodilator metabolites causes vasodilation of the arterioles, thus increasing the tissue blood flow and returning the tissue concentration of the metabolites toward normal.

Adenosine appears to be an important vasodilator for controlling local blood flow. For example, minute quantities of adenosine are released from heart muscle cells when coronary blood flow becomes too little, and this release of adenosine causes enough local vasodilation in the heart to return coronary blood flow to normal. Also, whenever the heart becomes more active than normal,

the heart's metabolism increases, causing increased utilization of oxygen, followed by (1) decreased oxygen concentration in the heart muscle cells with (2) consequent degradation of adenosine triphosphate (ATP), which (3) increases release of adenosine. Much of this adenosine leaks out of the heart muscle cells to cause coronary vasodilation, providing increased coronary blood flow to supply the increased nutrient demands of the active heart.

Although research evidence is less clear, the same adenosine mechanism may be an important controller of blood flow in skeletal muscle and many other tissues, as well as in the heart. However, it has been difficult to prove that sufficient quantities of any single vasodilator substance, including adenosine, are formed in the tissues to cause all the measured increase in blood flow. It is likely that a combination of several different vasodilators released by the tissues contributes to blood flow regulation.

Oxygen Demand Theory for Local Blood Flow Control. Although the vasodilator theory is widely accepted, several critical facts are consistent with another theory, which can be called the *oxygen demand theory* or, more accurately, the *nutrient demand theory* because other nutrients besides oxygen are involved. Oxygen is one of the metabolic nutrients required to cause vascular muscle contraction, with other nutrients required as well. Therefore, in the absence of adequate oxygen, blood vessels may relax and therefore dilate. Also, increased utilization of oxygen in the tissues as a result of increased metabolism could decrease the availability of oxygen to the smooth muscle fibers in the local blood vessels, causing local vasodilation.

A mechanism whereby oxygen availability could operate is shown in **Fig. 17.3**. This figure shows a tissue vascular unit, consisting of a metarteriole with a single sidearm capillary and its surrounding tissue. At the origin of the capillary in some tissues is a *precapillary sphincter*, and around the metarteriole are several other smooth muscle fibers. The precapillary sphincters are normally completely open or completely closed. The number of precapillary sphincters that are open at any given time is roughly proportional to the requirements of the tissue for nutrition. The precapillary sphincters and metarterioles open and close cyclically several times per minute, with the duration of the open phases being proportional to the metabolic needs of the tissues for oxygen. This cyclical opening and closing is called *vasomotion*.

Because smooth muscle requires oxygen to remain contracted, the strength of contraction of the sphincters increases with an increase in oxygen concentration. Consequently, when the oxygen concentration in the tissue rises above a certain level, the precapillary and metarteriole sphincters presumably would close until the tissue cells consume the excess oxygen. However, when the excess oxygen is gone and the oxygen concentration falls low enough, the sphincters open once more to begin the cycle again.

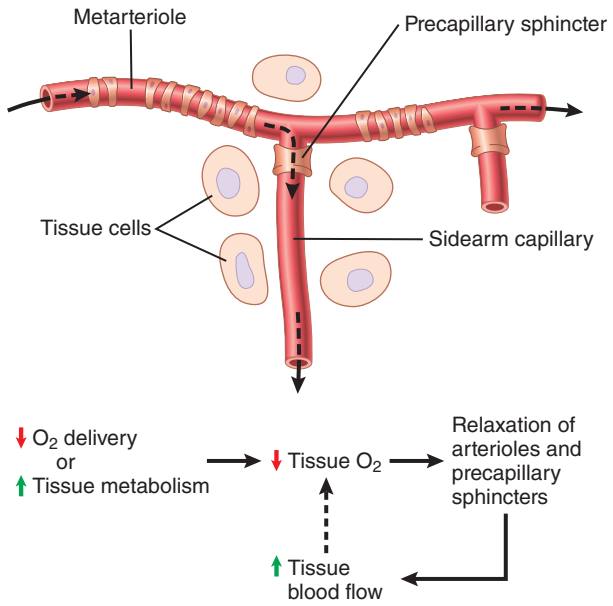

Figure 17.3 Diagram of a tissue unit area for an explanation of acute local feedback control of blood flow, showing a *metarteriole* passing through the tissue and a *sidearm capillary* with its *precapillary sphincter* for controlling capillary blood flow.

Thus, on the basis of available data, either the *vasodilator substance theory* or *oxygen demand theory* could explain acute local blood flow regulation in response to the metabolic needs of the tissues. A combination of the two mechanisms likely contributes to blood flow regulation.

Possible Role of Other Nutrients Besides Oxygen in Control of Local Blood Flow. Under special conditions, a lack of glucose in the perfusing blood can cause local tissue vasodilation. It also is possible that this same effect occurs when other nutrients, such as amino acids or fatty acids, are deficient, although this is still uncertain. In addition, vasodilation occurs in the vitamin deficiency disease *beriberi*, in which patients have deficiencies of the vitamin B substances *thiamine, niacin*, and *riboflavin*. In this disease, the peripheral vascular blood flow almost everywhere in the body often increases 2-fold to 3-fold. Because all these vitamins are necessary for oxygen-induced phosphorylation, which is required to produce ATP in the tissue cells, one can understand how deficiency of these vitamins might lead to diminished smooth muscle contractile ability and therefore local vasodilation as well.

Special Examples of Acute Metabolic Control of Local Blood Flow

The mechanisms we have described thus far for local blood flow control are called *metabolic mechanisms* because they all function in response to the metabolic needs of the tissues. Two additional special examples of metabolic control of local blood flow are *reactive hyperemia* and *active hyperemia* (**Fig. 17.4**).

Reactive Hyperemia Occurs After Tissue Blood Flow Is Blocked for a Short Time. When the blood supply to a tissue is blocked for a few seconds to as long as 1 hour or more and then is unblocked, blood flow through the tissue usually increases immediately to four to seven times normal. This increased flow will continue for a few seconds if the block has lasted only a few seconds but sometimes continues for as long as many hours if the blood flow has been stopped for an hour or more. This phenomenon is called *reactive hyperemia*.

Reactive hyperemia is another manifestation of the local metabolic blood flow regulation mechanism—that is, lack of flow sets into motion all the metabolic factors that cause vasodilation. After short periods of vascular occlusion, the extra blood flow during the reactive hyperemia phase lasts long enough to repay almost exactly the tissue oxygen deficit that has accrued during the period of occlusion. This mechanism emphasizes the close connection between local blood flow regulation and delivery of oxygen and other nutrients to the tissues.

Active Hyperemia Occurs When Tissue Metabolic Rate Increases. When a tissue becomes highly active, such as an exercising muscle, the gut during digestion of food, a gastrointestinal gland during a hypersecretory period, or even the brain during increased mental activity, the rate of blood flow through the tissue increases (see **Fig. 17.4**). The increase in local metabolism causes the cells to devour tissue fluid nutrients rapidly and release increased quantities of vasodilator substances. The result is dilation of local blood vessels and increased local blood flow. In this way, the active tissue receives the additional nutrients required to sustain its increased level of activity. As noted earlier, active hyperemia in skeletal muscle can increase local muscle blood flow as much as 20-fold during intense exercise.

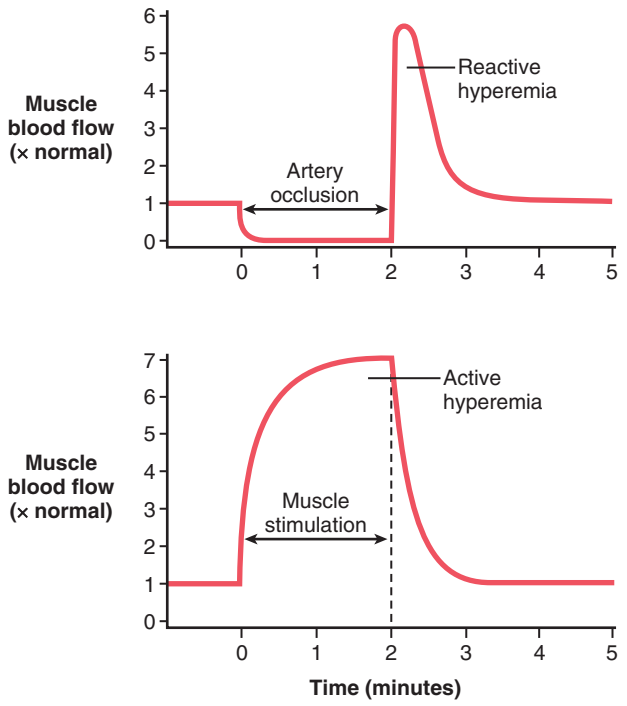

Figure 17.4 *Reactive hyperemia* in a tissue after temporary occlusion of the artery supplying blood flow and *active hyperemia* following increased tissue metabolic activity.

Autoregulation of Blood Flow During Changes in Arterial Pressure—Metabolic and Myogenic Mechanisms

In any tissue of the body, a rapid increase in arterial pressure causes an immediate rise in blood flow. However, within less than 1 minute, blood flow in most tissues returns almost to the normal level even though the arterial pressure is kept elevated. This return of flow toward normal is called *autoregulation*. After autoregulation has occurred, blood flow in most tissues will be related to arterial pressure approximately in accord with the solid acute curve in **Fig. 17.5**. Note that between arterial pressures of about 70 and 175 mm Hg, blood flow increases only 20% to 30%, even though arterial pressure increases 150%. In some tissues, such as the brain, kidneys, and heart, this autoregulation is even more precise.

Metabolic and *myogenic* mechanisms have been proposed to explain this acute blood flow autoregulation in many tissues. The basic metabolic mechanisms of local blood flow regulation were discussed in previous sections. Thus, when the arterial pressure becomes too great, the excess flow provides too much oxygen and too many other nutrients to the tissues and washes out the vasodilators released by tissue metabolism. These nutrients (especially oxygen) and decreased tissue levels of vasodilators then cause the blood vessels to constrict and return flow to nearly normal, despite the increased pressure.

The myogenic mechanism is based on the observation that a sudden stretch of small blood vessels causes the smooth muscle of the vessel wall to contract. Therefore, when high arterial pressure stretches the vessel, reactive

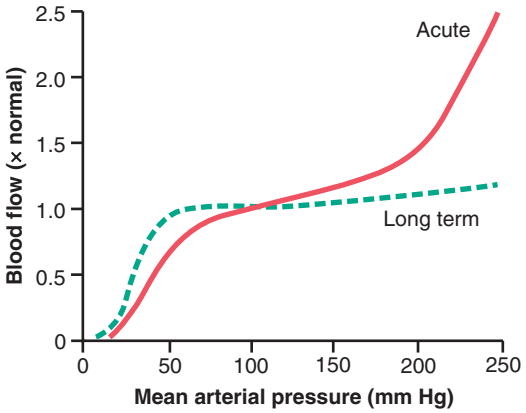

Figure 17.5 Effect of different levels of arterial pressure on blood flow through a muscle. The *solid red curve* shows the effect if the arterial pressure is raised over a period of a few minutes. The *dashed green curve* shows the effect if the arterial pressure is raised slowly over many weeks.

vascular constriction occurs and attenuates the increased blood flow. Conversely, at low pressures, the degree of stretch of the vessel is less, so the smooth muscle relaxes, reducing vascular resistance and helping to return flow toward normal.

The myogenic response is inherent to vascular smooth muscle and can occur in the absence of neural or hormonal influences. It is most pronounced in arterioles but can also be observed in arteries, venules, veins, and even lymphatic vessels. Myogenic contraction is initiated by *stretch-induced vascular depolarization*, which then rapidly increases calcium ion entry from the extracellular fluid into the cells, causing them to contract. Changes in vascular pressure may also open or close other ion channels that influence vascular contraction. The precise mechanisms whereby changes in pressure cause opening or closing of vascular ion channels are still uncertain but likely involve mechanical effects of pressure on extracellular proteins that are tethered to cytoskeleton elements of the vascular wall or to the ion channels themselves.

The myogenic mechanism is important in preventing excessive stretching of blood vessels when blood pressure is increased. However, the quantitative importance of the myogenic mechanism in blood flow regulation is less certain because this pressure-sensing mechanism cannot directly detect changes in tissue blood flow. Metabolic factors appear to override the myogenic mechanism in circumstances in which the metabolic demands of the tissues are significantly increased, such as during vigorous muscle exercise, which causes dramatic increases in skeletal muscle blood flow.

Special Mechanisms for Acute Blood Flow Control in Specific Tissues

Although the general mechanisms for local blood flow control discussed thus far are present in almost all tissues of the body, distinctly different mechanisms operate in a few special areas. Different mechanisms are discussed throughout this text in relation to specific organs, but three notable examples are as follows:

1. In the *kidneys*, blood flow control is significantly vested in a mechanism called *tubuloglomerular feedback*, in which the composition of the fluid in the early distal tubule is detected by an epithelial structure of the distal tubule, called the *macula densa*. This structure is located where the distal tubule lies adjacent to the afferent and efferent arterioles at the nephron *juxtaglomerular apparatus*. When too much fluid filters from the blood through the glomerulus into the tubular system, feedback signals from the macula densa cause constriction of the afferent arterioles, thereby reducing renal blood flow and glomerular filtration rate back toward normal. The details of this mechanism are discussed in Chapter 27. During changes in arterial pressure, the tubuloglomerular feedback and myogenic mechanisms operate together to provide highly effective autoregulation of renal blood flow.
2. In the *brain*, the concentrations of carbon dioxide and hydrogen ions, in addition to tissue oxygen concentration, play prominent roles in controlling blood flow. An increase of either or both of these substances dilates the cerebral vessels and allows rapid washout of the excess carbon dioxide or hydrogen ions from the brain tissues. This mechanism is important because the *level of excitability of the brain is highly dependent on exact control of both carbon dioxide concentration and hydrogen ion concentration*. This special mechanism for cerebral blood flow control is presented in Chapter 62.
3. In the *skin*, blood flow control is closely linked to body temperature regulation. Cutaneous and subcutaneous flow regulates heat loss from the body by metering the flow of heat from the core to the surface of the body, where heat is lost to the environment. Skin blood flow is controlled largely by the central nervous system through the sympathetic nerves, as discussed in Chapter 74. Although skin blood flow is only about 3 mL/min/100 g of tissue in cool weather, large changes in blood flow can occur as needed. For example, when humans are exposed to body heating, skin blood flow may increase greatly, to as high as *7 to 8 L/min* for the entire body. When body temperature is reduced, skin blood flow decreases, falling to barely above zero at very low temperatures. Even with severe vasoconstriction, skin blood flow is usually great enough to meet the basic metabolic demands of the skin.

Control of Tissue Blood Flow: Endothelium-Derived Relaxing or Constricting Factors

The endothelial cells lining the blood vessels synthesize several substances that when released can affect the degree of relaxation or contraction of the vascular wall. For some of these endothelium-derived relaxing or constrictor factors, the physiological roles are just beginning to be understood. However, two endothelial-derived substances that have been extensively studied are *nitric oxide*, a vasodilator, and *endothelin*, a potent vasoconstrictor.

Nitric Oxide Is a Vasodilator Released From Healthy Endothelial Cells. Perhaps the most important of the endothelium-derived relaxing factors is *nitric oxide* (NO), a lipophilic gas that is released from endothelial cells in response to a variety of chemical and physical stimuli. *Endothelial-derived nitric oxide synthase* (eNOS) *enzymes* synthesize NO from *arginine* and oxygen and by reduction of inorganic nitrate. After diffusing out of the endothelial cell, NO has a half-life in the blood of only about 6 seconds and acts mainly in the local tissues, where it

is released. NO activates *soluble guanylate cyclases* in vascular smooth muscle cells (**Fig. 17.6**), resulting in the conversion of guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP) and activation of *cGMP-dependent protein kinase* (PKG), which has several actions that cause the blood vessels to relax.

The flow of blood through the arteries and arterioles causes *shear stress* on the endothelial cells because of viscous drag of the blood against the vascular walls. This stress contorts the endothelial cells in the direction of flow and causes significant increase in NO release. The NO then relaxes the blood vessels. This is important because the local metabolic mechanisms for controlling tissue blood flow mainly dilate the very small arteries and arterioles in each tissue. Yet, when blood flow through a microvascular portion of the circulation increases, this action secondarily stimulates release of NO from larger vessels as a result of increased flow and shear stress in these vessels. The released NO increases the diameters of the larger upstream blood vessels whenever microvascular blood flow increases downstream. Without such a response, the effectiveness of local blood flow control would be decreased because a significant part of the resistance to blood flow is in the upstream small arteries.

NO synthesis and release from endothelial cells are also stimulated by some vasoconstrictors, such as *angiotensin II*, which bind to specific receptors on endothelial cells. The increased NO release protects against excessive vasoconstriction.

When endothelial cells are damaged by chronic hypertension or atherosclerosis, impaired NO synthesis may contribute to excessive vasoconstriction and worsening of the hypertension and endothelial damage. If untreated, this may eventually cause vascular injury and damage to vulnerable tissues such as the heart, kidneys, and brain.

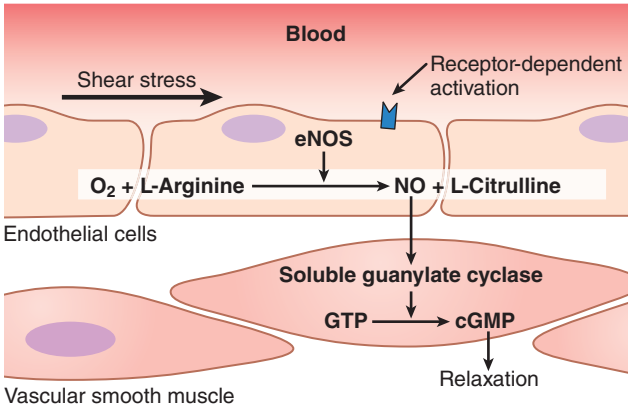

Figure 17.6 Nitric oxide synthase (eNOS) enzyme in endothelial cells synthesizes nitric oxide (NO) from arginine and oxygen. NO activates soluble guanylate cyclases in vascular smooth muscle cells, resulting in conversion of guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP), which ultimately causes the blood vessels to relax.

Clinical Application of Drugs That Increase Vascular Nitric Oxide. Even before NO was discovered, clinicians used nitroglycerin, amyl nitrate, and other nitrate derivatives to treat patients who had *angina pectoris*—severe chest pain caused by ischemia of the heart muscle. These drugs, when broken down chemically, release NO and cause dilation of blood vessels throughout the body, including the coronary blood vessels.

Other important applications of NO physiology and pharmacology include the development and clinical use of drugs (e.g., sildenafil) that inhibit *cGMP-specific phosphodiesterase-5* (PDE-5), an enzyme that degrades cGMP. By preventing the degradation of cGMP, the PDE-5 inhibitors effectively prolong the actions of NO to cause vasodilation. A major clinical use of the PDE-5 inhibitors is to treat *erectile dysfunction*. Penile erection is caused by parasympathetic nerve impulses through the pelvic nerves to the penis, where the neurotransmitters acetylcholine and NO are released. By preventing the degradation of NO, the PDE-5 inhibitors enhance the dilation of the blood vessels in the penis and aid in erection, as discussed in Chapter 81.

Endothelin Is a Powerful Vasoconstrictor Released By Damaged Endothelium. Endothelial cells also release vasoconstrictor substances. One of the most important of these is *endothelin*, a large, 21–amino acid peptide that requires only minute amounts (nanograms) to cause powerful vasoconstriction. This substance is present in endothelial cells of most blood vessels but greatly increases when the vessels are injured. The usual stimulus for release is damage to the endothelium, such as that caused by crushing of the tissues or a traumatizing chemical in the blood vessel. After severe blood vessel damage, local release of endothelin and subsequent vasoconstriction helps prevent extensive bleeding from arteries as large as 5 millimeters in diameter that might have been torn open by crushing injury.

Increased endothelin release may also contribute to vasoconstriction when the endothelium is damaged by hypertension. Drugs that block endothelin receptors have been used to treat *pulmonary hypertension* but generally have not been used for lowering blood pressure in patients with systemic arterial hypertension.

LONG-TERM BLOOD FLOW REGULATION

Thus far, most of the mechanisms for local blood flow regulation that we have discussed act within a few seconds to a few minutes after local tissue conditions have changed. Yet, even after full activation of these acute mechanisms, the blood flow usually is adjusted only about three-quarters of the way to the exact requirements of the tissues. For example, when the arterial pressure suddenly increases from 100 to 150 mm Hg, the blood flow increases almost instantaneously, by about 100%. Then, within 30 seconds to 2 minutes, the flow in many tissues decreases back to about 10% to 15% above the original control value.

Although this example illustrates the rapidity of the acute mechanisms for local blood flow regulation, it also demonstrates that the regulation is still incomplete because a 10% to 15% excess blood flow remains in some tissues.

However, over a period of hours, days, and weeks, long-term blood flow regulation develops, in addition to the acute control, providing more precise regulation. In the aforementioned example, if arterial pressure remains at 150 mm Hg indefinitely, blood flow through the tissues gradually approaches almost exactly the normal flow level within a few weeks. **Fig. 17.5** shows (*dashed green curve*) the extreme effectiveness of this long-term local blood flow regulation. Note that once the long-term regulation has had time to occur, long-term changes in arterial pressure between 50 and 200 mm Hg have little effect on the rate of tissue blood flow.

Long-term regulation of blood flow is especially important when the metabolic demands of a tissue change. Thus, if a tissue becomes chronically overactive and requires increased quantities of oxygen and other nutrients, the arterioles and capillary vessels usually increase both in number and size within a few weeks to match the needs of the tissue, unless the circulatory system has become pathological or too old to respond.

Blood Flow Regulation By Changes in Tissue Vascularity

A key mechanism for long-term local blood flow regulation is to change vascularity of the tissues. For example, if metabolism in a tissue is increased for a prolonged period, vascularity increases, a process generally called *angiogenesis*; if metabolism is decreased, vascularity decreases. **Fig. 17.7** shows the large increase in the number of capillaries in a rat anterior tibialis muscle that was stimulated electrically to contract for short periods each day for 30 days, compared with the unstimulated muscle in the other leg of the animal.

Thus, physical reconstruction of the tissue vasculature occurs to meet the needs of the tissues. This reconstruction occurs rapidly (within days) in young animals. It also occurs rapidly in new growth tissue, such as in cancerous tissue, but occurs much more slowly in old, well-established tissues. Therefore, the time required for long-term regulation to take place may be only a few days in the neonate or as long as months in older adults. Furthermore, the final degree of response is much better in younger than in older tissues; thus, in the neonate, the vascularity will adjust to match almost exactly the needs of the tissue for blood flow, whereas in older tissues, vascularity frequently lags far behind the needs of the tissues.

Role of Oxygen in Long-Term Regulation. Oxygen is important for long-term regulation of blood flow, as well as for acute control. One example of this is increased vascularity in tissues of animals that live at high altitudes, where atmospheric oxygen is low. Also, in premature babies who are put into oxygen tents for therapeutic purposes, the excess oxygen causes almost immediate cessation of new vascular growth in the retina of the baby's eyes and even causes degeneration of some of the small vessels that already have formed. When the infant is taken out of the oxygen tent, explosive overgrowth of new vessels then occurs to make up for the sudden decrease in available oxygen. Sometimes, so much overgrowth occurs that the retinal vessels grow out from the retina into the eye's vitreous humor, eventually causing blindness, a condition called *retrolental fibroplasia*.

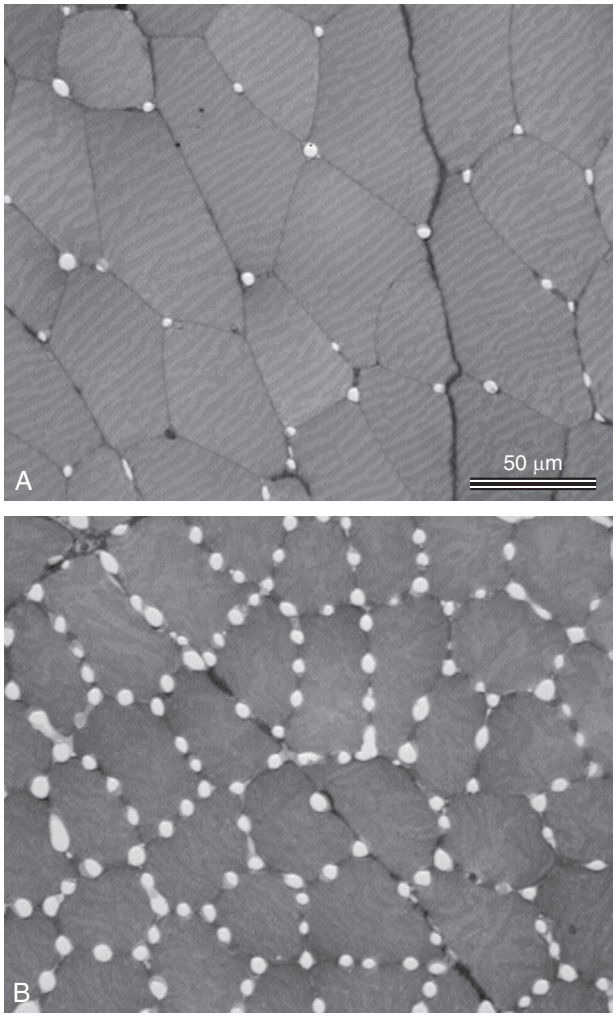

Figure 17.7 A large increase in the number of capillaries (*white dots*) in a rat anterior tibialis muscle that was stimulated electrically to contract for short periods each day for 30 days (B), compared with the unstimulated muscle (A). The 30 days of intermittent electrical stimulation converted the predominantly fast-twitch, glycolytic anterior tibialis muscle to a predominantly slow-twitch, oxidative muscle with increased numbers of capillaries and decreased fiber diameter, as shown. *(Courtesy Dr. Thomas Adair.)*

Importance of Vascular Growth Factors in Formation of New Blood Vessels. A dozen or more factors that increase growth of new blood vessels have been discovered, almost all of which are small peptides. The four factors that have been best characterized are *vascular endothelial growth factor* (VEGF), *fibroblast growth*

factor, *platelet-derived growth factor* (PDGF), and *angiogenin*, each of which has been isolated from tissues that have inadequate blood supply. Deficiency of tissue oxygen induces expression of *hypoxia inducible factors* (HIFs), transcription factors that in turn upregulate gene expression and formation of vascular growth factors (also called *angiogenic factors*).

Angiogenesis begins with new vessels sprouting from other small vessels (**Fig. 17.8**). Blood vessels grow toward the gradient of proangiogenic factors, such as VEGF, released from the hypoxic tissue. In this example, the source of the hypoxia and angiogenic factors is a rapidly growing tumor. The growth factors released from the hypoxic tissue activate endothelial cells, leading to release of proteases, which contribute to dissolution of the basement membrane of the endothelial cells at the point of sprouting. This step is followed by rapid reproduction of new endothelial cells, which stream outward through the vessel wall in extended cords directed toward the source of the angiogenic factor. The cells in each cord continue to divide and fold over into a tube. Next, the tube connects with another tube budding from another donor vessel (another arteriole or venule) and forms a capillary loop through which blood begins to flow. If the flow is great enough, smooth muscle cells eventually invade the wall, so some of the new vessels eventually grow to be new arterioles or venules or perhaps even larger vessels. Thus, angiogenesis explains how metabolic factors in local tissues can cause growth of new vessels.

Certain other substances, such as some steroid hormones, have the opposite effect on small blood vessels, occasionally even causing dissolution of vascular cells and disappearance of vessels. Therefore, blood vessels can also be made to disappear when they are not needed. Peptides produced in the tissues can also block the growth of new blood vessels. For example, *angiostatin*, a fragment of the protein plasminogen, is a naturally occurring inhibitor of angiogenesis. *Endostatin* is another antiangiogenic peptide derived from the breakdown of collagen type XVII.

There have been important advances in development of angiogenesis inhibitors to arrest blood vessel growth in cancerous tumors. Blocking angiogenesis prevents the large increases in blood flow needed to sustain the nutrient supply of rapidly growing tumors. For example, *anti-VEGF antibodies*, *anti-VEGF receptor antibodies*, and *small molecule tyrosine kinase inhibitors*, which block VEGF receptor signaling, all inhibit tumor growth. Unfortunately, many of the current angiogenesis inhibitors also have adverse effects on blood vessels in healthy tissues and efforts are therefore underway to target angiogenesis specifically in the tumors.

Vascularity Is Determined by Maximum Blood Flow Need, Not By Average Need. An especially valuable characteristic of long-term vascular control is that

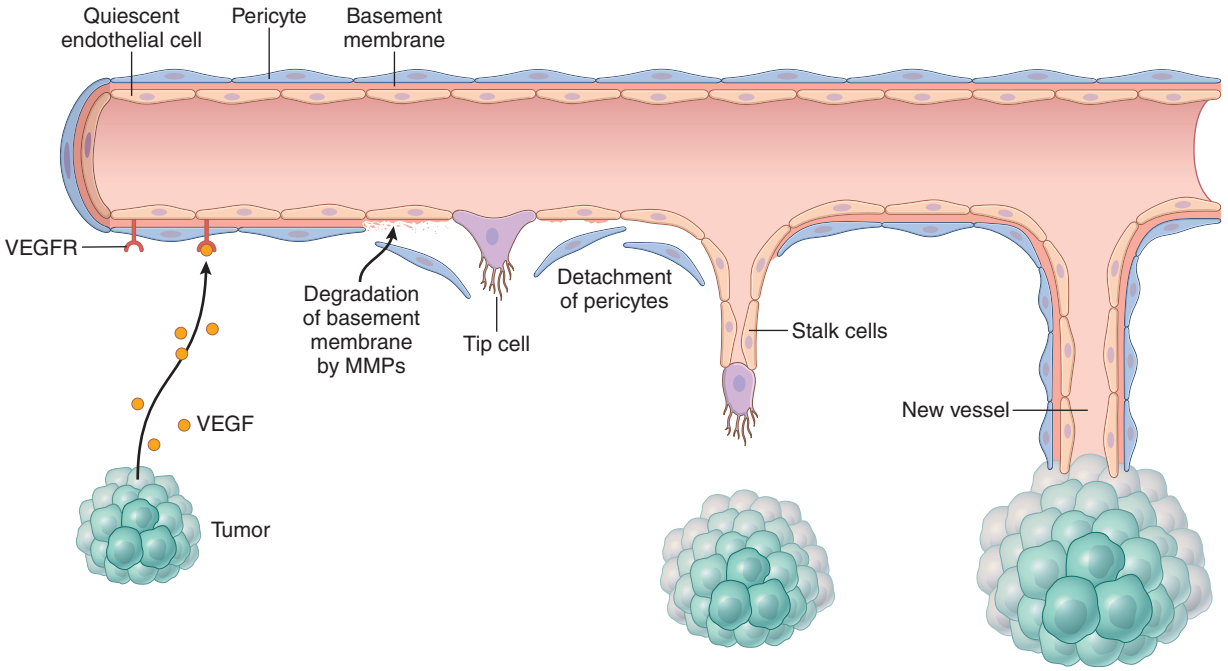

Figure 17.8 Sprouting type of angiogenesis that supplies increased blood flow to a developing tumor. Stimuli such as hypoxia induce release of proangiogenic growth factors such as vascular endothelial growth factor (VEGF), which binds and activates its receptor (VEGFR). Endothelial cells are activated, pericytes are detached, and the basement membrane is degraded by matrix metalloproteinases (MMPs). Endothelial cells in the newly forming vessel undergo phenotypic changes to form *tip cells* and *stalk cells*. The tip cells have specialized cytoplasmic protrusions containing a dense network of actin filaments that permit them to migrate and guide growth of the new sprout. Stalk cells are proliferating endothelial cells that form the body of the sprout. After the tip cells meet, they join together to develop lumens surrounded by the basement membranes of vessels that perfuse the tissue.

vascularity is determined mainly by the *maximum* level of blood flow required by the tissue rather than by average need. For example, during heavy exercise, the need for whole-body blood flow often increases to six to eight times the resting blood flow. This great increase of flow may not be required for more than a few minutes each day. Nevertheless, even this short time of need can cause enough angiogenic factors to be formed by the muscles to increase their vascularity as required. Were it not for this capability, every time a person attempted heavy exercise, the muscles would fail to receive the required nutrients, especially the required oxygen, and thus the muscles would fail to contract.

However, after extra vascularity develops, the additional blood vessels normally remain mainly vasoconstricted, opening to allow extra flow only when appropriate local stimuli such as a lack of oxygen, nerve vasodilatory stimuli, or other stimuli call forth the required extra flow.

Blood Flow Regulation By Development of Collateral Circulation

In most tissues of the body, when an artery or a vein is blocked, a new vascular channel usually develops around the blockage and allows at least partial resupply of blood to the affected tissue. The first stage in this process is dilation of small vascular loops that already connect the vessel above the blockage to the vessel below. This dilation occurs within the first minute or two, indicating that the dilation is likely mediated by metabolic factors. After this initial opening of collateral vessels, the blood flow often is still less than 25% of that required to supply all the tissue needs. However, further opening occurs within the ensuing hours, so that within 1 day as much as half the tissue needs may be met and, within a few days, the blood flow is usually sufficient to meet the tissue needs.

The collateral vessels continue to grow for many months thereafter, usually forming multiple small collateral channels rather than one single large vessel. Under resting conditions, the blood flow may return to nearly normal, but the new channels seldom become large enough to supply the blood flow needed during strenuous tissue activity. Thus, development of collateral vessels follows the usual principles of acute and long-term local blood flow control; the acute control is rapid metabolic dilation, followed chronically by growth and enlargement of new vessels over a period of weeks and months.

An important example of the development of collateral blood vessels occurs after thrombosis of one of the coronary arteries. By the age of 60 to 70 years, many people have experienced closure or at least partial occlusion of at least one of the smaller branch coronary vessels, but they are not aware of it because collateral blood vessels have developed rapidly enough to prevent myocardial damage. When collateral blood vessels are unable to develop quickly enough to maintain blood flow because of the rapidity or severity of the coronary insufficiency, serious heart attacks can occur.

Vascular Remodeling in Response to Chronic Changes in Blood Flow or Blood Pressure

Vascular growth and remodeling are critical components of tissue growth. For example, after several months of chronic exercise training, vascularity of the trained muscles increases to accommodate their higher blood flow requirements.

Vascular remodeling can also occur as an adaptive response to long-term changes in blood pressure or blood flow. In addition to changes in capillary density, there may also be changes in the structure of large blood vessels in response to long-term changes in blood pressure and blood flow. When blood pressure is chronically elevated above normal, for example, the large and small arteries and arterioles remodel to accommodate the increased mechanical wall stress of the higher blood pressure. In most tissues, the small arteries and arterioles rapidly respond (within seconds) to increased arterial pressure with vasoconstriction, which helps autoregulate tissue blood flow, as discussed previously. The vasoconstriction decreases lumen diameter, which in turn tends to normalize the vascular wall tension (T), which, according to *Laplace's equation*, is the product of the radius (r) of the blood vessel and its pressure (P): $T = r \times P$

In small blood vessels that constrict in response to increased blood pressure, the vascular smooth muscle cells and endothelial cells gradually—over a period of several days or weeks—rearrange themselves around the smaller lumen diameter, a process called *inward eutrophic remodeling*, with no change in the total cross-sectional area of the vascular wall (**Fig. 17.9**). In larger arteries that do not constrict in response to the increased pressure, the vessel wall is exposed to increased wall tension that stimulates a *hypertrophic remodeling* response and an increase in the cross-sectional area of the vascular wall. The hypertrophic response increases the size of vascular smooth muscle cells and stimulates formation of additional extracellular matrix proteins, such as collagen and fibronectin, that reinforce the strength of the vascular wall to withstand the higher blood pressures. However, this hypertrophic response also makes the large blood vessels stiffer, which is a hallmark of chronic hypertension.

Another example is the vascular remodeling that occurs when a large vein (often the saphenous vein) is implanted in a patient for a coronary artery bypass graft procedure. Veins are normally exposed to much lower pressures than arteries and have much thinner walls, but when a vein is sewn onto the aorta and connected to a coronary artery, it is exposed to increases in intraluminal pressure and wall tension. The increased wall tension initiates hypertrophy of vascular smooth muscle cells and increased extracellular matrix formation, which thicken and strengthen the wall of the vein; as a result, several months after implantation into the arterial system, the vein will typically have a wall thickness similar to that of an artery.

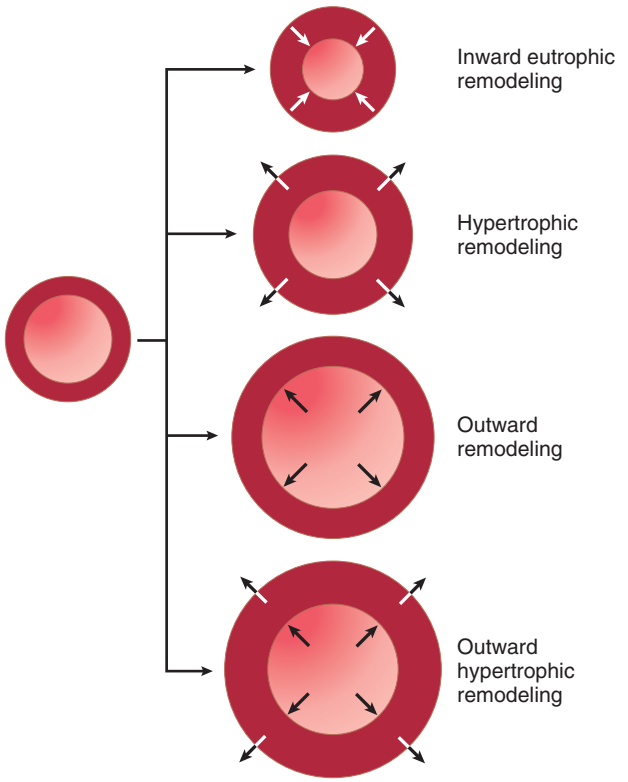

Figure 17.9 Vascular remodeling in response to a chronic increase in blood pressure or blood flow. In small arteries and arterioles that constrict in response to increased blood pressure, *inward eutrophic remodeling* typically occurs because the lumen diameter is smaller and the vascular wall is thicker, but the total cross-sectional area of the vessel wall is hardly changed. In large blood vessels that do not constrict in response to increased blood pressure, there may be *hypertrophic remodeling*, with increases in thickness and total cross-sectional area of the vascular wall. If blood vessels are exposed to chronic increases in blood flow, there is typically *outward remodeling*, with increases in lumen diameter, little change in wall thickness, and increased total cross-sectional area of the vascular wall. If the blood vessel is exposed to long-term increases in blood pressure and blood flow, there is usually *outward hypertrophic remodeling*, with increases in lumen diameter, wall thickness, and total cross-sectional area of the vascular wall. Chronic reductions in blood pressure and blood flow have the opposite effects, as previously described.

Vascular remodeling also occurs when a blood vessel is exposed chronically to increased or decreased blood flow. The creation of a fistula connecting a large artery and large vein, thereby completely bypassing high-resistance small vessels and capillaries, provides an especially interesting example of remodeling in the affected artery and vein. In patients with renal failure who undergo dialysis, an arterial-venous (A-V) fistula is created directly from the radial artery to the antecubital vein of the forearm to permit vascular access for dialysis. Blood flow rate in the radial artery may increase as much as 10 to 50 times the normal flow rate, depending on the patency of the fistula. As a result of the high flow rate and high shear stress on the vessel wall, the luminal diameter of the radial artery increases progressively (*outward remodeling*), whereas the thickness of the vessel wall may remain unchanged, resulting in an increase in cross-sectional area of the vascular wall. In contrast, wall thickness, lumen diameter, and cross-sectional area of the vascular wall on the venous side of the fistula increase in response to increases in pressure and blood flow (*outward hypertrophic remodeling*). This pattern of remodeling is consistent with the concept that long-term increases in vascular wall tension cause hypertrophy and increased wall thickness in large blood vessels, whereas increased blood flow rate and shear stress cause outward remodeling and increased luminal diameter to accommodate the increased blood flow.

Chronic reductions in blood pressure and blood flow have effects opposite to those previously described. When blood flow is greatly reduced, the diameter of the vascular lumen is also reduced and, when blood pressure is reduced, the thickness of the vascular wall usually decreases. Thus, vascular remodeling is an important adaptive response of the blood vessels to tissue growth and development, as well as to physiological and pathological changes in blood pressure and blood flow to the tissues.

HUMORAL CONTROL OF THE CIRCULATION

Substances secreted or absorbed into the body fluids, such as hormones and locally produced factors, also contribute to blood flow regulation. Some of these substances are formed by special glands and transported in the blood throughout the entire body. Others are formed in local tissue areas and cause only local circulatory effects. Among the most important of the humoral factors that affect circulatory function are those described in the following sections.

VASOCONSTRICTORS

Norepinephrine and Epinephrine. *Norepinephrine* is an especially powerful vasoconstrictor hormone; *epinephrine* is less powerful as a vasoconstrictor and, in some tissues, even causes mild vasodilation. A special example of vasodilation caused by epinephrine is that which occurs to dilate the coronary arteries during increased heart activity.

When the sympathetic nervous system is stimulated in most parts of the body during stress or exercise, the sympathetic nerve endings in the individual tissues release norepinephrine, which excites the heart and constricts the veins and arterioles. In addition, the sympathetic nerves to the adrenal medullae cause these glands to secrete norepinephrine and epinephrine into the blood. These hormones then circulate to all areas of the body and cause almost the same effects on the circulation as direct sympathetic stimulation, thus providing a dual system of control: (1) direct nerve stimulation; and (2) indirect effects of norepinephrine and/or epinephrine in the circulating blood.

Angiotensin II. Angiotensin II is another powerful vasoconstrictor. As little as *one-millionth* of a gram can increase the arterial pressure of a person by 50 mm Hg or more.

Angiotensin II powerfully constricts the small arterioles, and if this constriction occurs in an isolated tissue area, blood flow to that area can be severely depressed, at least transiently. When plasma levels of angiotensin II or other vasoconstrictors are chronically elevated, increases in blood pressure and local control mechanisms often restore blood flow to nearly normal levels.

The real importance of angiotensin II as a vasoconstrictor is that it normally acts on many arterioles of the body at the same time to increase the *total peripheral resistance*, which helps to prevent reductions in blood pressure in acute conditions, such as hemorrhage. Angiotensin II also decreases sodium and water excretion by the kidneys, which contributes to chronic control of blood pressure, as discussed in Chapter 19. Thus, this hormone plays an integral role in acute and long-term regulation of arterial pressure.

Vasopressin. *Vasopressin*, also called *antidiuretic hormone*, is even more powerful than angiotensin II as a vasoconstrictor, thus making it one of the body's most potent vascular constrictor substances. It is formed in nerve cells in the hypothalamus of the brain (see Chapters 29 and 76) but is then transported downward by nerve axons to the posterior pituitary gland, where it is secreted into the blood.

Only minute amounts of vasopressin are secreted in most physiological conditions. However, experiments have shown that the concentration of circulating blood vasopressin after severe hemorrhage can increase enough to attenuate reductions in arterial pressure markedly. In some cases, this action can, by itself, bring the arterial pressure almost back up to normal.

Vasopressin has the major function of greatly increasing water reabsorption from the renal tubules back into the blood (discussed in Chapters 28 and 29) and therefore helps control body fluid volume. That is why this hormone is also called *antidiuretic hormone*.

VASODILATORS

Bradykinin. Several substances called *kinins* cause powerful vasodilation when formed in the blood and tissue fluids of some organs. The kinins are small polypeptides that are split away from α_2-globulins by proteolytic enzymes in the plasma or tissue fluids. A proteolytic enzyme of particular importance for this purpose is *kallikrein*, which is present in the blood and tissue fluids in an inactive form. This inactive kallikrein is activated by maceration of the blood, tissue inflammation, or other similar chemical or physical effects on the blood or tissues. As kallikrein becomes activated, it acts immediately on α_2-globulin to release a kinin called *kallidin*, which is then converted by tissue enzymes into *bradykinin*. Once formed, bradykinin persists for only a few minutes because it is inactivated by the enzyme *carboxypeptidase* or by *converting enzyme*, the same enzyme that also plays an essential role in converting angiotensin I to angiotensin II, as discussed in Chapter 19. The activated kallikrein enzyme is destroyed by a *kallikrein inhibitor* that is also present in body fluids.

Bradykinin causes both powerful *arteriolar dilation* and *increased capillary permeability*. For example, injection of *1 microgram* of bradykinin into the brachial artery of a person increases blood flow through the arm as much as 6-fold, and even smaller amounts injected locally into tissues can cause marked local edema resulting from an increase in capillary pore size.

Kinins appear to play special roles in regulating blood flow and capillary leakage of fluids in inflamed tissues. Bradykinin also normally helps regulate blood flow in the skin, as well as in the salivary and gastrointestinal glands.

Histamine. Histamine is released in almost every tissue of the body if the tissue becomes damaged or inflamed or is the subject of an allergic reaction. Most of the histamine is derived from *mast cells* in the damaged tissues and from *basophils* in the blood.

Histamine has a powerful vasodilator effect on arterioles and, like bradykinin, has the ability to increase capillary porosity greatly, allowing leakage of fluid and plasma protein into the tissues. In many pathological conditions, the intense arteriolar dilation and increased capillary porosity produced by histamine cause substantial quantities of fluid and plasma proteins to leak out of the circulation into the tissues, inducing edema. The local vasodilatory and edema-producing effects of histamine are especially prominent during allergic reactions and are discussed in Chapter 35.

VASCULAR CONTROL BY IONS AND OTHER CHEMICAL FACTORS

Many different ions and other chemical factors can dilate or constrict local blood vessels. The following list briefly describes some of their specific effects:

1. An increase in intracellular *calcium ion* concentration causes *vasoconstriction* because of the general effect of calcium to stimulate smooth muscle contraction, as discussed in Chapter 8.
2. An increase in *potassium ion* concentration, within the physiological range, causes *vasodilation*. This effect results from the ability of potassium ions to inhibit smooth muscle contraction.
3. An increase in *magnesium* ion concentration causes *powerful vasodilation* because magnesium ions inhibit smooth muscle contraction.
4. An *increase in hydrogen ion* concentration (decrease in pH) causes dilation of the arterioles. Conversely, *a slight decrease in hydrogen ion concentration* causes arteriolar constriction.
5. *Anions* that have significant effects on blood vessels are *acetate* and *citrate*, both of which cause mild vasodilation.

6. An *increase in carbon dioxide concentration* causes moderate vasodilation in most tissues but *marked vasodilation in the brain*. Also, carbon dioxide in the blood, acting on the brain vasomotor center, has an extremely powerful indirect effect, transmitted through the sympathetic nervous vasoconstrictor system, that causes widespread vasoconstriction throughout the body.

Most Vasodilators or Vasoconstrictors Have Little Effect on Long-Term Blood Flow Unless They Alter the Metabolic Rate of the Tissues. In most experimental studies, tissue blood flow and cardiac output (the sum of flow to all the body's tissues) are not substantially altered, except for 1 or 2 days, when large amounts of powerful vasoconstrictors such as angiotensin II or vasodilators such as bradykinin are chronically infused. Why is blood flow not significantly altered in most tissues, even in the presence of very large amounts of these vasoactive agents?

To answer this question, we return to one of the fundamental principles of circulatory function that was previously discussed—the ability of each tissue to *autoregulate* its own blood flow according to the metabolic needs and other functions of the tissue. Administration of a powerful vasoconstrictor, such as angiotensin II, may cause transient decreases in tissue blood flow and cardiac output but usually has little long-term effect in most tissues if it does not alter metabolic rate of the tissues. Likewise, most vasodilators cause only short-term changes in tissue blood flow and cardiac output if they do not alter tissue metabolism. Therefore, blood flow is generally regulated according to the specific needs of the tissues, as long as the arterial pressure is adequate to perfuse the tissues.

CHAPTER 18

Nervous Regulation of the Circulation and Rapid Control of Arterial Pressure

NERVOUS REGULATION OF THE CIRCULATION

As discussed in Chapter 17, adjustment of blood flow in the tissues and organs of the body is mainly the function of local tissue control mechanisms. In this chapter, we discuss how nervous control of the circulation has more global functions, such as redistributing blood flow to different areas of the body, increasing or decreasing pumping activity by the heart, and providing rapid control of systemic arterial pressure.

The nervous system controls the circulation almost entirely through the *autonomic nervous system*. The total function of this system is presented in Chapter 61, and this subject was also introduced in Chapter 17. In this chapter, we consider additional specific anatomical and functional characteristics.

AUTONOMIC NERVOUS SYSTEM

The most important part of the autonomic nervous system for regulating the circulation is the *sympathetic nervous system*. The *parasympathetic nervous system*, however, contributes importantly to regulation of heart function, as described later in the chapter.

Sympathetic Nervous System Anatomy. **Fig. 18.1** illustrates the anatomy of sympathetic nervous control of the circulation. Sympathetic vasomotor nerve fibers leave the spinal cord through all the thoracic spinal nerves and through the first one or two lumbar spinal nerves. They then pass immediately into a *sympathetic chain*, one of which lies on each side of the vertebral column. Next, they pass by two routes to the circulation: (1) through specific *sympathetic nerves* that innervate mainly the vasculature of the internal viscera and the heart, as shown on the right side of **Fig. 18.1**; and (2) into peripheral portions of the *spinal nerves* distributed to the vasculature of the peripheral areas. The precise pathways of these fibers in the spinal cord and in the sympathetic chains are discussed in Chapter 61.

Sympathetic Innervation of Blood Vessels. **Fig. 18.2** shows the distribution of sympathetic nerve fibers to the blood vessels, demonstrating that in most tissues, all the vessels *except* the capillaries are innervated. Precapillary sphincters and metarterioles are innervated in some tissues, such as the mesenteric blood vessels, although their sympathetic innervation is usually not as dense as in the small arteries, arterioles, and veins.

The innervation of the *small arteries* and *arterioles* allows sympathetic stimulation to increase *resistance* to blood flow and thereby *decrease* the rate of blood flow through the tissues.

The innervation of the large vessels, particularly of the *veins*, makes it possible for sympathetic stimulation to *decrease* the volume of these vessels. This decrease in volume can push blood into the heart and thereby plays a major role in regulation of heart pumping, as we explain later in this and subsequent chapters.

Sympathetic Stimulation Increases Heart Rate and Contractility. Sympathetic fibers also go directly to the heart, as shown in **Fig. 18.1**. As discussed in Chapter 9, sympathetic stimulation markedly increases heart rate, as well as the heart's strength and volume of pumping.

Parasympathetic Stimulation Decreases Heart Rate and Contractility. Although the parasympathetic nervous system is exceedingly important for many other autonomic functions of the body, such as control of multiple gastrointestinal actions, it plays only a minor role in regulating vascular function in most tissues. However, it has a major role in controlling heart rate by way of *parasympathetic nerve fibers* to the heart in the *vagus nerves*, shown in **Fig. 18.1** by the dashed red line from the brain medulla directly to the heart.

The effects of parasympathetic stimulation on heart function were discussed in detail in Chapter 9. Principally, parasympathetic stimulation causes a marked *decrease* in heart rate and a slight decrease in heart muscle contractility.

Sympathetic Vasoconstrictor System and Its Control by the Central Nervous System

The sympathetic nerves carry large numbers of *vasoconstrictor nerve fibers* and only a few vasodilator fibers. The vasoconstrictor fibers are distributed to essentially all segments of the circulation, but more to some tissues than to

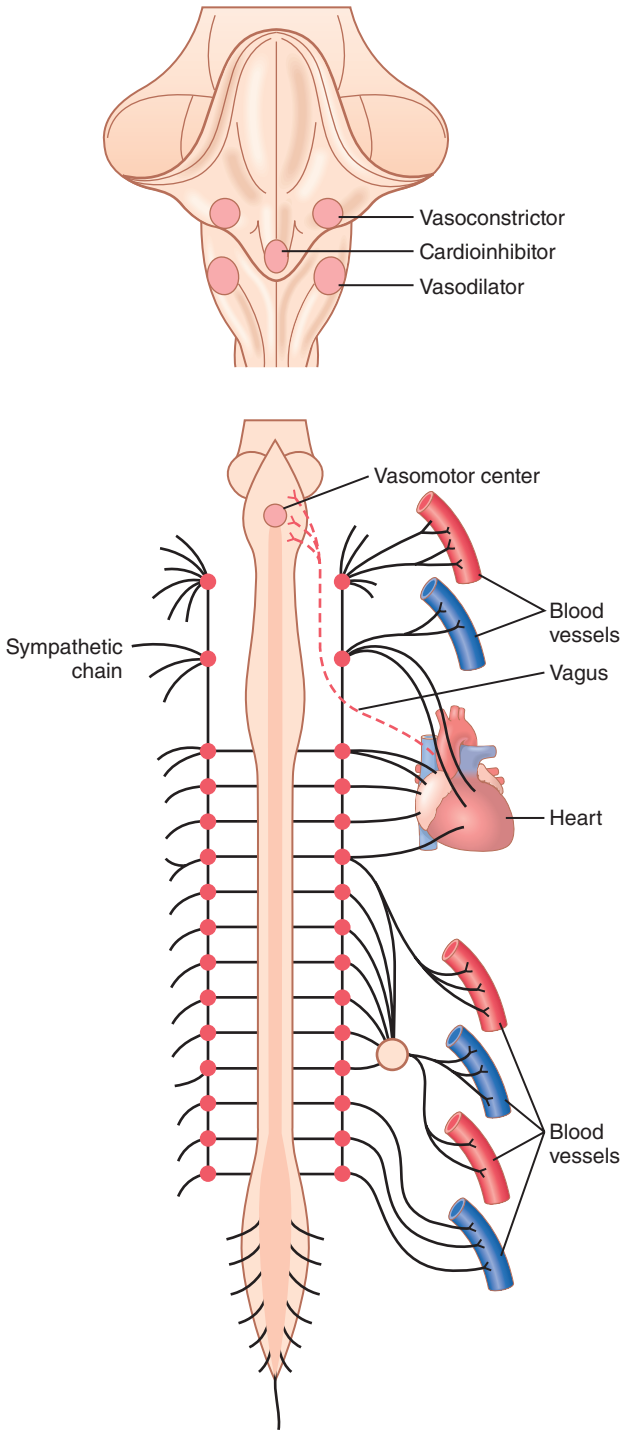

Figure 18.1 Anatomy of *sympathetic nervous control* of the circulation. Also, shown by the *dashed red line* is a vagus nerve that carries *parasympathetic signals* to the heart.

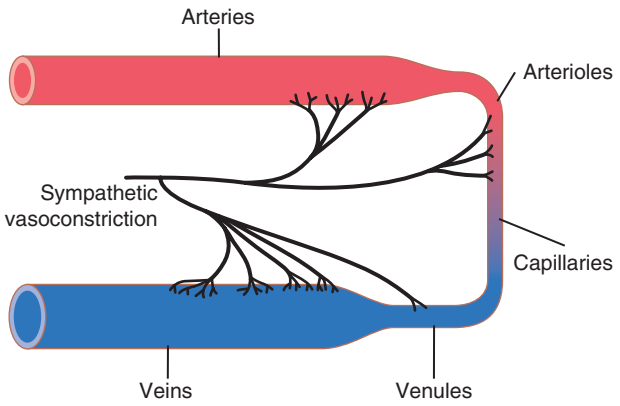

Figure 18.2 Sympathetic innervation of the systemic circulation.

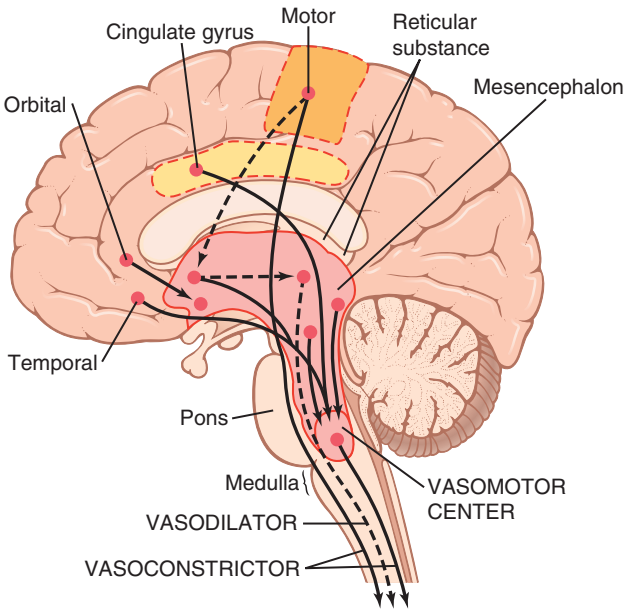

Figure 18.3 Areas of the brain that play important roles in the nervous regulation of the circulation. The *dashed lines* represent inhibitory pathways.

others. This sympathetic vasoconstrictor effect is especially powerful in the kidneys, intestines, spleen, and skin but is much less potent in skeletal muscle, heart, and the brain.

The Brain Vasomotor Center Regulates Vasoconstriction. Located bilaterally mainly in the reticular substance of the medulla and lower third of the pons is an area called the *vasomotor center*, shown in **Fig. 18.1** and **Fig. 18.3**. This center transmits parasympathetic impulses through the vagus nerves to the heart and sympathetic impulses through the spinal cord and peripheral sympathetic nerves to virtually all arteries, arterioles, and veins of the body.

Some of the major areas in the vasomotor center are:

1. A *vasoconstrictor area* located bilaterally in the anterolateral portions of the upper medulla. The neurons originating in this area distribute their fibers to all levels of the spinal cord, where they excite preganglionic vasoconstrictor neurons of the sympathetic nervous system.
2. A *vasodilator area* located bilaterally in the anterolateral portions of the lower half of the medulla. The fibers from these neurons project upward to the vasoconstrictor area just described, inhibiting the vasoconstrictor activity of this area and causing vasodilation.
3. A *sensory area* located bilaterally in the *nucleus tractus solitarius* in the posterolateral portions of the

medulla and lower pons. The neurons of this area receive sensory nerve signals from the circulatory system, mainly through the *vagus* and *glossopharyngeal nerves*, and output signals from this sensory area then help control activities of the vasoconstrictor and vasodilator areas of the vasomotor center, thus providing reflex control of many circulatory functions. An example is the *baroreceptor reflex* for controlling arterial pressure, described later in this chapter.

Continuous Partial Constriction of Blood Vessels By Sympathetic Vasoconstrictor Tone. Under normal conditions, the vasoconstrictor area of the vasomotor center transmits signals continuously to the sympathetic vasoconstrictor nerve fibers over the entire body, causing slow firing of these fibers at a rate of about 0.5 to 2 impulses per second. This continual firing is called *sympathetic vasoconstrictor tone*. These impulses normally maintain a partial state of constriction in the blood vessels, called *vasomotor tone*.

Fig. 18.4 demonstrates the significance of vasoconstrictor tone. In the experiment shown in this figure, a spinal anesthetic was administered to an experimental animal. This anesthetic blocked all transmission of sympathetic nerve impulses from the spinal cord to the periphery. As a result, the arterial pressure fell from 100 to 50 mm Hg, demonstrating the effect of the sudden loss of vasoconstrictor tone throughout the body. A few minutes later, a small amount of the hormone norepinephrine was injected into the blood (norepinephrine is the principal vasoconstrictor hormonal substance secreted at the endings of the sympathetic vasoconstrictor nerve fibers). As this injected hormone was transported in the blood to blood vessels, the vessels once again became constricted, and the arterial pressure rose to a level even greater than normal for 1 to 3 minutes until the norepinephrine was destroyed.

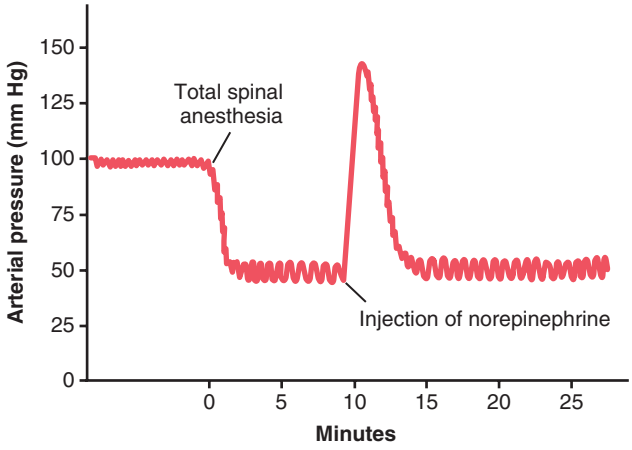

Figure 18.4 Effect of total spinal anesthesia on the arterial pressure, showing a marked decrease in pressure resulting from loss of vasomotor tone.

Control of Heart Activity By the Vasomotor Center. At the same time that the vasomotor center regulates the amount of vascular constriction, it also controls heart activity. The *lateral* portions of the vasomotor center transmit excitatory impulses through the sympathetic nerve fibers to increase heart rate and contractility. Conversely, the *medial* portion of the vasomotor center sends signals to the adjacent *dorsal motor nuclei of the vagus nerves*, which then transmit parasympathetic impulses through the vagus nerves to the heart to decrease heart rate and heart contractility. Therefore, the vasomotor center can increase or decrease heart activity. Heart rate and the strength of heart contractions ordinarily increase when vasoconstriction occurs and ordinarily decrease when vasoconstriction is inhibited.

Control of the Vasomotor Center By Higher Nervous Centers. Large numbers of small neurons located throughout the *reticular substance* of the *pons, mesencephalon*, and *diencephalon* can excite or inhibit the vasomotor center. This reticular substance is shown in **Fig. 18.3**. In general, the neurons in the more lateral and superior portions of the reticular substance cause excitation, whereas the more medial and inferior portions cause inhibition.

The *hypothalamus* plays a special role in controlling the autonomic nervous system because it can exert powerful excitatory or inhibitory effects on the vasomotor center. The *posterolateral portions* of the hypothalamus cause mainly excitation, whereas the *anterior portion* can cause mild excitation or inhibition, depending on the precise part of the anterior hypothalamus that is stimulated.

Many parts of the *cerebral cortex* can also excite or inhibit the vasomotor center. Stimulation of the *motor cortex*, for example, excites the vasomotor center because of impulses transmitted downward into the hypothalamus and then to the vasomotor center. Also, stimulation of the *anterior temporal lobe, orbital areas of the frontal cortex, anterior part of the cingulate gyrus, amygdala, septum*, and *hippocampus* can all excite or inhibit the vasomotor center, depending on the precise portions of these areas that are stimulated and the intensity of the stimulus. Thus, widespread basal areas of the brain can have profound effects on cardiovascular function.

Norepinephrine Is the Sympathetic Vasoconstrictor Neurotransmitter. The substance secreted at the endings of the vasoconstrictor nerves is almost entirely norepinephrine, which acts directly on the *alpha-adrenergic receptors* of the vascular smooth muscle to cause vasoconstriction, as discussed in Chapter 61.

Adrenal Medullae and Their Relationship to the Sympathetic Vasoconstrictor System. Sympathetic impulses are transmitted to the adrenal medullae at the same time that they are transmitted to the blood vessels. These impulses cause the medullae to *secrete epinephrine and norepinephrine into the circulating blood*. These two hormones are carried in the bloodstream to all parts of

the body, where they act directly on all blood vessels and usually cause vasoconstriction. In a few tissues, *epinephrine* causes vasodilation because it also stimulates *beta-adrenergic receptors*, which dilate rather than constrict certain vessels, as discussed in Chapter 61.

Sympathetic Vasodilator System and Its Control By the Central Nervous System. The sympathetic nerves to skeletal muscles carry *vasodilator* fibers, as well as constrictor fibers. In some animals, such as the cat, these dilator fibers release *acetylcholine*, not norepinephrine, at their endings. However, in primates, the vasodilator effect is believed to be caused by epinephrine exciting specific beta-adrenergic receptors in the muscle vasculature.

The pathway for central nervous system (CNS) control of the vasodilator system is shown by the dashed lines in **Fig. 18.3**. The principal area of the brain controlling this system is the *anterior hypothalamus*.

Possible Role of the Sympathetic Vasodilator System. The sympathetic vasodilator system does not appear to play a major role in the control of the circulation in humans because complete block of the sympathetic nerves to the muscles hardly affects the ability of these muscles to control their own blood flow in many physiological conditions. Yet, some experiments have suggested that at the onset of exercise, the sympathetic system might cause initial vasodilation in skeletal muscles to allow an *anticipatory increase in blood flow*, even before the muscles require increased nutrients. There is evidence in humans that this sympathetic vasodilator response in skeletal muscles may be mediated by circulating epinephrine, which stimulates beta-adrenergic receptors, or by nitric oxide released from the vascular endothelium in response to stimulation by acetylcholine.

Vasovagal Syncope. An interesting vasodilatory reaction occurs in people who experience intense emotional disturbances that cause fainting. In this case, the muscle vasodilator system becomes activated and, at the same time, the vagal cardioinhibitory center transmits strong signals to the heart to cause bradycardia, a marked slowing of the heart rate. The arterial pressure falls rapidly, which reduces blood flow to the brain and causes the person to lose consciousness. This overall effect is called *vasovagal syncope* or *reflex syncope*. Emotional fainting begins with disturbing thoughts in the cerebral cortex. The pathway probably then goes to the vasodilatory center of the anterior hypothalamus next to the vagal centers of the medulla, to the heart through the vagus nerves, and also through the spinal cord to the *sympathetic vasodilator* nerves of the muscles.

Role of the Nervous System in Rapid Control of Arterial Pressure

One of the most important functions of nervous control of the circulation is its capability to cause rapid increases in arterial pressure. For this purpose, the entire vasoconstrictor and cardioaccelerator functions of the sympathetic nervous system are stimulated together. At the same time, there is reciprocal inhibition of parasympathetic vagal inhibitory signals to the heart. Thus, the following three major changes occur simultaneously, each of which helps increase arterial pressure:

1. *Most arterioles of the systemic circulation are constricted*, which greatly increases the total peripheral resistance, thereby increasing the arterial pressure.
2. *The veins and some other large vessels of the circulation are strongly constricted*. This constriction displaces blood out of the large peripheral blood vessels toward the heart, thus increasing the volume of blood in the heart chambers. The stretch of the heart then causes the heart to beat with greater force and therefore to pump increased quantities of blood. This also increases the arterial pressure.
3. Finally, *the heart is directly stimulated by the autonomic nervous system, further enhancing cardiac pumping*. Much of this enhanced cardiac pumping is caused by an increase in the heart rate, which sometimes increases to as much as three times normal. In addition, sympathetic nervous signals directly increase the contractile force of the heart muscle, increasing the capability of the heart to pump larger volumes of blood. During strong sympathetic stimulation, the heart can pump about two times as much blood as under normal conditions, which contributes still more to the acute rise in arterial pressure.

Nervous Control of Arterial Pressure Is Rapid. An especially important characteristic of nervous control of arterial pressure is its rapidity of response, beginning within seconds and often increasing the pressure to two times normal within 5 to 10 seconds. Conversely, sudden inhibition of nervous cardiovascular stimulation can decrease the arterial pressure to as little as half-normal within 10 to 40 seconds. Therefore, nervous control is the most rapid mechanism for arterial pressure regulation.

Increases in Arterial Pressure During Muscle Exercise and Other Stresses

An important example of the nervous system's ability to increase arterial pressure is the rise in pressure that occurs during muscle exercise. During heavy exercise, the muscles require greatly increased blood flow. Part of this increase results from local vasodilation of the muscle vasculature caused by increased metabolism of the muscle cells, as explained in Chapter 17. An additional increase results from simultaneous elevation of arterial pressure caused by sympathetic stimulation of the overall circulation during exercise. In heavy exercise, the arterial pressure rises by about 30% to 40%, which further increases blood flow by almost 2-fold.

The increase in arterial pressure during exercise results mainly from effects of the nervous system. At the same time that the motor areas of the brain become activated to cause exercise, most of the reticular activating system of the brain stem is also activated, which includes greatly increased stimulation of the vasoconstrictor and

cardioacceleratory areas of the vasomotor center. These effects rapidly increase the arterial pressure to keep pace with the increase in muscle activity.

In many other types of stress besides muscle exercise, a similar rise in pressure can also occur. For example, during extreme fright, the arterial pressure sometimes rises by as much as 75 to 100 mm Hg within a few seconds. This response is called the *alarm reaction*, and it provides an elevated arterial pressure that can immediately supply blood to the muscles of the body that might be needed to respond instantly to enable flight from danger.

REFLEX MECHANISMS FOR MAINTAINING NORMAL ARTERIAL PRESSURE

Aside from the exercise and stress functions of the autonomic nervous system to increase arterial pressure, multiple subconscious special nervous control mechanisms operate all the time to maintain the arterial pressure at or near normal. Almost all these are *negative feedback reflex mechanisms*, described in the following sections.

Baroreceptor Arterial Pressure Control System—Baroreceptor Reflexes

The best known of the nervous mechanisms for arterial pressure control is the *baroreceptor reflex*. Basically, this reflex is initiated by stretch receptors, called *baroreceptors* or *pressoreceptors*, located at specific points in the walls of several large systemic arteries. A rise in arterial pressure stretches the baroreceptors and causes them to transmit signals into the CNS. Feedback signals are then sent back through the autonomic nervous system to the circulation to reduce arterial pressure down toward the normal level. Conversely, low arterial pressure reduces stretch of the baroreceptors, which decreases feedback signals sent to the CNS and triggers reflexes that raise arterial pressure back toward normal.

Physiologic Anatomy of the Baroreceptors and Their Innervation. Baroreceptors are spray-type nerve endings that lie in the walls of the arteries and are stimulated when stretched. A few baroreceptors are located in the wall of almost every large artery of the thoracic and neck regions but, as shown in **Fig. 18.5**, baroreceptors are extremely abundant in the following regions: (1) the wall of each internal carotid artery, slightly above the carotid bifurcation, an area known as the *carotid sinus*; and (2) the wall of the aortic arch.

Fig. 18.5 shows that signals from the carotid baroreceptors are transmitted through small *Hering's nerves* to the *glossopharyngeal nerves* in the high neck and then to the *nucleus tractus solitarius* in the medullary area of the brain stem. Signals from the aortic baroreceptors in the

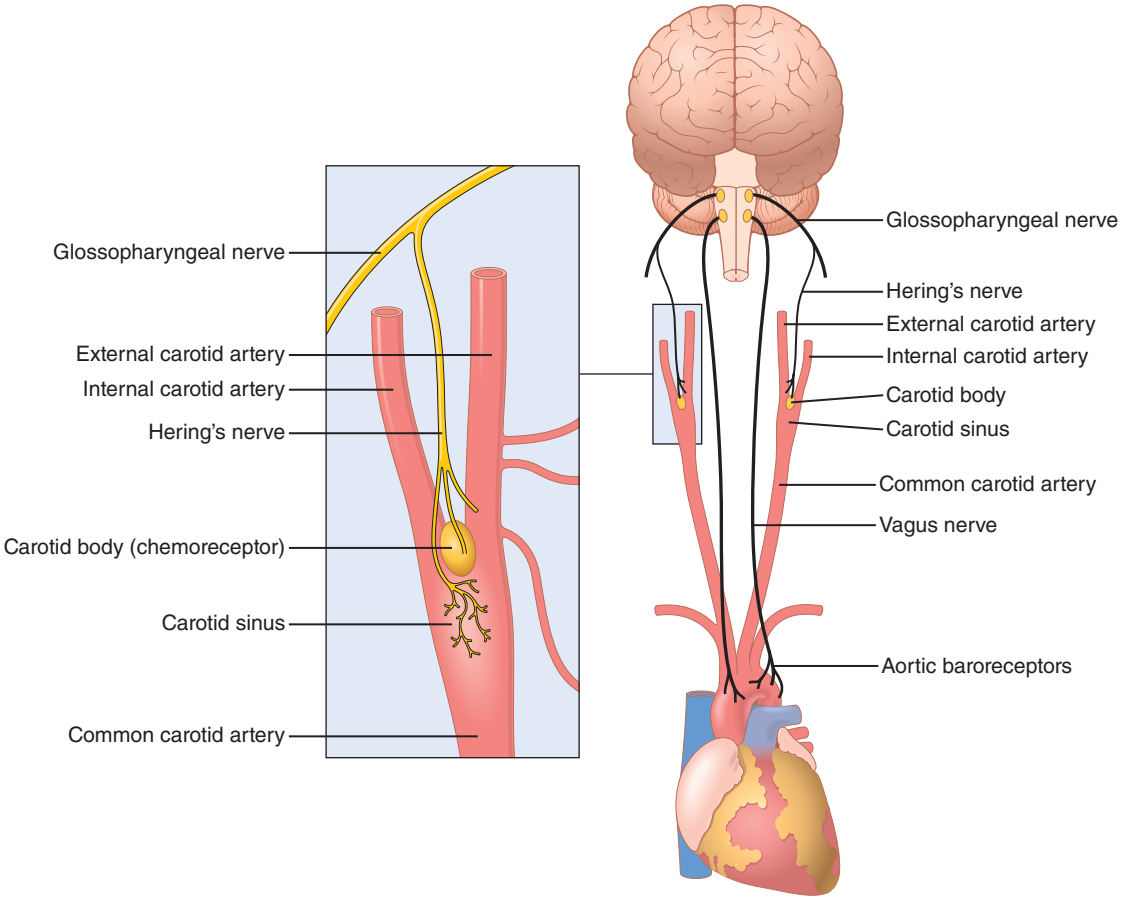

Figure 18.5 Baroreceptor system for controlling arterial pressure.

arch of the aorta are transmitted through the *vagus nerves* to the same nucleus tractus solitarius of the medulla.

Response of the Baroreceptors to Changes in Arterial Pressure. Fig. 18.6 shows the effects of different arterial pressure levels on the rate of impulse transmission in a Hering's carotid sinus nerve. Note that the carotid sinus baroreceptors are not stimulated at all by pressures between 0 and 50 to 60 mm Hg but, above these levels, they respond progressively more rapidly and reach a maximum at about 180 mm Hg. The responses of the aortic baroreceptors are similar to those of the carotid receptors except that they operate, in general, at arterial pressure levels about 30 mm Hg higher.

Note especially that in the normal operating range of arterial pressure, around 100 mm Hg, even a slight change in pressure causes a strong change in the baroreflex signal to readjust arterial pressure back toward normal. Thus, the baroreceptor feedback mechanism functions most effectively in the pressure range where it is most needed.

The baroreceptors respond rapidly to changes in arterial pressure; the rate of impulse firing increases in the fraction of a second during each systole and decreases again during diastole. Furthermore, the baroreceptors *respond much more to a rapidly changing pressure* than to a stationary pressure. That is, if mean arterial pressure is 150 mm Hg but at that moment is rising rapidly, the rate of impulse transmission may be as much as twice that when the pressure is stationary at 150 mm Hg.

Circulatory Reflex Initiated By the Baroreceptors. After the baroreceptor signals have entered the nucleus tractus solitarius of the medulla, secondary signals *inhibit the vasoconstrictor center* of the medulla and *excite the vagal parasympathetic center*. The net effects are as follows: (1) *vasodilation* of veins and arterioles throughout the peripheral circulatory system; and (2) *decreased heart rate* and *strength of heart contraction*. Therefore, excitation of the baroreceptors by high pressure in the arteries reflexly *causes arterial pressure to decrease* because of a decrease in peripheral resistance and a decrease in cardiac output. Conversely, low pressure has the opposite effects, reflexly causing the pressure to rise back toward normal.

Fig. 18.7 shows a typical reflex change in arterial pressure caused by occluding the two common carotid arteries. This decreases carotid sinus pressure, causing reduced signals from the baroreceptors and less inhibitory effect on the vasomotor center. The vasomotor center then becomes much more active than usual, causing aortic arterial pressure to rise and remain elevated during the 10 minutes that the carotids are occluded. Removal of the occlusion allows the pressure in the carotid sinuses to rise, and the carotid sinus reflex now causes aortic pressure to fall almost immediately to slightly below normal as a momentary overcompensation and then return to normal in another minute.

Baroreceptors Attenuate Blood Pressure Changes During Changes in Body Posture. The ability of the baroreceptors to maintain relatively constant arterial pressure in the upper body is important when a person stands up after lying down. Immediately on standing, arterial pressure in the head and upper part of the body tends to fall, and marked reduction of this pressure could cause loss of consciousness. However, the falling pressure at the baroreceptors elicits an immediate reflex, resulting in strong sympathetic discharge throughout the body that minimizes the decrease in pressure in the head and upper body.

Pressure Buffer Function of the Baroreceptor Control System. Because the baroreceptor system opposes increases or decreases in arterial pressure, it is called a *pressure buffer system*, and the nerves from the baroreceptors are called *buffer nerves*.

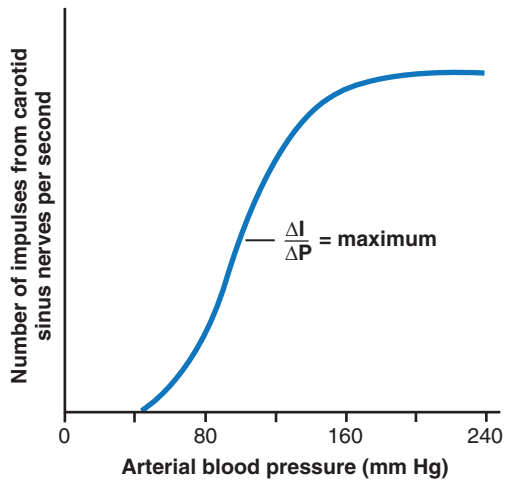

Figure 18.6 Activation of the baroreceptors at different levels of arterial pressure. *ΔI*, Change in carotid sinus nerve impulses per second; *ΔP*, change in arterial blood pressure (in mm Hg).

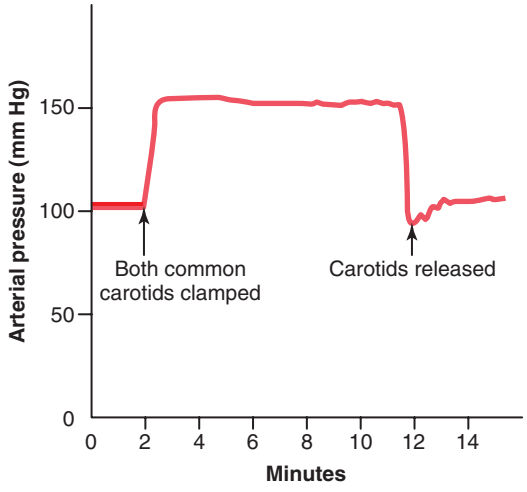

Figure 18.7 Typical carotid sinus reflex effect on aortic arterial pressure caused by clamping both common carotids (after the two vagus nerves have been cut).

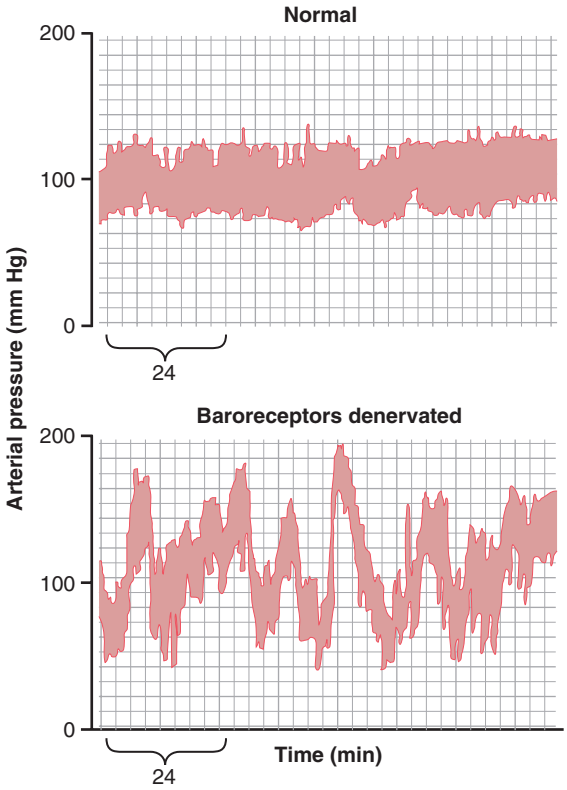

Figure 18.8 Two-hour records of arterial pressure in a normal dog (*top*) and in the same dog (*bottom*) several weeks after the baroreceptors had been denervated. *(Modified from Cowley Jr AW, Liard JF, Guyton AC. Role of baroreceptor reflex in daily control of arterial blood pressure and other variables in dogs.* Circ Res. *1973;32:564.)*

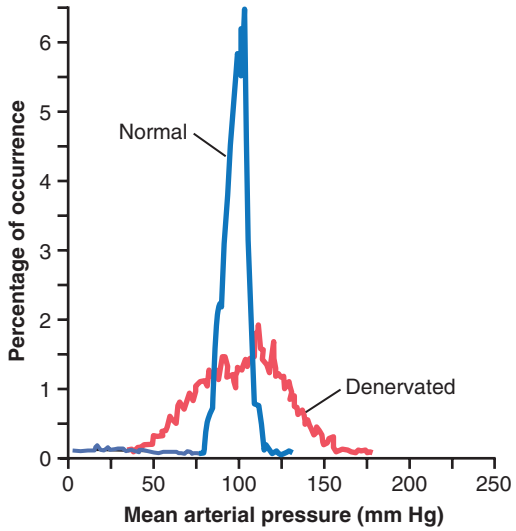

Figure 18.9 Frequency distribution curves of the arterial pressure for a 24-hour period in a normal dog and in the same dog several weeks after the baroreceptors had been denervated. *(Modified from Cowley Jr AW, Liard JF, Guyton AC. Role of baroreceptor reflex in daily control of arterial blood pressure and other variables in dogs.* Circ Res. *1973;32:564.)*

Fig. 18.8 shows the importance of this buffer function of the baroreceptors. The upper panel in this figure shows an arterial pressure recording for 2 hours from a normal dog, and the lower panel shows an arterial pressure recording from a dog whose baroreceptor nerves from the carotid sinuses and the aorta had been removed. Note the extreme variability of pressure in the denervated dog caused by simple events of the day, such as lying down, standing, excitement, eating, defecation, and noises.

Fig. 18.9 shows the frequency distributions of the mean arterial pressures recorded for a 24-hour day in a normal dog and in the same dog several weeks after baroreceptor denervation. Note that when the baroreceptors were functioning normally, the mean arterial pressure remained within a narrow range of between 85 and 115 mm Hg throughout the day and, for most of the day, it remained at about 100 mm Hg. After denervation of the baroreceptors, however, the frequency distribution curve flattened, showing that the pressure range increased 2.5-fold, frequently falling to as low as 50 mm Hg or rising to more than 160 mm Hg. Thus, in the absence of the arterial baroreceptor system there is extreme variability of arterial pressure.

A primary purpose of the arterial baroreceptor system is therefore to reduce the minute-by-minute variation in arterial pressure to about one-third that which would occur if the baroreceptor system were not present.

Are the Baroreceptors Important in Long-Term Regulation of Arterial Pressure? Although the arterial baroreceptors provide powerful moment-to-moment control of arterial pressure, their importance in long-term blood pressure regulation has been controversial. One reason that the baroreceptors have been considered by some physiologists to be relatively unimportant in chronic regulation of arterial pressure is that they tend to *reset* in 1 to 2 days to the pressure level to which they are exposed. That is, if the arterial pressure rises from the normal value of 100 to 160 mm Hg, a very high rate of baroreceptor impulses is at first transmitted. During the next few minutes, the rate of firing diminishes considerably. Then, it diminishes much more slowly during the next 1 to 2 days, when the rate of firing returns to nearly normal, despite the fact that the mean arterial pressure still remains at 160 mm Hg. Conversely, when the arterial pressure falls to a very low level, the baroreceptors at first transmit no impulses but gradually, over 1 to 2 days, the rate of baroreceptor firing returns toward the control level.

This resetting of the baroreceptors may attenuate their potency as a control system for correcting disturbances that tend to change arterial pressure for longer than a few days at a time. Experimental studies, however, have suggested that the baroreceptors do not completely reset and may therefore contribute to long-term blood pressure regulation, especially by influencing sympathetic nerve activity of the kidneys. For example, with prolonged increases in arterial pressure, the baroreceptor reflexes may mediate decreases in renal sympathetic nerve activity that promote increased excretion of sodium and water by the kidneys. This action, in turn, causes a gradual decrease in blood volume, which helps restore arterial pressure toward normal. Thus, long-term regulation of mean arterial pressure by the baroreceptors requires interaction with additional

systems, especially the renal–body fluid–pressure control system (along with its associated nervous and hormonal mechanisms), discussed in Chapters 19 and 30.

Experimental studies and clinical trials have shown that chronic electrical stimulation of carotid sinus afferent nerve fibers can cause sustained reductions in sympathetic nervous system activity and arterial pressure of 15 to 20 mm Hg. These observations suggest that most, if not all, the baroreceptor reflex resetting that occurs when increases in arterial pressure are sustained, as in chronic hypertension, is due to resetting of the carotid sinus nerve mechanoreceptors themselves rather than resetting in central nervous system vasomotor centers.

Control of Arterial Pressure By the Carotid and Aortic Chemoreceptors. Closely associated with the baroreceptor pressure control system is a *chemoreceptor reflex* that operates in much the same way as the baroreceptor reflex except that *chemoreceptors*, instead of stretch receptors, initiate the response.

The chemoreceptor cells are sensitive to low oxygen or elevated carbon dioxide and hydrogen ion levels. They are located in several small *chemoreceptor organs*, about 2 millimeters in size, in two *carotid bodies*, one of which lies in the bifurcation of each common carotid artery, and usually one to three *aortic bodies* adjacent to the aorta. The chemoreceptors excite nerve fibers that along with the baroreceptor fibers, pass through Hering's nerves and the vagus nerves into the vasomotor center of the brain stem.

Each carotid or aortic body is supplied with an abundant blood flow through a small nutrient artery, so the chemoreceptors are always in close contact with arterial blood. Whenever arterial pressure falls below a critical level, the chemoreceptors become stimulated because diminished blood flow reduces oxygen delivery and causes excess buildup of carbon dioxide and hydrogen ions that are not removed by the slowly flowing blood.

The signals transmitted from the chemoreceptors *excite* the vasomotor center, and this response elevates the arterial pressure back toward normal. However, this chemoreceptor reflex is not a powerful arterial pressure controller until the arterial pressure falls below 80 mm Hg. Therefore, it is mainly at the lower pressures that this reflex becomes important to help prevent further decreases in arterial pressure.

The chemoreceptors are discussed in much more detail in Chapter 42 in relation to *respiratory control*, in which they normally play a far more important role than in blood pressure control. However, activation of the chemoreceptors may also contribute to increases in arterial pressure in conditions such as severe obesity and *obstructive sleep apnea*, a serious sleep disorder associated with repetitive episodes of nocturnal breathing cessation and hypoxia.

Atrial and Pulmonary Artery Reflexes Regulate Arterial Pressure. The atria and pulmonary arteries have stretch receptors in their walls called *low-pressure receptors*. Low-pressure receptors are similar to the baroreceptor stretch receptors of the large systemic arteries. These low-pressure receptors play an important role in minimizing arterial pressure changes in response to changes in blood volume. For example, if 300 milliliters of blood suddenly are infused into a dog with all receptors intact, the arterial pressure rises only about 15 mm Hg. With the *arterial baroreceptors denervated*, the pressure rises about 40 mm Hg. If the *low-pressure receptors* also are denervated, the arterial pressure rises about 100 mm Hg.

Thus, one can see that even though the low-pressure receptors in the pulmonary artery and in the atria cannot detect the systemic arterial pressure, they do detect simultaneous changes in pressure in the low-pressure areas of the circulation caused by changes in volume. Also, they elicit reflexes parallel to the baroreceptor reflexes to make the total reflex system more potent for control of arterial pressure.

Atrial Reflexes That Activate the Kidneys—The Volume Reflex. Stretch of the atria and activation of low-pressure atrial receptors also cause reflex reductions in renal sympathetic nerve activity, decreased tubular reabsorption, and dilation of afferent arterioles in the kidneys (**Fig. 18.10**). Signals are also transmitted simultaneously from the atria to the hypothalamus to decrease secretion of antidiuretic hormone (ADH). Decreased afferent arteriolar resistance in the kidneys increases glomerular capillary pressure and filtration of fluid into the kidney tubules. The decrease in ADH level diminishes water reabsorption from the tubules. The combination of these effects—an increase in glomerular filtration and a decrease in reabsorption of the fluid—increases fluid loss by the kidneys and attenuates the increased blood volume. Atrial stretch caused by increased blood volume also elicits release of *atrial natriuretic peptide*, a hormone that adds further to the excretion of sodium and water in the urine and return of blood volume toward normal (see **Fig. 18.10**).

All these mechanisms that tend to return blood volume back toward normal after a volume overload act indirectly as pressure controllers, as well as blood volume controllers, because excess volume drives the heart to greater cardiac output and higher arterial pressure. This *volume reflex* mechanism is discussed again in Chapter 30, along with other mechanisms of blood volume control.

Increased Atrial Pressure May Increase Heart Rate Via the Bainbridge Reflex. Increases in atrial pressure sometimes increase the heart rate as much as 75%, particularly when the prevailing heart rate is slow. In contrast, when the heart rate is rapid, atrial stretch caused by infusion of fluids may reduce heart rate due to activation of arterial baroreceptors. Thus, the net effect of increased blood volume and atrial stretch on heart rate depends on the relative contributions of the baroreceptor reflexes (which tend to slow the heart rate) and the *Bainbridge reflex*, which tends to accelerate the heart rate,

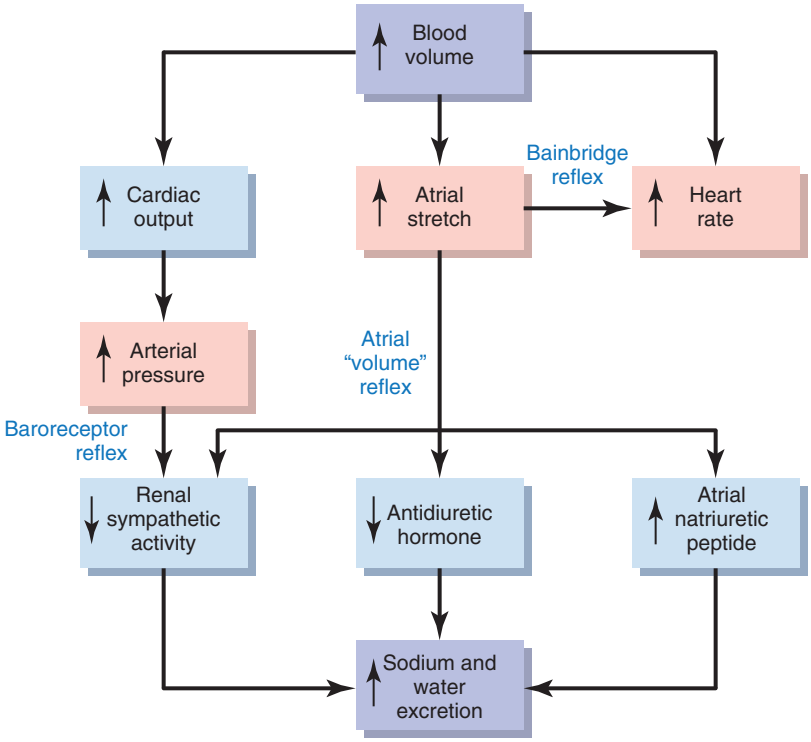

Figure 18.10 Reflex responses to increased blood volume, which increase arterial pressure and atrial stretch.

as shown in **Fig. 18.10**. When blood volume is increased above normal, the Bainbridge reflex often increases heart rate despite the inhibitory actions of the baroreflexes.

A small part of the increased heart rate associated with increased blood volume and atrial stretch is caused by a direct effect of the increased atrial volume to stretch the sinus node; in Chapter 10 we noted that such direct stretch can increase the heart rate as much as 15%. An additional 40% to 60% increase in heart rate is caused by the Bainbridge reflex. The stretch receptors of the atria that elicit the Bainbridge reflex transmit their afferent signals through the vagus nerves to the medulla of the brain. Then efferent signals are transmitted back through vagal and sympathetic nerves to increase the heart rate and strength of heart contraction. Thus, this reflex helps prevent damming of blood in the veins, atria, and pulmonary circulation.

DECREASED BLOOD FLOW TO BRAIN VASOMOTOR CENTER ELICITS INCREASED BLOOD PRESSURE THROUGH THE CNS ISCHEMIC RESPONSE

Most nervous control of blood pressure is achieved by reflexes that originate in the baroreceptors, chemoreceptors, and low-pressure receptors, all of which are located in the peripheral circulation outside the brain. However, when blood flow to the vasomotor center in the lower brain stem becomes decreased severely enough to cause nutritional deficiency—that is, to cause *cerebral ischemia*—the vasoconstrictor and cardioaccelerator neurons in the vasomotor center become strongly excited by the ischemia. This strong excitation may increase arterial pressure to as high as the heart can possibly pump. This effect is believed to be caused by failure of the slowly flowing blood to carry carbon dioxide away from the brain stem vasomotor center. The increased local concentration of carbon dioxide has an extremely potent effect to stimulate the sympathetic vasomotor nervous control areas in the brain's medulla.

It is possible that other factors, such as buildup of lactic acid and other acidic substances in the vasomotor center, also contribute to the marked stimulation and elevation in arterial pressure. This arterial pressure elevation in response to cerebral ischemia is known as the *CNS ischemic response*.

The ischemic effect on vasomotor activity can elevate the mean arterial pressure dramatically, sometimes to as high as 250 mm Hg for as long as 10 minutes. *The degree of sympathetic vasoconstriction caused by intense cerebral ischemia is often so great that some of the peripheral vessels become totally or almost totally occluded*. The kidneys, for example, often cease their production of urine entirely because of renal arteriolar constriction in response to the strong sympathetic discharge. Therefore, *the CNS ischemic response is one of the most powerful of all the activators of the sympathetic vasoconstrictor system*.

Importance of CNS Ischemic Response as a Regulator of Arterial Pressure. Despite the powerful nature of the CNS ischemic response, it does not become significant until the arterial pressure falls far below normal, down to 60 mm Hg and below, reaching its greatest degree

of stimulation at a pressure of 15 to 20 mm Hg. Therefore, the CNS ischemic response is not one of the normal mechanisms for regulating arterial pressure. Instead, it operates principally as an *emergency pressure control system that acts rapidly and powerfully to prevent further decrease in arterial pressure whenever blood flow to the brain decreases dangerously close to the lethal level*. It is sometimes called the *last-ditch stand pressure control mechanism*.

Cushing Reaction to Increased Pressure Around the Brain. The *Cushing reaction* is a special type of CNS ischemic response that results from increased pressure of the cerebrospinal fluid in the cranial vault around the brain. For example, when the cerebrospinal fluid pressure rises to equal the arterial pressure, it compresses the whole brain, as well as the arteries in the brain, and shuts off the blood supply to the brain. This action initiates a CNS ischemic response that causes the arterial pressure to rise. When the arterial pressure has risen to a level higher than the cerebrospinal fluid pressure, blood flows once again into the vessels of the brain to relieve the brain ischemia. Ordinarily, the blood pressure reaches a new equilibrium level slightly higher than the cerebrospinal fluid pressure, thus allowing blood to begin to flow through the brain again. The Cushing reaction helps protect vital centers of the brain from loss of nutrition if the cerebrospinal fluid pressure ever rises high enough to compress the cerebral arteries.

SPECIAL FEATURES OF NERVOUS CONTROL OF ARTERIAL PRESSURE

ROLE OF THE SKELETAL NERVES AND SKELETAL MUSCLES IN INCREASING CARDIAC OUTPUT AND ARTERIAL PRESSURE

Although most rapidly acting nervous control of the circulation is affected through the autonomic nervous system, at least two conditions exist in which the skeletal nerves and muscles also play major roles in circulatory responses.

Abdominal Compression Reflex Increases Cardiac Output and Arterial Pressure. When a baroreceptor or chemoreceptor reflex is elicited, nerve signals may be transmitted simultaneously through skeletal nerves to skeletal muscles of the body, particularly to the abdominal muscles. Muscle contraction then compresses all the venous reservoirs of the abdomen, helping translocate blood out of the abdominal vascular reservoirs toward the heart. As a result, increased quantities of blood are made available for the heart to pump. This overall response is called the *abdominal compression reflex*. The resulting effect on the circulation is the same as that caused by sympathetic vasoconstrictor impulses when they constrict the veins—an increase in cardiac output and arterial pressure. The abdominal compression reflex is probably much more important than was realized in the past because it is well known that people whose skeletal muscles have been paralyzed are considerably more prone to hypotensive episodes than people with normal skeletal muscles.

Skeletal Muscle Contraction Increases Cardiac Output and Arterial Pressure During Exercise. When the skeletal muscles contract during exercise, they compress blood vessels throughout the body. Even anticipation of exercise tightens the muscles, thereby compressing the vessels in the muscles and in the abdomen. This compression translocates blood from the peripheral vessels into the heart and lungs and, therefore, increases cardiac output. This effect is essential in helping cause the 5-fold to 7-fold increase in cardiac output that sometimes occurs during heavy exercise. The rise in cardiac output, in turn, is an essential ingredient in increasing the arterial pressure during exercise, from a normal mean of 100 mm Hg up to 130 to 160 mm Hg.

RESPIRATORY WAVES IN THE ARTERIAL PRESSURE

With each cycle of respiration, the arterial pressure usually rises and falls 4 to 6 mm Hg in a wavelike manner, causing *respiratory waves* in the arterial pressure. The waves result from several different effects, some of which are reflex in nature, as follows:

1. Many of the breathing signals that arise in the respiratory center of the medulla spill over into the vasomotor center with each respiratory cycle.
2. Every time a person inspires, the pressure in the thoracic cavity becomes more negative than usual, causing the blood vessels in the chest to expand. This reduces the quantity of blood returning to the left side of the heart and thereby momentarily decreases the cardiac output and arterial pressure.
3. The pressure changes caused in the thoracic vessels by respiration can excite vascular and atrial stretch receptors.

The net result of all of these factors during normal respiration is usually an increase in arterial pressure during the early part of expiration and a decrease in pressure during the remainder of the respiratory cycle. During deep respiration, the blood pressure can rise and fall as much as 20 mm Hg with each respiratory cycle.

Arterial Pressure Vasomotor Waves—Oscillation of Pressure Reflex Control Systems

Often while recording arterial pressure, in addition to the small pressure waves caused by respiration, some much larger waves are also noted—as high as 10 to 40 mm Hg at times—that rise and fall more slowly than the respiratory waves. The duration of each cycle varies from 26 seconds in the anesthetized dog to 7 to 10 seconds in the unanesthetized human. These waves are called *vasomotor waves* or *Mayer waves*. Such records are illustrated in **Fig. 18.11**, showing the cyclical rise and fall in arterial pressure.

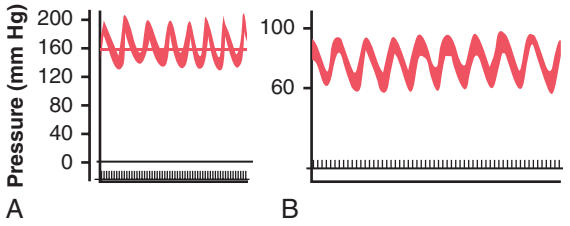

Figure 18.11 (A) Vasomotor waves caused by oscillation of the CNS ischemic response. (B) Vasomotor waves caused by baroreceptor reflex oscillation.

Vasomotor waves are coupled with oscillations of sympathetic nervous activity and are enhanced during states of sympathetic activation. The cause of vasomotor waves is reflex oscillation of one or more nervous pressure control mechanisms, some of which are the following.

Oscillation of Baroreceptor and Chemoreceptor Reflexes. The vasomotor waves of **Fig. 18.11B** are often seen in experimental pressure recordings, although they are usually much less intense than shown in the figure. They are caused mainly by oscillation of the *baroreceptor reflex*. That is, a high pressure excites the baroreceptors, which then inhibits the sympathetic nervous system and lowers the pressure a few seconds later. The decreased pressure, in turn, reduces the baroreceptor stimulation and allows the vasomotor center to become active once again, elevating the pressure to a high value. The response is not instantaneous, and it is delayed until a few seconds later. This high pressure then initiates another cycle, and the oscillation continues.

The *chemoreceptor reflex* can also oscillate to give the same type of waves. This reflex usually oscillates simultaneously with the baroreceptor reflex. It probably plays the major role in causing vasomotor waves when the arterial pressure is in the range of 40 to 80 mm Hg because, in this low range, chemoreceptor control of the circulation becomes powerful, whereas baroreceptor control becomes weaker.

Oscillation of CNS Ischemic Response. The record in **Fig. 18.11A** resulted from oscillation of the CNS ischemic pressure control mechanism. In this experiment, the cerebrospinal fluid pressure increased to 160 mm Hg, which compressed the cerebral vessels and initiated a CNS ischemic pressure response up to 200 mm Hg. When the arterial pressure rose to such a high value, the brain ischemia was relieved, and the sympathetic nervous system became inactive. As a result, the arterial pressure fell rapidly back to a much lower value, causing brain ischemia once again. The ischemia then initiated another rise in pressure. Again, the ischemia was relieved, and again the pressure fell. This response repeated itself cyclically as long as the cerebrospinal fluid pressure remained elevated.

Thus, any reflex pressure control mechanism can oscillate if the intensity of feedback is strong enough and if there is a delay between excitation of the pressure receptor and the subsequent pressure response. The vasomotor waves illustrate that the nervous reflexes that control arterial pressure obey the same principles as those applicable to mechanical and electrical control systems. For example, if the feedback gain is too great in the guiding mechanism of an automatic pilot for an airplane, and there is also delay in the response time of the guiding mechanism, the plane will oscillate from side to side instead of following a straight course.

CHAPTER 19

Role of the Kidneys in Long-Term Control of Arterial Pressure and in Hypertension: The Integrated System for Arterial Pressure Regulation

In addition to the rapidly acting mechanisms for regulation of arterial pressure discussed in Chapter 18, the body also has powerful mechanisms for regulating arterial pressure week after week and month after month. This long-term control of arterial pressure is closely intertwined with body fluid volume homeostasis, which is determined by the balance between fluid intake and output. For long-term survival, fluid intake and output must be balanced, a task that is performed by multiple nervous and hormonal controls and by local kidney control systems that regulate their excretion of salt and water. In this chapter, we discuss the major role of these renal–body fluid systems in long-term blood pressure regulation.

RENAL–BODY FLUID SYSTEM FOR ARTERIAL PRESSURE CONTROL

The renal–body fluid system for arterial pressure control acts slowly but powerfully, as follows. If blood volume increases and vascular capacitance is not altered, arterial pressure will also increase. The rising pressure, in turn, causes the kidneys to excrete the excess volume, thus returning the pressure back toward normal.

In the phylogenetic history of animal development, this renal–body fluid system for pressure control is a primitive one. It is fully operative in one of the lowest of vertebrates, the hagfish. This animal has a low arterial pressure, only 8 to 14 mm Hg, and this pressure increases almost directly in proportion to its blood volume. The hagfish continually drinks sea water, which is absorbed into its blood, increasing the blood volume and blood pressure. However, when the pressure rises too high, the kidney excretes the excess volume into the urine and relieves the pressure. At low pressure, the kidney excretes less fluid than is ingested; as the hagfish continues to drink, extracellular fluid volume, blood volume, and blood pressure all build up again to the higher levels.

Although this primitive mechanism of pressure control has survived throughout the ages, multiple nervous control systems, hormones, and local control systems have been added for regulation of salt and water excretion. In humans, kidney output of water and salt is just as sensitive, if not more so, to pressure changes as in the hagfish. Indeed, an increase in arterial pressure in the human of only a few mm Hg can double the renal output of water, a phenomenon called *pressure diuresis*, as well as double the output of salt, called *pressure natriuresis*.

In humans, just as in the hagfish, the renal–body fluid system for arterial pressure control is a fundamental mechanism for long-term arterial pressure control. However, through the stages of evolution, multiple refinements have been added to make this system much more precise in its control. An especially important refinement, as discussed later, has been the addition of the renin-angiotensin-aldosterone system, which has powerful effects on salt and water excretion.

QUANTITATION OF PRESSURE DIURESIS AS A BASIS FOR ARTERIAL PRESSURE CONTROL

Fig. 19.1 shows the approximate average effect of different arterial pressure levels on the renal output of salt (*pressure natriuresis*) and water (*pressure diuresis*) by an isolated kidney, demonstrating markedly increased urine output as the pressure rises. The curve in this figure is called a *renal urinary output curve* or a *renal function curve*. In humans, at an arterial pressure of 50 mm Hg, the urine output is nearly zero. At 100 mm Hg, it is normal and, at 200 mm Hg, it is 4 to 6 times normal. Furthermore, not only does increasing the arterial pressure increase urine volume output, but it also causes an approximately equal increase in sodium output, which is the phenomenon of pressure natriuresis.

Experiment Demonstrating the Renal–Body Fluid System for Arterial Pressure Control. **Fig. 19.2** shows the results of an experiment in dogs in which all the nervous reflex mechanisms for blood pressure control were first blocked. Then, the arterial pressure was elevated by infusing about 400 mL of blood intravenously. Note the rapid increase in cardiac output to about double normal and the increase in mean arterial pressure to 205 mm Hg, 115 mm Hg above its resting level. Shown by the middle curve is the effect of this increased arterial pressure on urine output, which increased 12-fold. Along with this tremendous loss of fluid in the urine, both the cardiac output and arterial pressure returned to normal during the subsequent hour. Thus, the kidneys have extreme

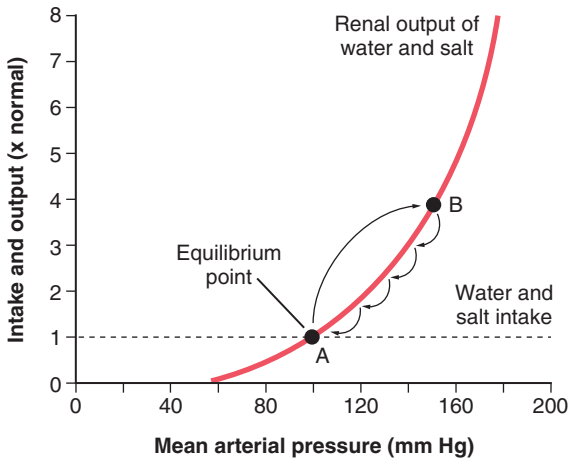

Figure 19.1 A typical arterial pressure–renal urinary output curve measured in a perfused isolated kidney, showing pressure diuresis when the arterial pressure rises above normal (point A) to approximately 150 mm Hg (point B). The equilibrium point A describes the level to which the arterial pressure will be regulated if intake is not altered. (Note that the small portion of the salt and water intake that is lost from the body through nonrenal routes is ignored in this and similar figures in this chapter.)

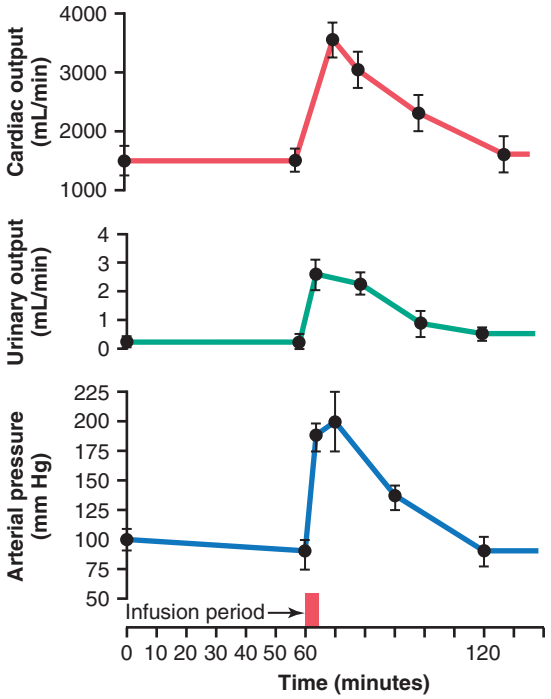

Figure 19.2 Increases in cardiac output, urinary output, and arterial pressure caused by increased blood volume in dogs whose nervous pressure control mechanisms had been blocked. This figure shows return of arterial pressure to normal after about 1 hour of fluid loss into the urine. (*Courtesy Dr. William Dobbs.*)

capability to eliminate excess fluid volume from the body via pressure diuresis and, in so doing, to return the arterial pressure back to normal.

Renal–Body Fluid Mechanism Provides Nearly Infinite Feedback Gain for Long-Term Arterial Pressure Control. **Fig. 19.1** shows the relationship of the following: (1) the renal output curve for water and salt in response to rising arterial pressure; and (2) the line that represents the net water and salt intake. Over a long period, the water and salt output must equal the intake. Furthermore, the only point on the graph in **Fig. 19.1** at which output equals intake is where the two curves intersect, called the *equilibrium point* (point A). Let us see what happens if the arterial pressure increases above or decreases below the equilibrium point.

First, assume that the arterial pressure rises to 150 mm Hg (point B). At this level, the renal output of water and salt is almost three times as great as intake. Therefore, the body loses fluid, blood volume decreases, and arterial pressure decreases. Furthermore, this negative balance of fluid will not cease until pressure falls *all the way* back exactly to the equilibrium level. Even when arterial pressure is only a few mm Hg greater than the equilibrium level, there still is slightly more loss of water and salt than intake, so blood pressure continues to fall *until the pressure eventually returns to the equilibrium point.*

If arterial pressure falls below the equilibrium point, the intake of water and salt is greater than the output. Therefore, body fluid volume increases, blood volume increases, and arterial pressure rises until once again it returns to the equilibrium point. This return of the arterial pressure *always back to the equilibrium point* is known as the *near-infinite feedback gain principle* for control of arterial pressure by the renal–body fluid mechanism.

Two Key Determinants of Long-Term Arterial Pressure. In **Fig. 19.1**, one can also see that two basic long-term factors determine the long-term arterial pressure level. As long as the two curves representing the renal output of salt and water and the intake of salt and water remain exactly as they are shown in **Fig. 19.1**, the mean arterial pressure level will eventually readjust to 100 mm Hg, which is the pressure level depicted by the equilibrium point of this figure. Furthermore, there are only two ways in which the pressure of this equilibrium point can be changed from the 100 mm Hg level. One is by shifting the pressure level of the renal output curve for salt and water, and the other is by changing the level of the water and salt intake line. Therefore, expressed simply, two primary determinants of the long-term arterial pressure level are as follows:

1. The degree of pressure shift of the renal output curve for water and salt
2. The level of the water and salt intake

Operation of these two determinants in the control of arterial pressure is demonstrated in **Fig. 19.3**. In **Fig. 19.3A**, some abnormality of the kidneys has caused the renal output curve to shift 50 mm Hg in the high-pressure direction (to the right). Note that the equilibrium point has also shifted to 50 mm Hg higher than normal. Therefore, if the renal output curve shifts to a new pressure level, the arterial pressure will follow to this new pressure level within a few days.

Fig. 19.3B shows how a change in salt and water intake also can change the arterial pressure. In this case,

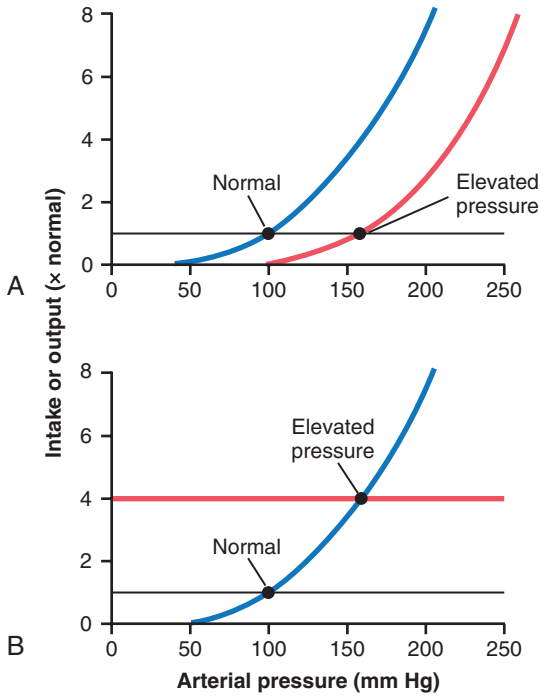

Figure 19.3 Two ways in which the arterial pressure can be increased. (A) By shifting the renal output curve in the right-hand direction toward a higher pressure level or by increasing the intake level of salt and water (B).

the intake level has increased 4-fold in the absence of a change in the renal output curve, and the equilibrium point has shifted to a pressure level of 160 mm Hg, 60 mm Hg above the normal level. Conversely, a decrease in the intake level with no change in the renal output curve would reduce the arterial pressure. Thus, *the long-term mean arterial pressure level* cannot be changed chronically to a new value without changing one or both of the two basic determinants of long-term arterial pressure, either (1) the level of salt and water intake or (2) the degree of shift of the renal function curve along the pressure axis. However, if either of these is changed, the arterial pressure thereafter will be regulated at a new arterial pressure level where the two new curves intersect.

In most people, however, the renal function curve is much steeper than that shown in **Fig. 19.3**, and changes in salt intake have only a modest effect on arterial pressure, at least over the short term, as discussed in the next section.

Chronic Renal Output Curve Is Steeper Than the Acute Curve. An important characteristic of pressure natriuresis (and pressure diuresis) is that chronic changes in arterial pressure, lasting for days, have a much greater effect on the renal output of salt and water than observed during acute changes in pressure (**Fig. 19.4**). Thus, when the kidneys are functioning normally, the *chronic renal output curve* is much steeper than the acute curve.

The powerful effects of chronic increases in arterial pressure on urine output occur because increased pressure not only has direct hemodynamic effects on the

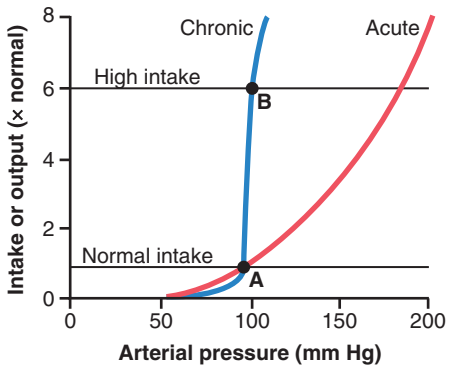

Figure 19.4 Acute and chronic renal output curves. Under steady-state conditions, the renal output of salt and water is equal to intake of salt and water. Points A and B represent the equilibrium points for long-term regulation of arterial pressure when salt intake is normal or six times normal, respectively. Because of the steepness of the chronic renal output curve, increased salt intake normally causes only small changes in arterial pressure. In persons with impaired kidney function, the steepness of the renal output curve may be reduced, similar to the acute curve, resulting in increased sensitivity of arterial pressure to changes in salt intake.

kidney to increase excretion, but also indirect effects mediated by nervous and hormonal changes. For example, increased arterial pressure decreases activity of the sympathetic nervous system, partly through the baroreceptor reflex mechanisms discussed in Chapter 18, and by reducing formation of various hormones such as angiotensin II and aldosterone that tend to reduce salt and water excretion by the kidneys. Reduced activity of these *antinatriuretic* systems therefore amplifies the effectiveness of pressure natriuresis and diuresis in raising salt and water excretion during chronic increases in arterial pressure (see Chapters 28 and 30 for further discussion).

Conversely, when blood pressure is reduced, the sympathetic nervous system is activated, and formation of antinatriuretic hormones is increased, adding to the direct effects of reduced pressure to decrease renal output of salt and water. This combination of direct effects of pressure on the kidneys and indirect effects of pressure on the sympathetic nervous system and various hormone systems makes pressure natriuresis and diuresis extremely powerful for long-term control of arterial pressure and body fluid volumes.

The importance of neural and hormonal influences on pressure natriuresis is especially evident during chronic changes in sodium intake. If the kidneys, as well as the nervous and hormonal mechanisms, are functioning normally, chronic increases in intakes of salt and water to as high as six times normal are usually associated with little effect on arterial pressure. Note in **Fig. 19.4** that the blood pressure equilibrium point B on the curve is nearly the same as point A, the equilibrium point at normal salt intake. Conversely, decreases in salt and water intake to as low as one-sixth normal typically have little effect on arterial pressure. Thus, many persons are said to be *salt-insensitive* because large variations in salt intake do not change blood pressure more than a few mm Hg.

Although most healthy, young people can accommodate a wide range of sodium intakes over several days or weeks with minimal changes in arterial pressure, some individuals may be *salt-sensitive*, with an attenuated renal output curve similar to the acute curve shown in **Fig. 19.4**. In these cases, even moderate increases in salt intake may cause significant increases in arterial pressure.

Factors That Cause Blood Pressure to Be Salt-Sensitive. Some of the factors that cause blood pressure to be salt-sensitive include loss of functional nephrons due to kidney injury and excessive formation of antinatriuretic hormones such as angiotensin II or aldosterone (**Table 19.1**). For example, surgical reduction of kidney mass, kidney injury, and loss of functional nephrons associated with aging, hypertension, diabetes, and various kidney diseases all cause blood pressure to be more sensitive to changes in salt intake.

Abnormalities of the renin-angiotensin-aldosterone system that prevent adequate suppression of angiotensin II or aldosterone when sodium intake is increased also greatly increase salt sensitivity of arterial pressure. Drugs that block the renin-angiotensin-aldosterone system also greatly increase the sensitivity of blood pressure to change in sodium intake. Therefore, reductions in salt intake generally cause much greater reductions in blood pressure in patients with hypertension who are being treated with renin-angiotensin-aldosterone system blockers.

Several genetic disorders that increase reabsorption of sodium chloride by the renal distal and collecting tubules also increase salt sensitivity of arterial pressure (**Table 19.1**). For example, *Liddle syndrome*, a genetic disorder resulting from mutations that greatly increase activity of the epithelial sodium channel (ENaC) in the distal and collecting tubules, is associated with increased renal sodium reabsorption and salt-sensitive hypertension. In these cases, greater than normal increases in arterial pressure are required to raise renal output sufficiently to maintain a balance between the intake and output of salt and water.

There is evidence that long-term high salt intake, lasting for several years, may actually damage the kidneys and eventually make blood pressure more salt-sensitive. We will discuss salt sensitivity of blood pressure in patients with hypertension later in this chapter.

Table 19.1 Some Factors Associated With Salt-Sensitivity of Blood Pressure

Loss of Functional Kidney Nephrons
• Old age
• Surgical removal of kidney mass
• Kidney diseases
• Obesity and diabetes mellitus
• Chronic hypertension
Renin-Angiotensin-Aldosterone System Abnormalities
• Excessive angiotensin II formation (e.g., renin secreting tumor)
• Excessive aldosteronism secretion (e.g., primary aldosteronism)
• "Nonmodulators" (low, normal, or high renin)
Genetic Causes of Increased Distal and Collecting Tubule Renal Sodium Reabsorption
• Liddle syndrome (excessive sodium channel activity)
• Gordon syndrome (excessive sodium chloride co-transporter activity)
• Glucocorticoid-remediable aldosteronism (excess aldosterone)
• Congenital adrenal hyperplasia (excess aldosterone)
• Apparent mineralocorticoid excess (glucocorticoid activation of renal tubule mineralocorticoid receptor)
Administration of Renin-Angiotensin-Aldosterone System Blockers
• Angiotensin II receptor blockers (ARBs)
• Angiotensin converting enzyme (ACE) inhibitors
• Mineralocorticoid receptor antagonists

Failure of Increased Total Peripheral Resistance to Elevate Long-Term Level of Arterial Pressure If Fluid Intake and Renal Function Do Not Change

Recalling the basic equation for arterial pressure—*arterial pressure* equals *cardiac output* times *total peripheral resistance*—it is clear that an increase in total peripheral resistance should elevate the arterial pressure. Indeed, *when the total peripheral resistance is acutely increased*, the arterial pressure does rise immediately. Yet, if renal vascular resistance and the kidney output curve are unchanged, the acute rise in arterial pressure usually is not maintained. Instead, the arterial pressure returns all the way to normal within a few days.

The reason that blood pressure returns to normal despite increased total peripheral resistance is that increasing vascular resistance everywhere else in the body *besides in the kidneys* does not change the equilibrium point for blood pressure control as dictated by the kidneys (see **Figs. 19.1** and **19.3**). Instead, the kidneys respond to the high arterial pressure with pressure diuresis and natriuresis. Within hours, large amounts of salt and water are lost from the body; this process continues until arterial pressure returns to the equilibrium pressure level. At this point, blood pressure is normalized, and extracellular fluid volume and blood volume are decreased to levels below normal.

Fig. 19.5 shows the approximate cardiac outputs and arterial pressures in different clinical conditions in which the *long-term total peripheral resistance* is much less than or much greater than normal, but kidney excretion of salt and water is normal. Note that in all these different clinical conditions the arterial pressure is also normal.

Although increases in nonrenal vascular resistance do not appear to elevate arterial pressure chronically, increases in total peripheral resistance are often associated with increases in renal vascular resistance. *Increased*

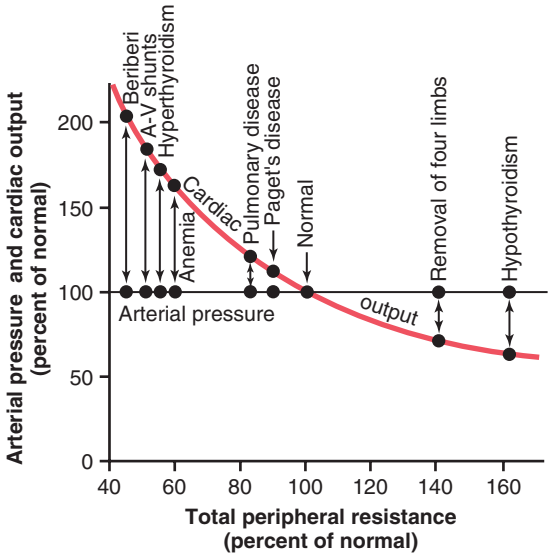

Figure 19.5 Relationships of total peripheral resistance to the long-term levels of arterial pressure and cardiac output in different clinical abnormalities. In these conditions, the kidneys were functioning normally. Note that changing the whole-body total peripheral resistance caused equal and opposite changes in cardiac output but, in all cases, had no effect on arterial pressure. *A-V*, Arterial-venous. (*Modified from Guyton AC.* Arterial Pressure and Hypertension. *Philadelphia: WB Saunders; 1980.*)

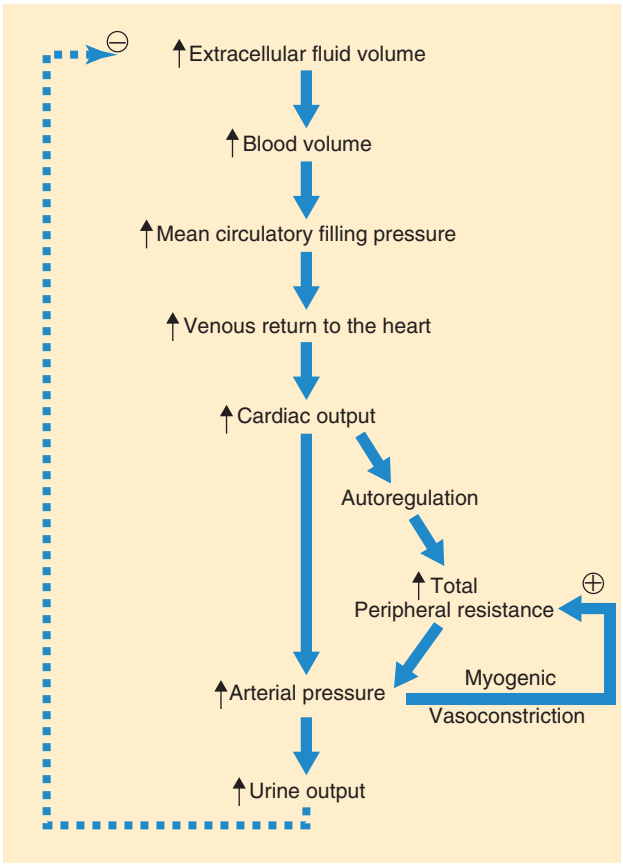

Figure 19.6 Sequential steps whereby increased extracellular fluid volume increases the arterial pressure. Note especially that increased cardiac output has both a *direct effect* to increase arterial pressure and an *indirect effect* by increasing the total peripheral resistance due to autoregulation of blood flow in many organs and tissues. Increased arterial pressure also secondarily increases vascular resistance via myogenic vasoconstriction.

intrarenal vascular resistance can alter kidney function and cause hypertension by shifting the renal function curve to a higher pressure level, as shown in **Fig. 19.3A**. We will see an example of this mechanism later in this chapter when we discuss hypertension caused by vasoconstrictor mechanisms. However, *it is the increase in renal resistance* that is the culprit, *not the increased total peripheral resistance*—an important distinction.

Increased Fluid Volume Can Elevate Arterial Pressure By Increasing Cardiac Output or Total Peripheral Resistance

The overall mechanism whereby increased extracellular fluid volume may elevate arterial pressure, *if vascular capacity is not simultaneously increased*, is shown in **Fig. 19.6**. The sequential events are as follows: (1) increased extracellular fluid volume, which (2) increases the blood volume, which (3) increases the mean circulatory filling pressure, which (4) increases venous return of blood to the heart, which (5) increases cardiac output, which (6) increases arterial pressure. The increased arterial pressure, in turn, increases renal excretion of salt and water and may return extracellular fluid volume to nearly normal if kidney function is normal and vascular capacity is unaltered.

Note especially in this case the two ways in which an increase in cardiac output can increase the arterial pressure. One of these is the direct effect of increased cardiac output to increase the pressure, and the other is an indirect effect to raise total peripheral vascular resistance through *autoregulation* of blood flow. The second effect can be explained as follows.

Referring to Chapter 17, let us recall that whenever an excess amount of blood flows through a tissue, the local tissue vasculature constricts and decreases the blood flow back toward normal. This phenomenon is called *autoregulation*, which simply means regulation of blood flow by the tissue itself. When increased blood volume raises the cardiac output, blood flow tends to increase in all tissues of the body; if the increased blood flow exceeds the metabolic needs of the tissues, the autoregulation mechanisms constrict blood vessels in most tissues of the body, which increases the total peripheral resistance. In addition, increased pressure in most blood vessels tends to cause vasoconstriction through the myogenic mechanism discussed in Chapter 16 and shown in **Fig. 19.6**.

Because arterial pressure is equal to *cardiac output* times *total peripheral resistance*, the secondary increase in total peripheral resistance that results from the autoregulation mechanism helps increase the arterial pressure. For example, only a 5% to 10% increase in cardiac output can increase the arterial pressure from the normal mean arterial pressure of 100 mm Hg up to 150 mm Hg when

accompanied by an increase in total peripheral resistance due to tissue blood flow autoregulation or other factors that cause vasoconstriction. The slight increase in cardiac output is often not measurable.

Importance of Salt (NaCl) in the Renal–Body Fluid Schema for Arterial Pressure Regulation

Although the discussions thus far have emphasized the importance of volume in regulation of arterial pressure, experimental studies have shown that an increase in salt intake is far more likely to elevate the arterial pressure, especially in people who are salt-sensitive, than is an increase in water intake. The reason for this finding is that pure water is not retained in the extracellular fluid and is normally excreted by the kidneys almost as rapidly as it is ingested, but salt is not excreted so easily. As salt accumulates in the body, it also indirectly increases the extracellular fluid volume for two basic reasons:

1. Although some additional sodium may be stored in the tissues when salt accumulates in the body, excess salt in the extracellular fluid increases the fluid osmolality. The increased osmolarity stimulates the thirst center in the brain, making the person drink extra amounts of water. This additional water returns the extracellular salt concentration to normal but increases the extracellular fluid volume.
2. The increase in osmolality caused by the excess salt in the extracellular fluid also stimulates the hypothalamic–posterior pituitary gland secretory mechanism to secrete increased quantities of *antidiuretic hormone* (discussed in Chapter 29). The antidiuretic hormone then causes the kidneys to reabsorb increased quantities of water from the renal tubular fluid, thereby diminishing the excreted volume of urine and increasing the extracellular fluid volume.

Thus, the amount of salt that accumulates in the body is an important determinant of the extracellular fluid volume. Relatively small increases in extracellular fluid and blood volume can increase the arterial pressure substantially. This is true, however, only if the excess salt accumulation leads to an increase in blood volume and if vascular capacity is not simultaneously increased. As discussed previously, increasing salt intake in the absence of impaired kidney function or excessive formation of antinatriuretic hormones usually does not increase arterial pressure much because the kidneys rapidly eliminate the excess salt, and blood volume is hardly altered.

CHRONIC HYPERTENSION (HIGH BLOOD PRESSURE) CAUSED BY IMPAIRED RENAL FUNCTION

When people have chronic *hypertension* (or high blood pressure), this means that their *arterial pressure* is greater than the upper range of the accepted normal pressure. A normal *systolic* blood pressure is less than 120 mm Hg, and a normal *diastolic* pressure is less than 80 mm Hg, with a *mean* arterial pressure of approximately 90 mm Hg. Stage 1 hypertension occurs when systolic pressure is between 130 and 139 mm Hg or diastolic pressure is between 80 and 89 mm Hg. In persons with severe hypertension, the *mean* arterial pressure can rise to 150 to 170 mm Hg, with *diastolic* pressure as high as 130 mm Hg and *systolic* pressure occasionally as high as 250 mm Hg.

Even moderate elevation of arterial pressure leads to shortened life expectancy. At severely high pressures—that is, mean arterial pressures 50% or more above normal—a person can expect to live no more than a few more years unless appropriately treated. The lethal effects of hypertension are caused mainly in three ways:

1. Hypertension causes excess workload on the heart and coronary heart disease, leading to early heart failure and death as a result of pulmonary edema or a heart attack.
2. The high pressure frequently damages a major blood vessel in the brain, followed by death of major portions of the brain (*cerebral infarct*). Clinically, this is called a *stroke* or *brain attack*. Depending on which part of the brain is involved, a stroke can be fatal or cause paralysis, dementia, blindness, or multiple other serious brain disorders.
3. High pressure often causes injury in the kidneys, producing many areas of renal destruction and, eventually, kidney failure, uremia, and death.

Lessons learned from the type of hypertension called *volume-loading hypertension* have been helpful in understanding the role of the renal–body fluid volume mechanism for arterial pressure regulation. Volume-loading hypertension means hypertension caused by excess accumulation of extracellular fluid in the body, some examples of which follow.

Experimental Volume-Loading Hypertension Caused By Reduced Kidney Mass and Increased Salt Intake. **Fig. 19.7** shows an experiment demonstrating volume-loading hypertension in dogs with 70% of their kidney mass removed. At the first circled point on the curve, the two poles of one of the kidneys were removed, and at the second circled point, the entire opposite kidney was removed, leaving the animals with only 30% of their normal renal mass. Note that removal of this amount of kidney mass increased the arterial pressure by only 6 mm Hg. Then, the dogs were given isotonic (0.9%) sodium chloride (salt) solution to drink instead of water. Because salt solution fails to quench the thirst, the dogs drank two to four times the normal amounts of volume, and within a few days, their average arterial pressure rose to about 40 mm Hg above normal. After 2 weeks, the dogs were given tap water again instead of salt solution; the pressure returned to normal within 2 days. Finally, at the end of the experiment, the dogs were given salt solution again, and this time the pressure rose rapidly to a high level, again demonstrating volume-loading hypertension.

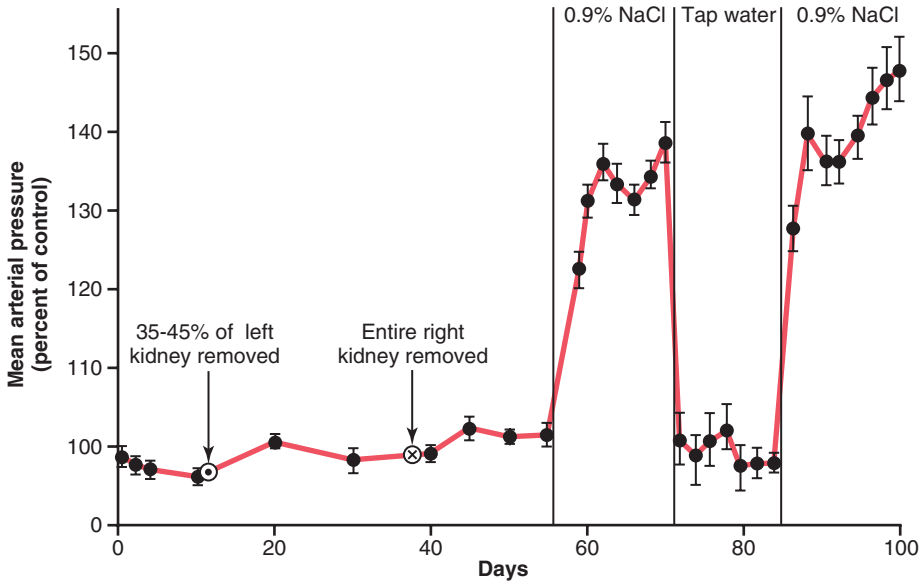

Figure 19.7 The average effect on arterial pressure of drinking 0.9% saline solution (0.9% NaCl) instead of water in dogs with 70% of their renal tissue removed. (*Modified from Langston JB, Guyton AC, Douglas BH, et al. Effect of changes in salt intake on arterial pressure and renal function in partially nephrectomized dogs.* Circ Res. *1963;12:508.*)

If one considers again the basic determinants of long-term arterial pressure regulation, it is apparent why hypertension occurred in the volume-loading experiment illustrated in **Fig. 19.7**. First, reduction of the kidney mass to 30% of normal greatly reduced the ability of the kidneys to excrete salt and water. Therefore, salt and water accumulated in the body and, in a few days, raised the arterial pressure high enough to excrete the excess salt and water intake.

Sequential Changes in Circulatory Function During Development of Volume-Loading Hypertension. It is especially instructive to study the sequential changes in circulatory function during progressive development of volume-loading hypertension (**Fig. 19.8**). A week or so before the point labeled "0" days, the kidney mass had already been decreased to only 30% of normal. Then, at this point, the intake of salt and water was increased to about six times normal and kept at this high intake thereafter. The acute effect was to increase extracellular fluid volume, blood volume, and cardiac output to 20% to 40% above normal. Simultaneously, the arterial pressure began to rise but not nearly so much at first as the fluid volumes and cardiac output. The reason for this slower rise in pressure can be discerned by studying the total peripheral resistance curve, which shows an initial *decrease* in total peripheral resistance. This decrease was caused by the baroreceptor mechanism discussed in Chapter 18, which transiently attenuated the rise in pressure. However, after 2 to 4 days, the baroreceptors adapted (reset) and were no longer able to prevent the rise in blood pressure. At this time, the arterial pressure had risen almost to its full height because of the increase in cardiac output, even though the total peripheral resistance was still almost at the normal level.

After these early acute changes in the circulatory variables had occurred, more prolonged secondary changes

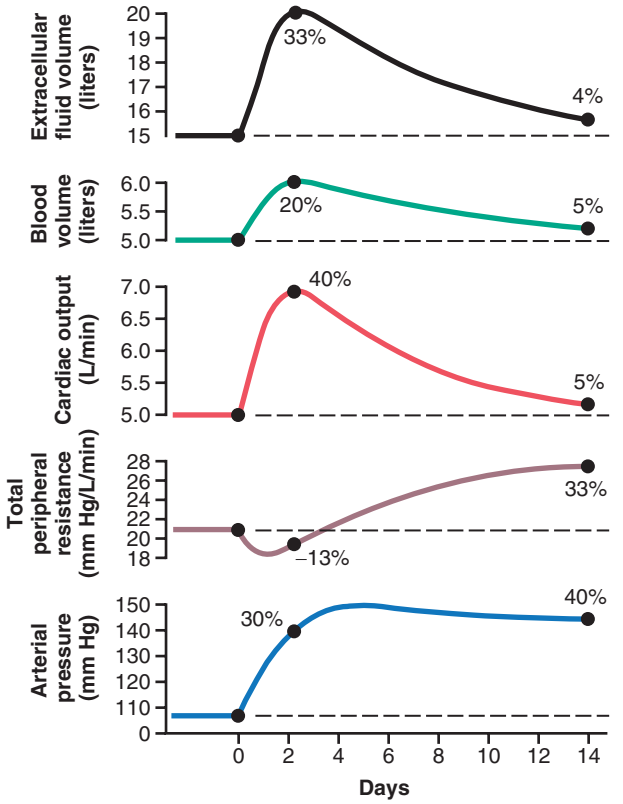

Figure 19.8 Progressive changes in important circulatory system variables during the first few weeks of *volume-loading hypertension*. Note especially the initial increase in cardiac output as the basic cause of the hypertension. Subsequently, the autoregulation mechanism returns the cardiac output almost to normal while simultaneously causing a *secondary increase in total peripheral resistance*. (*Modified from Guyton AC.* Arterial Pressure and Hypertension. *Philadelphia: WB Saunders; 1980.*)

occurred during the next few weeks. Especially important was a *progressive increase in total peripheral resistance*, while at the same time *the cardiac output decreased back toward normal*, at least partly as a result of *the long-term*

blood flow autoregulation mechanism discussed in Chapter 17 and earlier in this chapter. That is, after cardiac output rose to a high level and initiated the hypertension, the excess blood flow through the tissues then caused progressive constriction of the local arterioles, thus returning the local blood flow in the body tissues and also the cardiac output toward normal while simultaneously causing a *secondary increase in total peripheral resistance*.

Note that the extracellular fluid volume and blood volume also returned toward normal along with the decrease in cardiac output. This outcome resulted from two factors. First, the increase in arteriolar resistance decreased the capillary pressure, which allowed the fluid in the tissue spaces to be absorbed back into the blood. Second, the elevated arterial pressure now caused the kidneys to excrete the excess volume of fluid that had initially accumulated in the body.

Several weeks after the initial onset of volume loading, the following effects were found:

1. Hypertension
2. Marked increase in total peripheral resistance
3. Almost complete return of the extracellular fluid volume, blood volume, and cardiac output back to normal

Therefore, volume-loading hypertension usually occurs in two sequential stages. The first stage results from increased fluid volume, causing increased cardiac output and hypertension. The second stage in volume-loading hypertension is characterized by high blood pressure and high total peripheral resistance but return of the cardiac output so close to normal that the usual measuring techniques frequently cannot detect an abnormally elevated cardiac output.

Thus, increased total peripheral resistance in volume-loading hypertension occurs after the hypertension has developed and is secondary to the hypertension rather than being the cause of the hypertension.

Volume-Loading Hypertension in Patients Who Have No Kidneys But Are Being Maintained With an Artificial Kidney. When a patient is maintained with an artificial kidney, it is especially important to keep the patient's body fluid volume at a normal level by removing the appropriate amount of water and salt each time the patient undergoes dialysis. If this step is not performed, and extracellular fluid volume is allowed to increase, hypertension almost invariably develops in exactly the same way as shown in **Fig. 19.8**, except that the rate of volume loading and resultant increases in blood pressure may be slower to develop, depending on the salt and water intake of the patient. That is, the cardiac output increases at first and causes hypertension. Then, the autoregulation mechanism returns cardiac output back toward normal while causing a secondary increase in total peripheral resistance. In the end, the hypertension appears to be a high peripheral resistance type of hypertension, although the initial cause is excess volume accumulation.

Hypertension Caused By Excess Aldosterone

Another type of hypertension initiated by reduced ability of the kidneys to excrete sodium is caused by excess aldosterone secretion or, occasionally, by excesses of other types of steroids. A small tumor in one of the adrenal glands occasionally secretes large quantities of aldosterone, which is the condition called *primary aldosteronism*. As discussed in Chapters 28 and 30, aldosterone increases the rate of salt and water reabsorption by the tubules of the kidneys, thereby increasing blood volume, extracellular fluid volume, and arterial pressure. If salt intake is increased at the same time, the hypertension becomes even greater. Furthermore, if the condition persists for months or years, the hypertension often causes pathological changes in the kidneys that make the kidneys retain even more salt and water in addition to that caused directly by the aldosterone. Therefore, the hypertension often finally becomes severe to the point of being lethal.

In the early stages of aldosterone-induced hypertension, cardiac output is often increased but, in later stages, the cardiac output generally returns almost to normal while total peripheral resistance becomes secondarily elevated, as explained earlier in the chapter for primary volume-loading hypertension.

ROLE OF THE RENIN-ANGIOTENSIN SYSTEM IN ARTERIAL PRESSURE CONTROL

Aside from the capability of the kidneys to control arterial pressure through changes in extracellular fluid volume, the kidneys also have another powerful mechanism for controlling pressure, the *renin-angiotensin system*.

Renin is a protein enzyme released by the kidneys when the arterial pressure falls too low or when salt intake is reduced. In turn, it raises the arterial pressure and the tendency toward volume depletion caused by low salt intake in several ways, thus helping correct the initial fall in pressure.

COMPONENTS OF THE RENIN-ANGIOTENSIN SYSTEM

Fig. 19.9 shows the main functional steps whereby the renin-angiotensin system helps regulate arterial pressure. Renin is synthesized and stored in the *juxtaglomerular cells* (JG cells) of the kidneys. The JG cells are modified smooth muscle cells located mainly *in the walls of the afferent arterioles immediately proximal to the glomeruli*. Multiple factors control renin secretion, including the sympathetic nervous system, various hormones, and local autacoids such as prostaglandins, nitric oxide, and endothelin. When the arterial pressure falls, the JG cells release renin by at least three major mechanisms:

1. *Pressure-sensitive baroreceptors* in the JG cells respond to decreased arterial pressure with increased release of renin.
2. *Decreased sodium chloride delivery to the macula densa cells* in the early distal tubule stimulates renin release (discussed further in Chapter 27).
3. *Increased sympathetic nervous system activity* stimulates renin release by activating beta-adrenergic receptors in the JG cells. Sympathetic stimulation also activates alpha-adrenergic receptors, which can increase renal sodium chloride reabsorption and reduce the glomerular filtration rate in cases of strong sympathetic activation. Increased renal sympathetic activity also enhances the sensitivity of renal baroreceptor and macula densa mechanisms for renin release.

Most of the renin enters the renal blood and then passes out of the kidneys to circulate throughout the entire body. However, small amounts of renin remain in the local fluids of the kidney and initiate several intrarenal functions.

Renin itself is an enzyme, not a vasoactive substance. As shown in **Fig. 19.9**, renin acts enzymatically on another plasma protein, a globulin called *angiotensinogen* (or *renin substrate*), to release a 10–amino acid peptide, *angiotensin I*. Angiotensin I has mild vasoconstrictor properties but not enough to cause significant changes in circulatory function. Renin persists in the blood for 30 to 60 minutes and continues to cause formation of additional angiotensin I during this entire time.

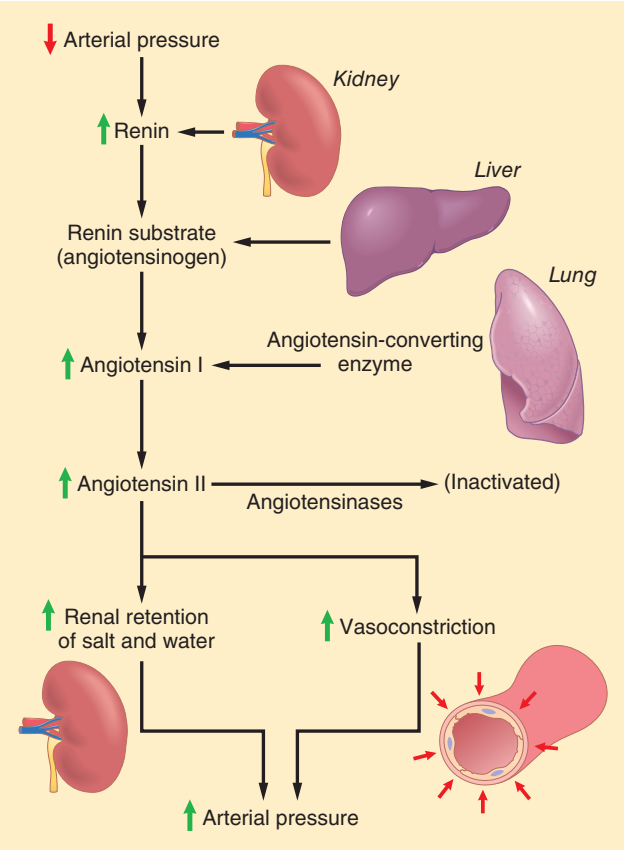

Figure 19.9 The renin-angiotensin vasoconstrictor and kidney salt and water retention mechanisms for arterial pressure control.

Within a few seconds to minutes after the formation of angiotensin I, two additional amino acids are split from angiotensin I to form the 8–amino acid peptide *angiotensin II*. This conversion occurs to a great extent in the lungs while blood flows through the small vessels of the lungs, catalyzed by an enzyme called *angiotensin-converting enzyme* (ACE) that is present in the endothelium of the lung vessels. Other tissues such as the kidneys, intestines, adrenal glands, and blood vessels also contain ACE and therefore form angiotensin II locally.

Angiotensin II is an extremely powerful vasoconstrictor, and it also affects circulatory function in other ways. However, it persists in the blood only for 1 or 2 minutes because it is rapidly inactivated by multiple blood and tissue enzymes collectively called *angiotensinases*.

Angiotensin II has two principal effects that can elevate arterial pressure. The first of these, *vasoconstriction in many areas of the body*, occurs rapidly. Vasoconstriction occurs intensely in the arterioles and less so in the veins. Constriction of the arterioles increases total peripheral resistance, thereby raising the arterial pressure, as demonstrated at the bottom of **Fig. 19.9**. Also, the mild constriction of the veins promotes increased venous return of blood to the heart, thereby helping the heart pump against the increasing pressure.

The second principal means whereby angiotensin II increases arterial pressure is *decreased excretion of salt and water* by the kidneys due to stimulation of aldosterone secretion, as well as direct effects on the kidneys. The salt and water retention by the kidneys slowly increases the extracellular fluid volume, which then increases the arterial pressure during subsequent hours and days. This long-term effect, through the direct and indirect actions of angiotensin II on the kidneys, is even more powerful than the acute vasoconstrictor mechanism in eventually raising the arterial pressure.

Rapidity and Intensity of the Vasoconstrictor Pressure Response to the Renin-Angiotensin System

Fig. 19.10 shows an experiment demonstrating the effect of hemorrhage on the arterial pressure under two separate conditions: (1) with the renin-angiotensin system functioning; and (2) after blocking the system with a renin-blocking antibody. Note that after hemorrhage—enough to cause acute decrease of the arterial pressure to 50 mm Hg—arterial pressure rose back to 83 mm Hg when the renin-angiotensin system was functional. In contrast, it rose to only 60 mm Hg when the renin-angiotensin system was blocked. This phenomenon shows that the renin-angiotensin system is powerful enough to return the arterial pressure at least halfway back to normal within a few minutes after severe hemorrhage. Therefore, this system can be lifesaving, especially when blood volume

is severely reduced or in other conditions that markedly reduce blood pressure.

Note also that the renin-angiotensin vasoconstrictor system requires about 20 minutes to become fully active. Therefore, it is somewhat slower for blood pressure control than the nervous reflexes and sympathetic norepinephrine-epinephrine system.

Angiotensin II–Mediated Renal Salt and Water Retention Is an Important Mechanism for Long-Term Control of Arterial Pressure

Angiotensin II causes the kidneys to retain both salt and water in two major ways:

1. Angiotensin II acts directly on the kidneys to increase tubular reabsorption of salt and water (see Chapter 28).
2. Angiotensin II stimulates the adrenal glands to secrete aldosterone, and the aldosterone in turn increases salt and water reabsorption by the kidney tubules.

Thus, when renin secretion and angiotensin II formation are increased due to factors that tend to lower arterial pressure, such as hemorrhage or salt and water depletion, the angiotensin II–mediated salt and water retention acts slowly, but powerfully, to help return arterial pressure toward normal. Whenever there is excess angiotensin II formation, the salt and water retaining actions of angiotensin II cause the long-term renal–body fluid mechanism for arterial pressure control to become reset to a higher arterial pressure level than normal.

Mechanisms of the Direct Renal Effects of Angiotensin II to Cause Renal Retention of Salt and Water. Angiotensin has several direct renal effects that make the kidneys retain salt and water. One major effect is to constrict the renal arterioles, especially the glomerular *efferent arterioles*, thereby diminishing blood flow through the kidneys. The slow flow of blood reduces the pressure in the peritubular capillaries, which increases reabsorption of fluid from the tubules. Angiotensin II also has important direct actions on the tubular cells to increase tubular reabsorption of sodium and water, as discussed in Chapter 28. The combined effects of angiotensin II can sometimes decrease urine output to less than one-fifth normal.

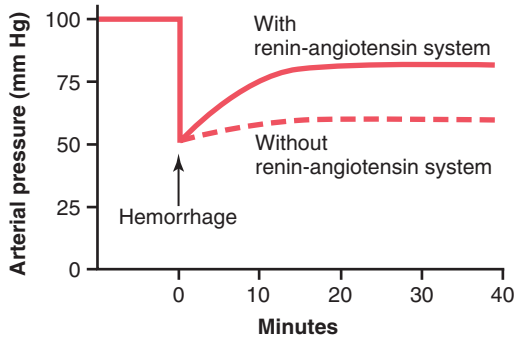

Figure 19.10 The pressure-compensating effect of the renin-angiotensin vasoconstrictor system after severe hemorrhage. (Drawn from experiments by Dr. Royce Brough.)

Angiotensin II Increases Kidney Salt and Water Retention By Stimulating Aldosterone. Angiotensin II is also one of the most powerful stimulators of aldosterone secretion by the adrenal glands, as discussed in relation to body fluid regulation in Chapter 30 and in relation to adrenal gland function in Chapter 78. Therefore, when the renin-angiotensin system becomes activated, the rate of aldosterone secretion usually also increases; an important function of aldosterone is to cause marked increase in sodium reabsorption by the kidney tubules, thus increasing the total body extracellular fluid sodium and, as already explained, extracellular fluid volume. Thus, both the direct effect of angiotensin II on the kidneys and its effect acting through aldosterone are important in long-term arterial pressure control.

Quantitative Analysis of Arterial Pressure Changes Caused By Angiotensin II. **Fig. 19.11** shows a quantitative analysis of the effect of angiotensin in arterial pressure control. This figure shows two renal function curves, as well as a line depicting a normal level of sodium intake. The left-hand renal function curve is that measured in dogs whose renin-angiotensin system had been blocked by an ACE inhibitor drug that blocks the conversion of angiotensin I to angiotensin II. The right-hand curve was measured in dogs infused continuously with angiotensin II at a level about 2.5 times the normal rate of angiotensin formation in the blood. Note the shift of the renal output curve toward higher pressure levels under the influence of angiotensin II. This shift is caused by the direct effects of angiotensin II on the kidney and the indirect effect acting through aldosterone secretion, as explained earlier.

Finally, note the two equilibrium points, one for zero angiotensin showing an arterial pressure level of 75 mm Hg, and one for elevated angiotensin showing a pressure level of 115 mm Hg. Therefore, the effect of angiotensin to cause renal retention of salt and water can have a powerful effect in promoting chronic elevation of the arterial pressure.

Role of the Renin-Angiotensin System in Maintaining a Normal Arterial Pressure Despite Large Variations in Salt Intake

One of the most important functions of the renin-angiotensin system is to allow a person to ingest very small or very large amounts of salt without causing major changes in extracellular fluid volume or arterial pressure. This function is explained by **Fig. 19.12**, which shows that increased salt intake tends to elevate the extracellular fluid volume, which tends to elevate the arterial pressure. Multiple effects of increased salt intake, including small increases in arterial pressure and pressure-independent effects, reduce the rate of renin secretion and angiotensin II formation, which then helps eliminate the additional

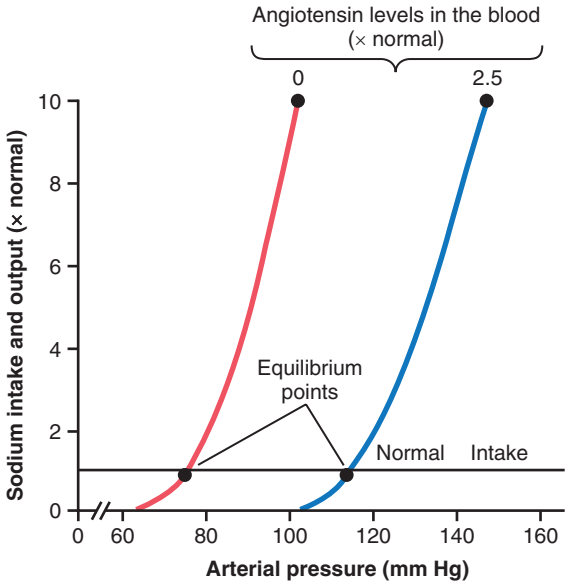

Figure 19.11 The effect of two angiotensin II levels in the blood on the renal output curve showing regulation of the arterial pressure at an equilibrium point of 75 mm Hg, when the angiotensin II level is low, and at 115 mm Hg, when the angiotensin II level is high.

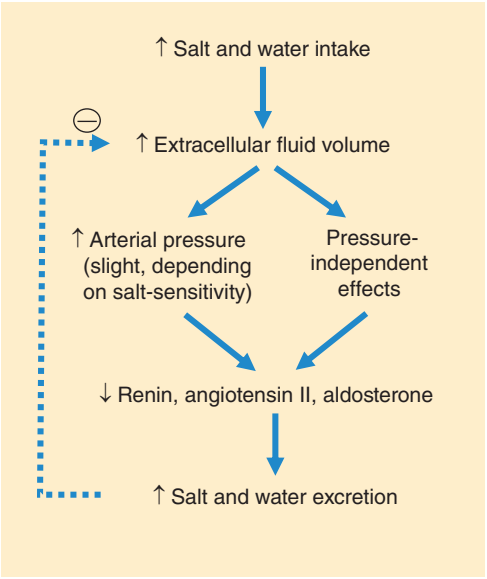

Figure 19.12 Sequential events whereby increased salt intake tends to elevate arterial pressure, but feedback decreases in activity of the renin-angiotensin-aldosterone system minimize increases in extracellular fluid volume and arterial pressure.

salt with minimal increases in extracellular fluid volume or arterial pressure. Thus, the renin-angiotensin system is an automatic feedback mechanism that helps maintain the arterial pressure at or near the normal level, even when salt intake is increased or decreased within a wide range of intakes.

When the system functions normally, the pressure usually rises no more than 4 to 6 mm Hg in response to as much as a 100-fold increase in salt intake (**Fig. 19.13**). In contrast, when the usual suppression of angiotensin formation is prevented due to continuous infusion of small amounts of angiotensin II so that blood levels cannot decrease, the same increase in salt intake may elevate the pressure by 40 mm Hg or more (see **Fig. 19.13**). When salt intake is reduced to as low as one-tenth normal, arterial pressure barely changes as long as the renin-angiotensin system functions normally. However, when angiotensin II formation is blocked with an ACE inhibitor, blood pressure decreases markedly as salt intake is reduced (see **Fig. 19.13**). Thus, the renin-angiotensin system is perhaps the body's most powerful system for accommodating wide variations in salt intake with minimal changes in arterial pressure.

HYPERTENSION CAUSED BY RENIN-SECRETING TUMOR OR RENAL ISCHEMIA

Occasionally, a tumor of the renin-secreting JG cells occurs and secretes large quantities of renin, causing formation of large amounts of angiotensin II. In all patients in whom this phenomenon has occurred, severe hypertension has developed. Also, when large amounts of angiotensin II are infused continuously for days or weeks into experimental animals, similar severe long-term hypertension develops.

We have already noted that angiotensin II can increase the arterial pressure in two ways:

1. By constricting the arterioles throughout the entire body, thereby increasing the total peripheral resistance and arterial pressure; this effect occurs within seconds after one begins to infuse large amounts of angiotensin II.
2. By causing the kidneys to retain salt and water; over a period of days, even moderate amounts of angiotensin II can cause hypertension through its renal actions, the principal cause of the long-term elevation of arterial pressure.

Renal Artery Stenosis in One-Kidney Goldblatt Hypertension. When one kidney is removed, and a constrictor is placed on the renal artery of the remaining kidney, as shown in **Fig. 19.14**, the immediate effect is reduced pressure in the renal artery beyond the constrictor, as demonstrated by the dashed curve in the figure Then, within minutes, the systemic arterial pressure begins to rise and continues to rise for several days. The pressure usually rises rapidly for the first hour or so, and this effect is followed by a slower additional rise during the next several days. When the *systemic* arterial pressure reaches its new stable pressure level, the *renal arterial pressure* distal to the constriction (the dashed curve in the figure) will have returned almost all the way back to normal. The hypertension produced in this way is called *one-kidney Goldblatt hypertension* in honor of Harry Goldblatt, who first studied the important quantitative features of hypertension caused by renal artery constriction.

The early rise in arterial pressure in Goldblatt hypertension is caused by the renin-angiotensin vasoconstrictor mechanism. That is, because of poor blood flow through

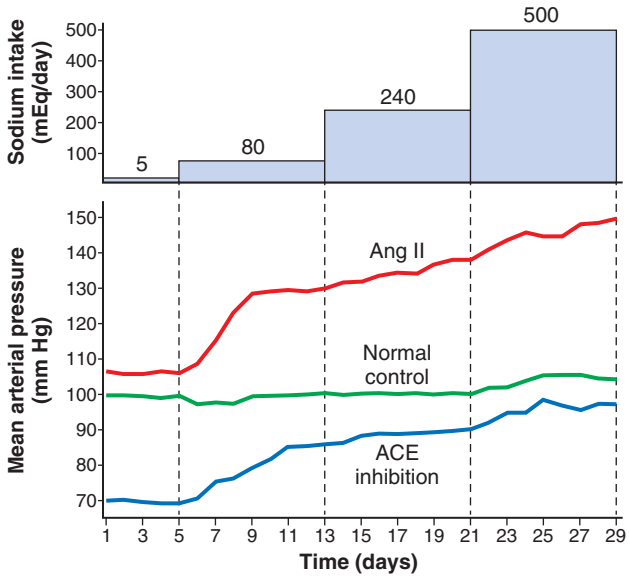

Figure 19.13 Changes in mean arterial pressure during chronic changes in sodium intake in normal control dogs and in dogs treated with an angiotensin-converting enzyme (ACE) inhibitor to block angiotensin II (Ang II) formation or infused with Ang II to prevent Ang II from being suppressed when salt intake is increased. Sodium intake was raised in steps from a low level of 5 mmol/day to 80, 240, and 500 mmol/day for 8 days at each level. (*Modified from Hall JE, Guyton AC, Smith Jr MJ, et al. Blood pressure and renal function during chronic changes in sodium intake: role of angiotensin.* Am J Physiol. *1980;239:F271.*)

the kidney after acute constriction of the renal artery, large quantities of renin are secreted by the kidney, as demonstrated by the lowermost curve in **Fig. 19.14**, and this action increases angiotensin II and aldosterone levels in the blood. The angiotensin II, in turn, raises the arterial pressure acutely. The secretion of renin rises to a peak in about 1 or 2 hours but returns nearly to normal in 5 to 7 days because the *renal* arterial pressure by that time has also risen back to normal, so the kidney is no longer ischemic.

The second rise in arterial pressure is caused by retention of salt and water by the constricted kidney, which is also stimulated by angiotensin II and aldosterone. In 5 to 7 days, the body fluid volume increases enough to raise arterial pressure to its new sustained level. The quantitative value of this sustained pressure level is determined by the degree of renal artery constriction. That is, aortic pressure must rise enough so that renal arterial pressure distal to the constrictor is high enough to cause normal urine output.

A similar scenario occurs in patients with stenosis of the renal artery of a single remaining kidney, as sometimes occurs after a person receives a kidney transplant, or because of aortic constriction above both renal arteries. Also, widespread functional or pathological increases in resistance of the renal arterioles in both kidneys, due to atherosclerosis or excessive levels of vasoconstrictors, can cause hypertension through the same mechanisms as constriction of the main renal artery.

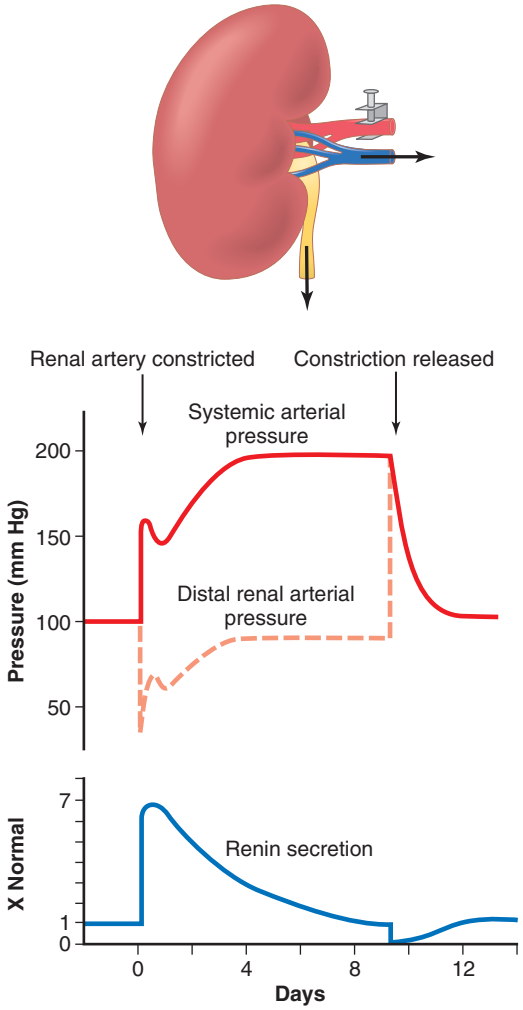

Figure 19.14 Effect of placing a constricting clamp on the renal artery of one kidney after the other kidney has been removed. Note the changes in systemic arterial pressure, renal artery pressure distal to the clamp, and rate of renin secretion. The resulting hypertension is called *one-kidney Goldblatt hypertension*.

Renal Artery Stenosis in One Kidney With a Normal Renal Artery in the Contralateral Kidney: Two-Kidney Goldblatt Hypertension. Hypertension also can result when the artery to only one kidney is constricted while the artery to the other kidney is normal. The constricted kidney secretes renin and also retains salt and water because of decreased renal arterial pressure in this kidney. Then, the "normal" opposite kidney retains salt and water because of the renin produced by the ischemic kidney. This renin causes increased formation of angiotensin II and aldosterone, both of which circulate to the opposite kidney and cause it also to retain salt and water. Thus, both kidneys—but for different reasons—become salt and water retainers. Consequently, hypertension develops.

The clinical counterpart of two-kidney Goldblatt hypertension occurs when there is stenosis of a single renal artery—for example, caused by atherosclerosis—in a person who has two kidneys.

Hypertension Caused By Diseased Kidneys That Secrete Renin Chronically. Often, patchy areas of one or both kidneys are diseased and become ischemic because of local vascular constrictions or infarctions, whereas other areas of the kidneys are normal. When this situation occurs, almost identical effects occur as in the two-kidney type of Goldblatt hypertension. That is, the patchy ischemic kidney tissue secretes renin, which increases formation of angiotensin II and causes the remaining kidney mass to retain salt and water. One of the most common causes of renal hypertension, especially in older persons, is this patchy ischemic kidney disease.

Other Types of Hypertension Caused By Combinations of Volume Loading and Vasoconstriction.

Hypertension in the Upper Part of the Body Caused By Coarctation of the Aorta. Approximately one out of every 3000 to 4000 babies is born with pathological constriction or blockage of the aorta at a point above the renal arteries, a condition called *coarctation of the aorta*. When this occurs, blood flow to the lower body is carried by multiple small collateral arteries in the body wall, with high vascular resistance between the upper aorta and lower aorta. As a consequence, the arterial pressure in the upper part of the body may be 40% to 50% higher than that in the lower body.

The mechanism of this upper body hypertension is almost identical to that of one-kidney Goldblatt hypertension. That is, when a constrictor is placed on the aorta above the renal arteries, the blood pressure in both kidneys falls at first, renin is secreted, angiotensin and aldosterone are formed, and hypertension occurs in the upper body. The arterial pressure in the lower body at the level of the kidneys rises approximately to normal, but high pressure persists in the upper body. The kidneys are no longer ischemic, and thus secretion of renin and formation of angiotensin and aldosterone return to nearly normal. Likewise, in coarctation of the aorta, the arterial pressure in the lower body is usually almost normal, whereas the pressure in the upper body is far higher than normal.

Role of Autoregulation in Hypertension Caused By Aortic Coarctation. A significant feature of hypertension caused by aortic coarctation is that blood flow in the arms, where the pressure may be 40% to 60% above normal, is almost exactly normal. Also, blood flow in the legs, where the pressure is not elevated, is almost exactly normal. How could this be, with the pressure in the upper body 40% to 60% greater than in the lower body? There are no differences in vasoconstrictor substances in the blood of the upper and lower body because the same blood flows to both areas. Likewise, the nervous system innervates both areas of the circulation similarly, so there is no reason to believe that there is a difference in nervous control of the blood vessels. The main reason is that *long-term autoregulation develops so nearly completely* that the local blood flow control mechanisms have compensated almost 100% for the differences in pressure. The result is that in both the high-pressure and low-pressure areas of the body, blood flow is controlled by local autoregulatory mechanisms in accordance with the needs of the tissue and not by the level of the blood pressure within a wide range of pressures.

Hypertension in Preeclampsia (Toxemia of Pregnancy). A syndrome called *preeclampsia* (also called *toxemia of pregnancy*) develops in approximately 5% to 10% of expectant mothers. One of the manifestations of preeclampsia is hypertension that usually subsides after delivery of the baby. Although the precise causes of preeclampsia are not completely understood, ischemia of the placenta and subsequent release by the placenta of toxic factors are believed to play a role in causing many of the manifestations of this disorder, including hypertension in the mother. Substances released by the ischemic placenta, in turn, cause dysfunction of vascular endothelial cells throughout the body, including the blood vessels of the kidneys. This *endothelial dysfunction decreases release of nitric oxide* and other vasodilator substances, causing vasoconstriction, decreased rate of fluid filtration from the glomeruli into the renal tubules, impaired renal pressure natriuresis, and development of hypertension.

Another pathological abnormality that may contribute to hypertension in preeclampsia is thickening of the kidney glomerular membranes (perhaps caused by an autoimmune process), which also reduces the glomerular fluid filtration rate. For obvious reasons, the arterial pressure level required to cause normal formation of urine becomes elevated, and the long-term level of arterial pressure becomes correspondingly elevated. These patients are especially prone to extra degrees of hypertension when they have excess salt intake.

Neurogenic Hypertension. *Acute neurogenic hypertension* can be caused by strong *stimulation of the sympathetic nervous system*. For example, when a person becomes excited for any reason or during states of anxiety, the sympathetic system becomes excessively stimulated, peripheral vasoconstriction occurs everywhere in the body, and *acute* hypertension ensues.

Another type of *acute* neurogenic hypertension occurs when the nerves leading from the baroreceptors are cut or when the tractus solitarius is destroyed in each side of the medulla oblongata. These are the areas where the nerves from the carotid and aortic baroreceptors connect in the brain stem. The sudden cessation of normal nerve signals from the baroreceptors has the same effect on the nervous pressure control mechanisms as a sudden reduction of the arterial pressure in the aorta and carotid arteries. That is, loss of the normal inhibitory effect on the vasomotor center caused by normal baroreceptor nervous signals allows the vasomotor center suddenly to become extremely active, and the mean arterial pressure may increase from 100 mm Hg to as high as 160 mm Hg. The pressure returns to nearly normal within about 2 days because the response of the vasomotor center to the absent baroreceptor signal fades away, which is called *central resetting of the baroreceptor pressure control mechanism*. Therefore, the neurogenic hypertension caused by sectioning the baroreceptor nerves is mainly an acute type of hypertension, not a chronic type.

The sympathetic nervous system also plays an important role in some forms of chronic hypertension, in large part by activation of the renal sympathetic nerves. For

example, excess weight gain and obesity often lead to activation of the sympathetic nervous system, which in turn stimulates the renal sympathetic nerves, impairs renal pressure natriuresis, and causes chronic hypertension. These abnormalities appear to play a major role in a large percentage of patients with *primary (essential) hypertension*, as discussed later.

Genetic Causes of Hypertension. Spontaneous hereditary hypertension has been observed in several strains of animals, including different strains of rats and rabbits and at least one strain of dogs. In one strain of rats that has been widely studied, the Okamoto *spontaneously hypertensive rat*, there is evidence that in early development of the hypertension, the sympathetic nervous system is considerably more active than in normal rats. In the later stages of this type of hypertension, structural changes have been observed in the nephrons of the kidneys: (1) increased preglomerular renal arterial resistance; and (2) decreased permeability of the glomerular membranes. These structural changes could also contribute to the long-term continuance of the hypertension. In other strains of hypertensive rats, impaired renal function also has been observed.

In humans, several different gene mutations have been identified that can cause hypertension. These forms of hypertension are called *monogenic hypertension* because they are caused by mutation of a single gene. An interesting feature of these genetic disorders is that they all cause impaired kidney function, either by increased resistance of the renal arterioles or by excessive salt and water reabsorption by the renal tubules. In some cases, the increased reabsorption is due to gene mutations that directly increase the transport of sodium or chloride in the renal tubular epithelial cells. In other cases, the gene mutations cause increased synthesis or activity of hormones that stimulate renal tubular salt and water reabsorption. Thus, in all monogenic hypertensive disorders discovered thus far, the final common pathway to hypertension appears to be impaired kidney function. Monogenic hypertension, however, is rare, and all the known forms together account for less than 1% of cases of human hypertension.

PRIMARY (ESSENTIAL) HYPERTENSION

About 90% to 95% of all people who have hypertension are said to have *primary hypertension*, also referred to as *essential hypertension* by many clinicians. These terms simply mean that *the hypertension is of unknown origin*, in contrast to the forms of hypertension that are *secondary* to known causes, such as renal artery stenosis or monogenic forms of hypertension.

In most patients with primary hypertension, *excess weight gain* and *a sedentary lifestyle* appear to play a major role in elevating blood pressure. Studies of different populations have suggested that excess adiposity may account for as much as 65% to 75% of the risk for developing primary hypertension. Clinical studies have clearly shown the value of weight loss for reducing blood pressure in most patients with hypertension, and clinical guidelines for treating hypertension recommend increased physical activity and weight loss as a first step in treating most patients with hypertension.

The following characteristics of primary hypertension, among others, are caused by excess weight gain and obesity:

1. *Cardiac output is increased* in part because of the additional blood flow required for the extra adipose tissue. However, blood flow in the heart, kidneys, gastrointestinal tract, and skeletal muscle also increases with weight gain because of increased metabolic rate and growth of the organs and tissues in response to their increased metabolic demands. As the hypertension is sustained for many months and years, total peripheral vascular resistance may be increased.
2. *Sympathetic nerve activity, especially in the kidneys, is increased in overweight and obese patients*. The causes of increased sympathetic activity in obese persons are not fully understood, but studies have suggested that hormones such as *leptin* that are released from fat cells may directly stimulate multiple regions of the hypothalamus, which in turn have an excitatory influence on the vasomotor centers of the brain medulla. There is also evidence that people who are obese have reduced sensitivity of arterial baroreceptors for buffering increases in arterial pressure, as well as activation of chemoreceptors, especially in those who also have obstructive sleep apnea.
3. *Angiotensin II and aldosterone levels are increased in many obese patients*. This increase may be caused partly by increased sympathetic nerve stimulation, which increases renal renin release and therefore formation of angiotensin II, which in turn stimulates the adrenal gland to secrete aldosterone.
4. *The renal-pressure natriuresis mechanism is impaired, and the kidneys will not excrete adequate amounts of salt and water unless the arterial pressure is high or kidney function is somehow improved*. If mean arterial pressure in a person with primary hypertension is 150 mm Hg, acute reduction of mean arterial pressure to the normal value of 100 mm Hg (but without otherwise altering renal function except for the decreased pressure) will cause almost total anuria. The person will then retain salt and water until the pressure rises back to the elevated value of 150 mm Hg. Chronic reductions in arterial pressure with effective antihypertensive therapies, however, usually do not cause marked salt and water retention by the kidneys because these therapies also improve renal pressure natriuresis, as discussed later.

Experimental studies in obese animals and obese patients have suggested that impaired renal pressure natriuresis in obesity hypertension is caused mainly by increased renal tubular reabsorption of salt and water due to increased sympathetic nerve activity, increased levels

of angiotensin II and aldosterone, and perhaps by physical compression of the kidneys due to excessive adipose tissue surrounding the kidneys or invading the renal sinuses. If hypertension is not effectively treated, there may also be vascular damage in the kidneys that can reduce glomerular filtration rate and increase the severity of hypertension. Eventually, uncontrolled hypertension associated with obesity and associated metabolic disorders can lead to severe vascular injury and loss of kidney function.

Graphic Analysis of Arterial Pressure Control in Primary (Essential) Hypertension. **Fig. 19.15** is a graphic analysis of primary (essential) hypertension. The curves of this figure are called *sodium-loading renal function curves* because the arterial pressure in each case is increased slowly, over many days or weeks, by gradually increasing the level of sodium intake. The sodium-loading type of curve can be determined by increasing the level of sodium intake to a new level every few days and then waiting for the renal output of sodium to come into balance with the intake and, at the same time, recording the changes in arterial pressure.

When this procedure is used in patients with primary hypertension, two types of curves, shown at the right in **Fig. 19.15**, can be recorded; one is called (1) *salt-insensitive* hypertension and the other (2) *salt-sensitive* hypertension. Note in both cases that the curves are shifted to the right, to higher pressures than for people with normal arterial pressure. In persons with salt-insensitive essential hypertension, arterial pressure does not increase significantly when changing from a normal salt intake to a high salt intake. However, in persons who have salt-sensitive essential hypertension, the high salt intake significantly exacerbates the hypertension.

Two additional points should be emphasized. First, salt sensitivity of blood pressure is not an all-or-none finding—it is a quantitative trait, with some individuals being more salt-sensitive than others. Second, salt sensitivity of blood pressure is not a fixed characteristic; instead, blood pressure usually becomes more salt sensitive as a person ages, especially after 50 or 60 years of age, when the number of functional units *(nephrons)* in the kidneys begins to decrease gradually.

The reason for the difference between salt-insensitive primary hypertension and salt-sensitive hypertension is presumably related to structural or functional differences in the kidneys of these two types of hypertension. For example, salt-sensitive hypertension may occur with different types of chronic renal disease because of the gradual loss of nephrons or because of normal aging, as discussed in Chapter 32. Abnormal function of the renin-angiotensin system can also cause arterial pressure to become salt-sensitive, as discussed previously in this chapter.

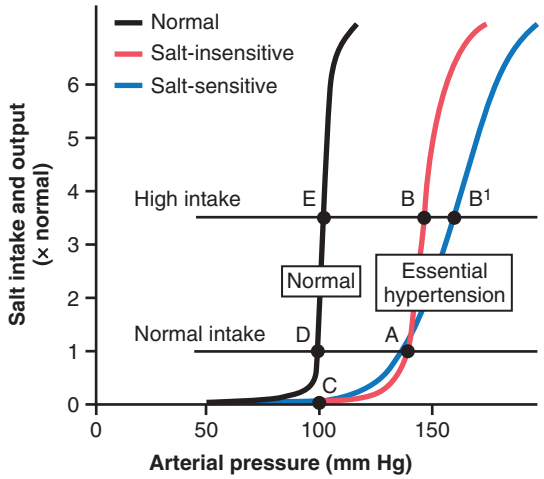

Figure 19.15 Analysis of arterial pressure regulation in (1) salt-insensitive essential hypertension and (2) salt-sensitive essential hypertension. (*Modified from Guyton AC, Coleman TG, Young DB, et al. Salt balance and long-term blood pressure control.* Annu Rev Med. *1980;31:15.*)

Treatment of Essential Hypertension. Current guidelines for treating hypertension recommend, as a first step, lifestyle modifications aimed at increasing physical activity and weight loss in most patients. Unfortunately, many patients are unable to maintain weight loss, and pharmacological treatment with antihypertensive drugs must be initiated. Two general classes of drugs are used to treat hypertension: (1) *vasodilator drugs*, which increase renal blood flow and glomerular filtration rate; and (2) *natriuretic or diuretic drugs*, which decrease tubular reabsorption of salt and water.

Vasodilator drugs usually cause vasodilation in many other tissues of the body, as well as in the kidneys. Many of the different vasodilators act in one of the following ways: (1) by inhibiting sympathetic nervous signals to the kidneys or by blocking the action of the sympathetic transmitter substance on the renal vasculature and renal tubules; (2) by directly relaxing the smooth muscle of the renal vasculature; or (3) by blocking the action of the renin-angiotensin-aldosterone system on the renal vasculature, as well as on the renal tubules.

Drugs that reduce the reabsorption of salt and water by the renal tubules include, in particular, drugs that block active transport of sodium through the tubular wall; this blockage in turn also prevents the reabsorption of water, as explained earlier in the chapter. These natriuretic or diuretic drugs are discussed in greater detail in Chapter 32.

SUMMARY OF INTEGRATED MULTIFACETED SYSTEMS FOR ARTERIAL PRESSURE REGULATION

It is clear that arterial pressure is regulated not by a single pressure controlling system but instead by several interrelated systems, each of which performs a specific function. For example, when a person bleeds so severely that the pressure falls suddenly, two problems confront the pressure control system. The first is survival; the arterial pressure must be rapidly returned to a high enough level

that the person can live through the acute episode. The second is to return the blood volume and arterial pressure eventually to their normal levels so that the circulatory system can reestablish full normality, not merely back to the levels required for survival.

In Chapter 18, we saw that the first line of defense against acute changes in arterial pressure is the nervous control system. In this chapter, we have emphasized a second line of defense achieved mainly by kidney mechanisms for the long-term control of arterial pressure. However, there are other pieces to the puzzle. **Fig. 19.16** helps put these pieces together.

Fig. 19.16 shows the approximate immediate (seconds and minutes) and long-term (hours and days) control responses, expressed as feedback gain, of eight arterial pressure control mechanisms. These mechanisms can be divided into three groups: (1) those that react rapidly, within seconds or minutes; (2) those that respond over an intermediate time period—that is, minutes or hours; and (3) those that provide long-term arterial pressure regulation for days, months, and years.

Arterial Pressure Control Mechanisms That Act Rapidly, Within Seconds or Minutes. The rapidly acting pressure control mechanisms are mainly acute nervous reflexes or other autonomic nervous system responses. Three mechanisms are shown in **Fig. 19.16** that respond within seconds: (1) the baroreceptor feedback mechanism; (2) the central nervous system ischemic mechanism; and (3) the chemoreceptor mechanism. Not only do these mechanisms begin to react within seconds, but they are also powerful. After any acute fall in pressure, as might be caused by severe hemorrhage, the nervous mechanisms combine to cause the following: (1) constriction of the veins and transfer of blood into the heart; (2) increased heart rate and contractility of the heart to provide greater pumping capability by the heart; and (3) constriction of most peripheral arterioles. All these effects occur almost instantly to raise the arterial pressure back into a survival range.

When the pressure suddenly rises too high, as might occur in response to a rapid transfusion of excess blood, the same control mechanisms operate in the reverse direction, again returning the pressure back toward normal.

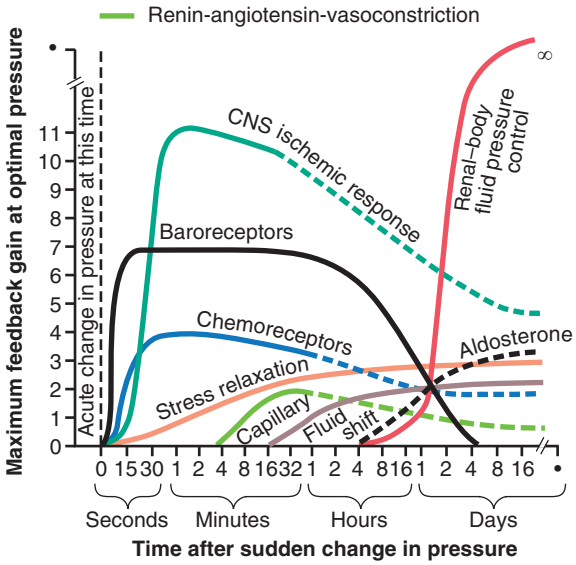

Figure 19.16 Approximate potency of various arterial pressure control mechanisms at different time intervals after the onset of a disturbance to the arterial pressure. Note especially the near-infinite gain (∞) of the renal body fluid pressure control mechanism that occurs after a few weeks' time. *CNS*, Central nervous system. (*Modified from Guyton AC.* Arterial Pressure and Hypertension. *Philadelphia: WB Saunders, 1980.*)

Arterial Pressure Control Mechanisms That Act After Many Minutes. Several pressure control mechanisms exhibit significant responses only after a few minutes following an acute arterial pressure change. Three of these mechanisms, shown in **Fig. 19.16**, are as follows: (1) the renin-angiotensin vasoconstrictor mechanism; (2) stress relaxation of the vasculature; and (3) shift of fluid through the tissue capillary walls in and out of the circulation to readjust the blood volume as needed.

We have already described at length the role of the renin-angiotensin vasoconstrictor system to provide a semiacute means for increasing the arterial pressure when necessary. The *stress relaxation mechanism* is demonstrated by the following example. When the pressure in the blood vessels becomes too high, they become stretched more and more for minutes or hours; as a result, the pressure in the vessels falls toward normal. This continuing stretch of the vessels, called *stress relaxation*, can serve as an intermediate-term pressure "buffer."

The *capillary fluid shift mechanism* means that whenever capillary pressure falls too low, fluid is absorbed from the tissues through the capillary membranes and into the circulation, thus building up the blood volume and increasing the pressure in the circulation. Conversely, when the capillary pressure rises too high, fluid is lost out of the circulation into the tissues, thus reducing the blood volume, as well as virtually all the pressures throughout the circulation.

These three intermediate mechanisms mostly become activated within 30 minutes to several hours.

Long-Term Mechanisms for Arterial Pressure Regulation. The goal of this chapter has been to explain the role of the kidneys in long-term control of arterial pressure. To the far right in **Fig. 19.16** is shown the renal–blood volume pressure control mechanism, which is the same as the renal–body fluid pressure control mechanism, demonstrating that it takes a few hours to begin showing significant response. Yet, it eventually develops a feedback gain for control of arterial pressure that is nearly equal to infinity. This means that this mechanism can eventually return the arterial pressure nearly *all the way* back, not merely partway back, to the pressure level that provides normal output of salt and water by the kidneys.

Many factors can affect the pressure-regulating level of the renal–body fluid mechanism. One of these, shown in **Fig. 19.16**, is aldosterone. A decrease in arterial pressure leads within minutes to an increase in aldosterone secretion and, over the next hour or days, this effect plays an important role in increasing renal tubular reabsorption of salt and water and therefore modifying the pressure control characteristics of the renal–body fluid mechanism.

Especially important is the interaction of the renin-angiotensin system with the aldosterone and renal fluid mechanisms. For example, a person's salt intake varies tremendously from one day to another. We have seen in this chapter that salt intake can decrease to as little as one-tenth normal or can increase to 10 to 15 times normal, and yet the regulated level of the mean arterial pressure will barely change if the renin-angiotensin-aldosterone system is fully operative. However, without a functional renin-angiotensin-aldosterone system, blood pressure becomes very sensitive to changes in salt intake.

Thus, arterial pressure control begins with the life-saving measures of the nervous pressure controls, then continues with the sustaining characteristics of the intermediate pressure controls and, finally, is stabilized at the long-term pressure level by the renal–body fluid mechanism. This long-term mechanism, in turn, has multiple interactions with the renin-angiotensin-aldosterone system, the nervous system, and several other factors that provide special blood pressure control capabilities for special purposes.

CHAPTER 20

Cardiac Output, Venous Return, and Their Regulation

Cardiac output is the quantity of blood pumped into the aorta each minute by the heart. This is also the quantity of blood that flows through the circulation. Because cardiac output is the sum of blood flows to all the tissues of the body, it is one of the most important factors to consider in relation to function of the cardiovascular system.

Venous return is equally important because it is the quantity of blood flowing from the veins into the right atrium each minute. The venous return and the cardiac output must equal each other except for a few heartbeats when blood is temporarily stored in or removed from the heart and lungs.

NORMAL VALUES FOR CARDIAC OUTPUT AT REST AND DURING ACTIVITY

Cardiac output varies widely with the level of activity of the body. The following factors, among others, directly affect cardiac output: (1) the basic level of body metabolism; (2) whether the person is exercising; (3) the person's age; and (4) the size of the body.

For *young healthy men* with a body weight of about 70 kg, resting cardiac output averages approximately 5.6 L/min. For *women*, this value is about 15% lower, or approximately 4.9 L/min. When one considers the factor of age as well—because with increasing age, body activity and mass of some tissues (e.g., skeletal muscle) diminish—the average cardiac output for resting adults, in round numbers, is often stated to be about 5 L/min. However, cardiac output varies considerably among healthy men and women, depending on muscle mass, adiposity, physical activity, age, and other factors that influence metabolic rate and nutritional needs of the tissues.

Over the past several decades, body weight of men and women in the United States and in many other countries has steadily increased. Recent estimates indicate that the average weight for adult men has risen to approximately 90 kg (198 lb) and for adult women to 77.5 kg (171 lb) in the United States. These increases in average body weight are generally associated with additional adipose tissue, as well as skeletal muscle, and with the size of some organs, all of which require additional blood flow to support their metabolic needs. Therefore, the current average cardiac output for adult men and women may be significantly higher than 5 L/min.

Cardiac Index

Experiments have shown that the cardiac output increases approximately in proportion to the surface area of the body. Therefore, cardiac output is frequently stated in terms of the *cardiac index*, which is the *cardiac output per square meter of body surface area*. A person who weighs 70 kg has an average body surface area of about 1.7 square meters, which means that the average cardiac index for adults weighing 70 kg is about 3 L/min/m^2 of body surface area.

Body surface area, calculated from body weight and height, is slightly overestimated with commonly used equations in people with obesity. Also, obesity is associated with substantial increases in adipose tissue, which has a lower blood flow per gram of tissue weight compared with many other tissues, such as skeletal muscle. Therefore, cardiac index may not be elevated in people with obesity despite substantial increases in cardiac output and blood flow in various tissues and organs due to their additional metabolic demands.

Effect of Age on Cardiac Output. Fig. 20.1 shows the cardiac output, expressed as cardiac index, at different ages. The cardiac index rises rapidly to a level greater than 4 L/min/m^2 at age 10 years and declines to about 2.4 L/min/m^2 at age 80 years. We explain later in this chapter that cardiac output is regulated throughout life almost directly in proportion to overall metabolic activity. Therefore, the declining cardiac index is indicative of declining activity and/or declining muscle mass and increasing adiposity with age.

CONTROL OF CARDIAC OUTPUT BY VENOUS RETURN—FRANK-STARLING MECHANISM OF THE HEART

Although heart function is obviously crucial in determining cardiac output, the various factors of the peripheral circulation that affect flow of blood into the heart from the veins, called *venous return*, are normally the primary controllers of cardiac output.

The main reason why peripheral factors are usually so important in controlling cardiac output is that the

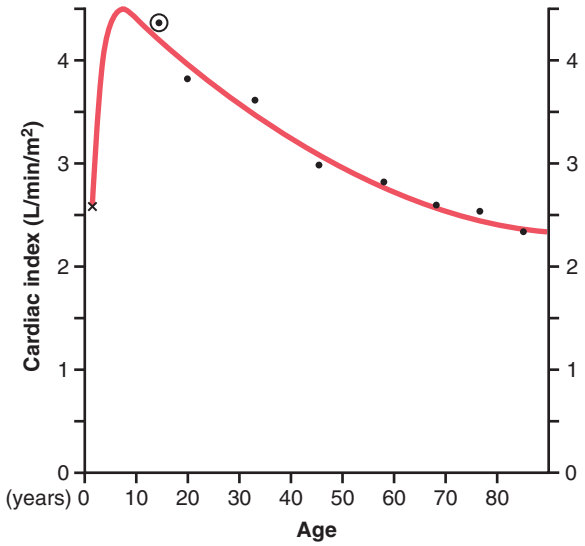

Figure 20.1 Cardiac index for a person—cardiac output per square meter of surface area—at different ages. *(Modified from Guyton AC, Jones CE, Coleman TG.* Circulatory Physiology: Cardiac Output and Its Regulation. *2nd ed. Philadelphia: WB Saunders; 1973.)*

heart has a built-in mechanism that normally allows it to pump automatically the amount of blood that flows from the veins into the right atrium. This mechanism, called the *Frank-Starling law of the heart*, was discussed in Chapter 9. When increased quantities of blood flow into the heart, the increased volume of blood stretches the walls of the heart chambers and causes the cardiac muscle to contract with increased force, ejecting the extra blood that has entered from the systemic circulation. Therefore, the blood that flows into the heart is automatically pumped without delay into the aorta and flows again through the circulation.

Another important factor, discussed in Chapters 10 and 18, is that stretching the heart increases heart rate. Stretch of the *sinus node* in the wall of the right atrium has a direct effect on the rhythmicity of the node to increase the heart rate as much as 10% to 15%. In addition, the stretched right atrium initiates a nervous reflex called the *Bainbridge reflex*, passing first to the vasomotor center of the brain and then back to the heart by way of the sympathetic nerves and vagi, which also increases the heart rate.

Under most normal unstressed conditions, the cardiac output is controlled mainly by peripheral factors that determine venous return. However, as we discuss later in the chapter, if the returning blood does become more than the heart can pump, then the heart becomes the limiting factor that determines cardiac output.

Cardiac Output Is the Sum of All Tissue Blood Flows—Tissue Metabolism Regulates Most Local Blood Flow

The venous return to the heart is the sum of all the local blood flow through all the individual tissue segments of the peripheral circulation (**Fig. 20.2**). Therefore, it follows that cardiac output regulation is normally determined by local blood flow regulation in all of the tissues of the body.

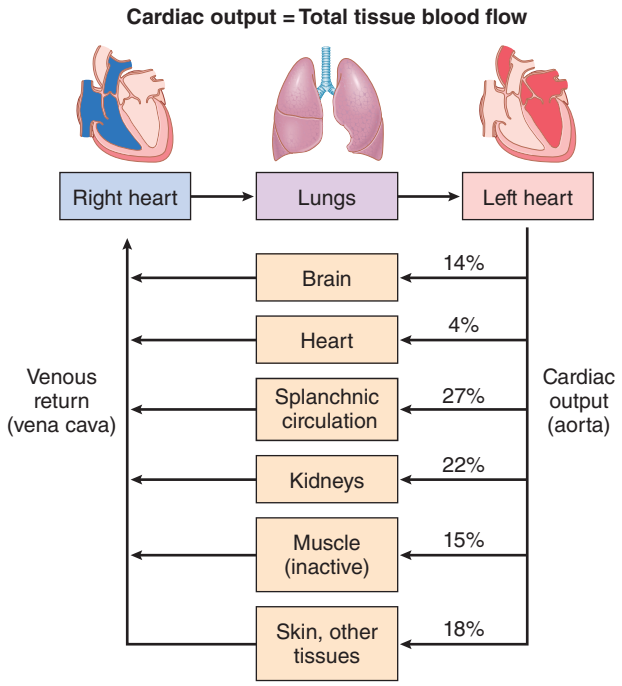

Figure 20.2 Cardiac output is equal to venous return and is the sum of tissue and organ blood flows. Except when the heart is severely weakened and unable to pump the venous return adequately, cardiac output (total tissue blood flow) is determined mainly by the metabolic needs of the tissues and organs of the body.

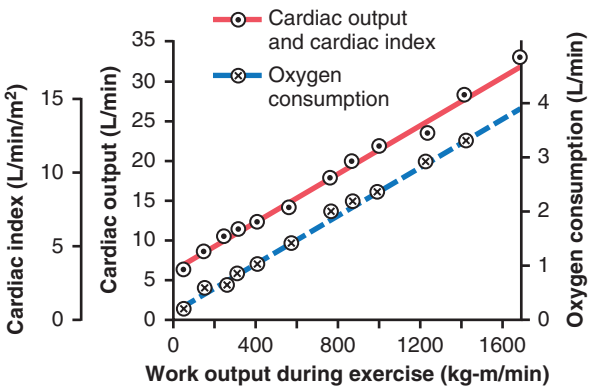

Figure 20.3 Effect of increasing levels of exercise to increase cardiac output (*red solid line*) and oxygen consumption (*blue dashed line*). *(Modified from Guyton AC, Jones CE, Coleman TG.* Circulatory Physiology: Cardiac Output and Its Regulation. *2nd ed. Philadelphia: WB Saunders; 1973.)*

The mechanisms of local blood flow regulation were discussed in Chapter 17. In most tissues, blood flow increases mainly in proportion to each tissue's metabolism. For example, local blood flow almost always increases when tissue oxygen consumption increases; this effect is demonstrated in **Fig. 20.3** for different levels of exercise. Note that at each increasing level of work output during exercise, oxygen consumption and cardiac output increase in parallel to each other.

To summarize, cardiac output is usually determined by the sum of all the various factors throughout the body that control local blood flow. All the local blood flows

summate to form the venous return, and the heart automatically pumps this returning blood back into the arteries to flow around the system again.

Cardiac Output Varies Inversely With Total Peripheral Vascular Resistance When Arterial Pressure Is Unchanged. **Fig. 20.4** is the same as **Fig. 19.5**. It is repeated here to illustrate an extremely important principle in cardiac output control: Under many conditions, the long-term cardiac output level varies reciprocally with changes in total peripheral vascular resistance as long as the arterial pressure is unchanged. Note in **Fig. 20.4** that when the total peripheral resistance is exactly normal (at the 100% mark in the figure), the cardiac output is also normal. Then, when the total peripheral resistance increases above normal, the cardiac output falls; conversely, when the total peripheral resistance decreases, the cardiac output increases. One can easily understand this phenomenon by reconsidering one of the forms of Ohm's law, as expressed in Chapter 14:

$$\text{Cardiac output} = \frac{\text{Arterial pressure}}{\text{Total peripheral resistance}}$$

Thus, any time the long-term level of total peripheral resistance changes (but no other functions of the circulation change), the cardiac output changes quantitatively in the opposite direction.

Limits for the Cardiac Output

There are definite limits to the amount of blood that the heart can pump, which can be expressed quantitatively in the form of *cardiac output curves*.

Fig. 20.5 demonstrates the *normal cardiac output curve*, showing the cardiac output per minute at each level of right atrial pressure. This is one type of *cardiac function curve*, which was discussed in Chapter 9. Note that the plateau level of this normal cardiac output curve is about 13 L/min, 2.5 times the normal cardiac output of about 5 L/min. This means that the normal human heart, functioning without any special stimulation, can pump a venous return up to about 2.5 times the normal venous return before the heart becomes a limiting factor in the control of cardiac output.

Shown in **Fig. 20.5** are several other cardiac output curves for hearts that are not pumping normally. The uppermost curves are for *hypereffective hearts* that are pumping more powerfully than normal. The lowermost curves are for *hypoeffective hearts* that are pumping at levels below normal.

Factors That Cause a Hypereffective Heart

Two general types of factors that can make the heart a stronger pump than normal are nervous stimulation and hypertrophy of the heart muscle.

Sympathetic Nervous Stimulation and Parasympathetic Inhibition Can Increase Heart Pumping. In Chapter 9, we saw that a combination of sympathetic *stimulation* and parasympathetic *inhibition* does two things to increase the pumping effectiveness of the heart: (1) it greatly increases the heart rate—sometimes, in young people, from the normal level of 72 beats/min up to 180 to 200 beats/min; and (2) it increases the strength of heart contraction (called *increased contractility*) to twice its normal strength. Combining these two effects, maximal

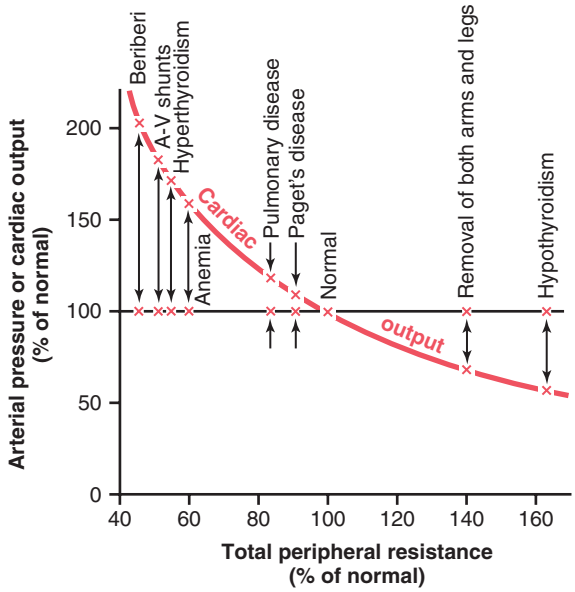

Figure 20.4 Chronic effect of different levels of total peripheral resistance on cardiac output, showing a reciprocal relationship between total peripheral resistance and cardiac output. *A-V*, Arterial-venous. *(Modified from Guyton AC.* Arterial Pressure and Hypertension. *Philadelphia: WB Saunders; 1980.)*

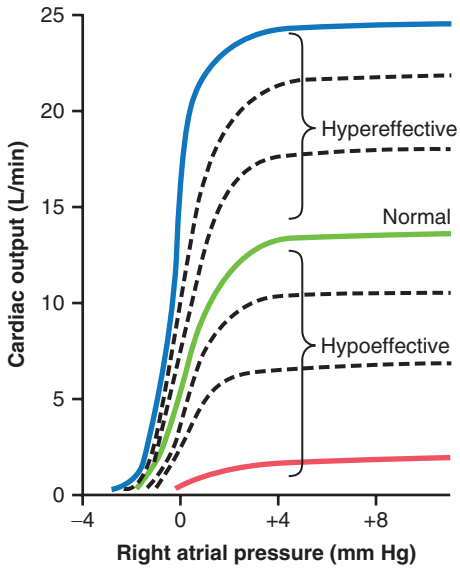

Figure 20.5 Cardiac output curves for the normal heart and for hypoeffective and hypereffective hearts. *(Modified from Guyton AC, Jones CE, Coleman TG.* Circulatory Physiology: Cardiac Output and Its Regulation. *2nd ed. Philadelphia: WB Saunders; 1973.)*

nervous excitation of the heart can raise the plateau level of the cardiac output curve to almost twice the plateau of the normal curve, resulting in a maximum cardiac output of about 25 L/min, as shown by the uppermost curve in Fig. 20.5.

Hypertrophy of the Heart Can Increase Its Pumping Effectiveness. A long-term increased workload, but not so much excess load that it damages the heart, causes the heart muscle to increase in mass and contractile strength in the same way that heavy exercise causes skeletal muscles to hypertrophy. For example, the hearts of marathon runners may be increased in mass by 50% to 75%. This factor increases the plateau level of the cardiac output curve, sometimes 60% to 100%, and therefore allows the heart to pump much greater than the usual amounts of cardiac output.

When one combines nervous excitation of the heart and hypertrophy, as occurs in marathon runners, the total effect can allow the heart to pump as much as 30 to 40 L/min, about 2.5 times the level that can be achieved in the average person. This increased level of pumping is one of the most important factors in determining the runner's running time.

Factors That Cause a Hypoeffective Heart

Any factor that decreases the heart's ability to pump blood causes hypoeffectivity. Some of the factors that can decrease the heart's ability to pump blood are the following:

- Increased arterial pressure against which the heart must pump, such as in severe hypertension
- Inhibition of nervous excitation of the heart
- Pathological factors that cause abnormal heart rhythm or rate of heartbeat
- Coronary artery blockage, causing a heart attack
- Valvular heart disease
- Congenital heart disease
- Myocarditis, an inflammation of the heart muscle
- Cardiac hypoxia

NERVOUS SYSTEM REGULATION OF CARDIAC OUTPUT

Importance of Nervous System for Maintaining Arterial Pressure When Peripheral Blood Vessels Are Dilated and Venous Return and Cardiac Output Increase. Fig. 20.6 shows an important difference in cardiac output control with and without a functioning autonomic nervous system. The solid curves demonstrate the effect in the normal dog of intense dilation of the peripheral blood vessels caused by administering the drug dinitrophenol, which increased the metabolism of virtually all tissues of the body about 4-fold. With nervous control mechanisms intact, dilating the peripheral blood vessels caused almost no change in arterial pressure but increased the cardiac output almost 4-fold. However, after autonomic control of the nervous system was blocked, dilation of the blood vessels with dinitrophenol (dashed curves) caused a profound fall in arterial pressure to about one-half normal, and the cardiac output increased only 1.6-fold instead of 4-fold.

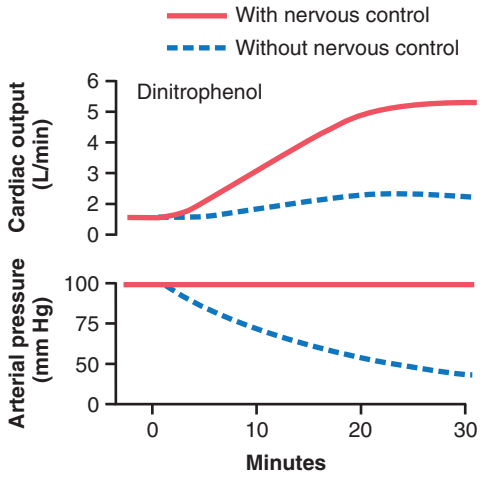

Figure 20.6 Experiment in a dog to demonstrate the importance of nervous maintenance of the arterial pressure as a prerequisite for cardiac output control. Note that with pressure control, the metabolic stimulant *dinitrophenol* increased cardiac output greatly; without pressure control, the arterial pressure fell, and the cardiac output increased very little. *(Drawn from experiments by Dr. M. Banet.)*

Thus, maintenance of a normal arterial pressure by the nervous system reflexes, by mechanisms explained in Chapter 18, is essential to achieve high cardiac outputs when the peripheral tissues intensely dilate their blood vessels to markedly increase the venous return.

Effect of Nervous System to Increase Arterial Pressure During Exercise. During exercise, intense increases in metabolism in active skeletal muscles cause relaxation of muscle arterioles to allow adequate oxygen and other nutrients needed to sustain muscle contraction. This greatly decreases the total peripheral resistance, which normally would decrease the arterial pressure. However, the nervous system immediately compensates. The same brain activity that sends motor signals to the muscles sends simultaneous signals into the autonomic nervous centers of the brain to excite circulatory activity, causing large vein constriction, increased heart rate, and increased contractility of the heart. All these changes acting together increase the arterial pressure above normal, which in turn forces still more blood flow through the active muscles.

In summary, when local tissue blood vessels dilate and increase venous return and cardiac output above normal, the nervous system plays a key role in preventing the arterial pressure from falling to low levels. During exercise, the nervous system goes even further, providing additional signals to raise the arterial pressure above normal, which serves to increase the cardiac output an extra 30% to 100%.

Pathologically High or Low Cardiac Outputs

Multiple clinical abnormalities can cause either high or low cardiac outputs. Some of the more important of these abnormal cardiac outputs are shown in **Fig. 20.7**.

High Cardiac Output Caused By Reduced Total Peripheral Resistance

The left side of **Fig. 20.7** identifies conditions that cause abnormally high cardiac outputs. One of the distinguishing features of these conditions is that *they all result from chronically reduced total peripheral resistance*. None of them result from excessive excitation of the heart itself, which we will explain subsequently. Let us consider some of the conditions that can decrease the peripheral vascular resistance and at the same time increase the cardiac output to above normal.

1. *Beriberi.* This disease is caused by insufficient quantity of the vitamin *thiamine* (vitamin B_1) in the diet. Lack of this vitamin causes diminished ability of the tissues to use some cellular nutrients, and local tissue blood flow control mechanisms in turn cause marked compensatory peripheral vasodilation. Sometimes the total peripheral resistance decreases to as little as half-normal. Consequently, the long-term levels of venous return and cardiac output also may increase to twice the normal value.
2. *Arterial-venous (A-V) fistula (shunt).* Earlier, we pointed out that whenever a fistula (also called an *A-V shunt*) occurs between a major artery and major vein, large amounts of blood flow directly from the artery into the vein. This also greatly decreases the total peripheral resistance and, likewise, increases the venous return and cardiac output.
3. *Hyperthyroidism.* In hyperthyroidism, the metabolism of most tissues of the body is greatly increased. Oxygen usage increases, and vasodilator products are released from the tissues. Therefore, total peripheral resistance decreases markedly because of local tissue blood flow control reactions throughout the body; consequently, venous return and cardiac output often increase to 40% to 80% above normal.
4. *Anemia.* In anemia, two peripheral effects decrease total peripheral resistance. One of these effects is reduced viscosity of the blood, resulting from decreased concentration of red blood cells. The other effect is diminished delivery of oxygen to the tissues, which causes local vasodilation. As a consequence, cardiac output increases.

Any other factor that decreases total peripheral resistance chronically also increases cardiac output if arterial pressure does not decrease too much.

Low Cardiac Output

Fig. 20.7 shows at the far right several conditions that cause abnormally low cardiac output. These conditions fall into two general categories: (1) abnormalities that decrease pumping effectiveness of the heart; and (2) abnormalities that decrease venous return.

Decreased Cardiac Output Caused By Cardiac Factors. Whenever the heart becomes severely damaged, regardless of the cause, its limited level of pumping may fall below that needed for adequate blood flow to the tissues. Some examples of this condition include the following: (1) *severe coronary blood vessel blockage and consequent myocardial infarction;* (2) *severe valvular heart disease;* (3) *myocarditis;* (4) *cardiac tamponade;* and (5) *cardiac metabolic derangements*. The effects of several of these conditions are shown on the right in **Fig. 20.7**, demonstrating the resultant low cardiac outputs.

When the cardiac output falls so low that the tissues throughout the body begin to suffer nutritional deficiency,

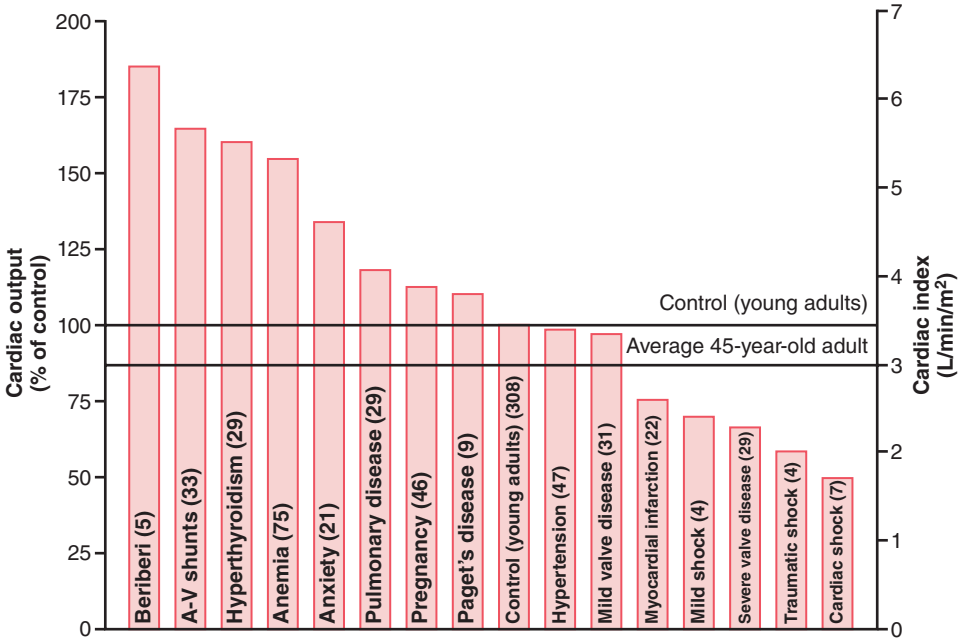

Figure 20.7 Cardiac output in different pathological conditions. The numbers in parentheses indicate the number of patients studied in each condition. *AV*, Atrioventricular. *(Modified from Guyton AC, Jones CE, Coleman TG.* Circulatory Physiology: Cardiac Output and Its Regulation. *2nd ed. Philadelphia: WB Saunders; 1973.)*

the condition is called *cardiac (cardiogenic) shock*. This condition is discussed in Chapter 22 in relationship to cardiac failure.

Decreased Cardiac Output Caused By Noncardiac Peripheral Factors—Decreased Venous Return. Anything that interferes with venous return also can lead to decreased cardiac output. Some of these factors are as follows:

1. *Decreased blood volume.* The most common noncardiac peripheral factor that leads to decreased cardiac output is decreased blood volume, often from hemorrhage. Loss of blood may decrease the filling of the vascular system to such a low level that there is not enough blood in the peripheral vessels to create peripheral vascular pressures high enough to push the blood back to the heart.
2. *Acute venous dilation.* Acute venous dilation results most often when the sympathetic nervous system suddenly becomes inactive. For example, fainting often results from sudden increases in parasympathetic activity or loss of sympathetic nervous system activity, which causes the peripheral capacitance vessels, especially the veins, to dilate markedly. This dilation decreases the filling pressure of the vascular system because the blood volume can no longer create adequate pressure in the now flaccid peripheral blood vessels. As a result, the blood pools in the vessels and does not return to the heart as rapidly as normal.
3. *Obstruction of the large veins.* On rare occasions, the large veins leading into the heart become obstructed, and the blood in the peripheral vessels cannot flow back into the heart. Consequently, the cardiac output falls markedly.
4. *Decreased tissue mass, especially decreased skeletal muscle mass.* With normal aging or with prolonged periods of physical inactivity, a reduction in the size of the skeletal muscles usually occurs. This reduction, in turn, decreases the total oxygen consumption and blood flow needs of the muscles, resulting in decreases in skeletal muscle blood flow and cardiac output.
5. *Decreased metabolic rate of the tissues.* If the tissue metabolic rate is reduced, as occurs in skeletal muscle during prolonged bed rest, the oxygen consumption and nutrition needs of the tissues will also be lower, which decreases blood flow to the tissues, resulting in reduced cardiac output. Other conditions, such as *hypothyroidism*, may also reduce metabolic rate and therefore tissue blood flow and cardiac output.

Regardless of whether a peripheral factor or a cardiac factor causes low cardiac output, if the cardiac output ever falls below the level required for adequate nutrition of the tissues, the person will experience *circulatory shock*. This condition can be lethal within a few minutes to a few hours. Circulatory shock is such an important clinical problem that it is discussed in detail in Chapter 24.

CARDIAC OUTPUT CURVES FOR QUANTITATIVE ANALYSIS OF CARDIAC OUTPUT REGULATION

Our discussion of cardiac output regulation thus far is adequate for understanding the factors that control cardiac output in most simple conditions. However, to understand cardiac output regulation in especially stressful situations, such as the extremes of exercise, cardiac failure, and circulatory shock, a more complex quantitative analysis is presented in the following sections.

To perform the more quantitative analysis, it is necessary to distinguish separately the two primary factors concerned with cardiac output regulation: (1) the pumping ability of the heart, as represented by *cardiac output curves*; and (2) the peripheral factors that affect flow of blood from the veins into the heart, as represented by *venous return curves*. Then we can put these curves together in a quantitative way to show how they interact with each other to determine cardiac output, venous return, and right atrial pressure at the same time.

Some of the cardiac output curves used to depict quantitative heart pumping effectiveness have already been shown in **Fig. 20.5**. However, an additional set of curves is required to show the effect on cardiac output caused by changing external pressures on the outside of the heart, as explained in the next section.

Effect of External Pressure Outside the Heart on Cardiac Output Curves. **Fig. 20.8** shows the effect of changes in external cardiac pressure on the cardiac output curve. The normal external pressure is equal to the normal intrapleural pressure (the pressure in the chest cavity), which is about −4 mm Hg. Note in the figure that a rise in intrapleural pressure, to −2 mm Hg for example, shifts the entire cardiac output curve to the right by the same amount. This shift occurs because filling the cardiac chambers with blood requires an extra 2 mm Hg of right atrial pressure to overcome the increased pressure on the outside of the heart. Likewise, an increase in intrapleural pressure to +2 mm Hg requires a 6 mm Hg increase in right atrial pressure from the normal −4 mm Hg, which shifts the entire cardiac output curve 6 mm Hg to the right.

Some factors that can alter the external pressure on the heart and shift the cardiac output curve are the following:

1. *Cyclical changes of intrapleural pressure during respiration*, which are about ±2 mm Hg during normal

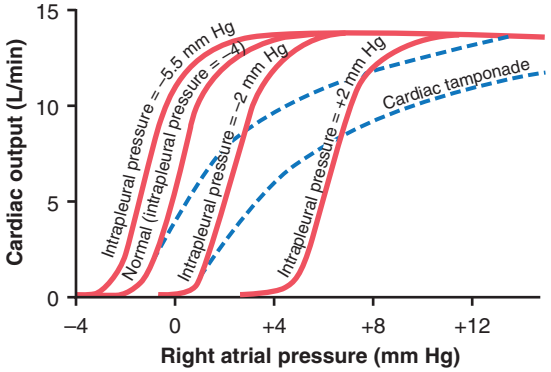

Figure 20.8 Cardiac output curves at different levels of intrapleural pressure and different degrees of cardiac tamponade. *(Modified from Guyton AC, Jones CE, Coleman TG.* Circulatory Physiology: Cardiac Output and Its Regulation. *2nd ed. Philadelphia: WB Saunders; 1973.)*

breathing but can be as much as ±50 mm Hg during strenuous breathing
2. *Breathing against a negative pressure*, which shifts the curve to a more negative right atrial pressure (to the left)
3. *Positive-pressure breathing*, which shifts the curve to the right
4. *Opening the thoracic cage*, which increases the intrapleural pressure to 0 mm Hg and shifts the cardiac output curve to the right by 4 mm Hg
5. *Cardiac tamponade*, which means accumulation of a large quantity of fluid in the pericardial cavity around the heart with a resultant increase in external cardiac pressure and shifting of the curve to the right

Note in **Fig. 20.8** that cardiac tamponade shifts the upper parts of the curves farther to the right than the lower parts because the external tamponade pressure rises to higher values as the chambers of the heart fill to increased volumes during high cardiac output.

Combinations of Different Patterns of Cardiac Output Curves. **Fig. 20.9** shows that the final cardiac output curve can change as a result of simultaneous changes in the following: (1) external cardiac pressure; and (2) effectiveness of the heart as a pump. For example, the combination of a hypereffective heart and increased intrapleural pressure would lead to an increased maximum level of cardiac output due to the increased pumping capability of the heart, but the cardiac output curve would be shifted to the right (to higher atrial pressures) because of the increased intrapleural pressure. Thus, by knowing what is happening to the external pressure, and to the capability of the heart as a pump, one can express the momentary ability of the heart to pump blood by a single cardiac output curve.

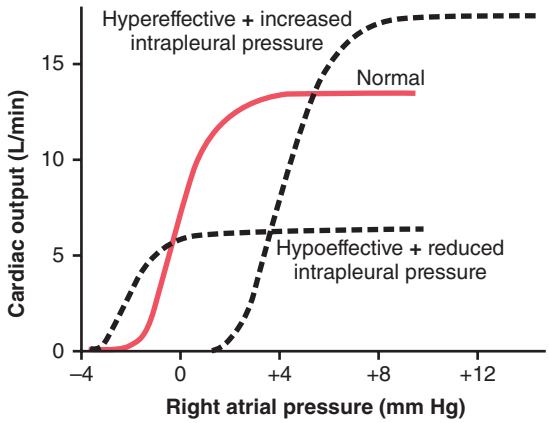

Figure 20.9 Combinations of two major patterns of cardiac output curves showing the effect of alterations in both extracardiac pressure and effectiveness of the heart as a pump. *(Modified from Guyton AC, Jones CE, Coleman TG.* Circulatory Physiology: Cardiac Output and Its Regulation. *2nd ed. Philadelphia: WB Saunders; 1973.)*

VENOUS RETURN CURVES

The entire systemic circulation must be considered before complete analysis of cardiac regulation can be achieved. To analyze the function of the systemic circulation experimentally, the heart and lungs were removed from the circulation of an animal and replaced with a pump and artificial oxygenator system. Then, different factors, such as blood volume, vascular resistances, and central venous pressure in the right atrium, were altered to determine how the systemic circulation operates in different circulatory states. From these studies, one finds the following three principal factors that affect venous return to the heart from the systemic circulation:

1. *Right atrial pressure*, which impedes flow of blood from the veins into the right atrium.
2. Degree of filling of the systemic circulation (measured by the *mean systemic filling pressure*), which forces the systemic blood toward the heart (this is the pressure measured everywhere in the systemic circulation when all flow of blood is stopped, as discussed in detail later).
3. *Resistance to blood flow* between the peripheral vessels and the right atrium.

These factors can all be expressed quantitatively by the *venous return curve*, as we explain in the next sections.

Normal Venous Return Curve

In the same way that the cardiac output curve relates pumping of blood by the heart to right atrial pressure, the *venous return curve relates venous return also to right atrial pressure*—that is, the venous flow of blood into the heart from the systemic circulation at different levels of right atrial pressure.

The curve in **Fig. 20.10** is the *normal* venous return curve. This curve shows that when heart pumping capability becomes diminished and causes the right atrial pressure to rise, the backward force of the rising atrial pressure on the veins of the systemic circulation decreases venous return of blood to the heart. *If all nervous circulatory reflexes are prevented from acting*, venous return decreases to zero when the right atrial

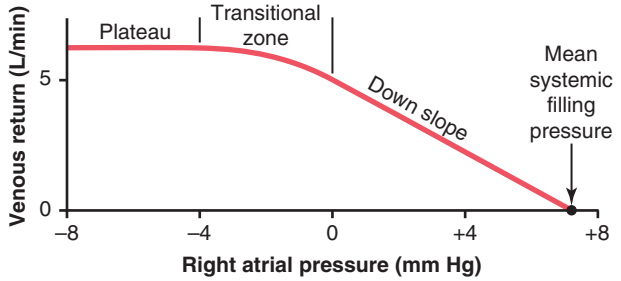

Figure 20.10 Normal *venous return curve*. The plateau is caused by *collapse* of the large veins entering the chest when the right atrial pressure falls below atmospheric pressure. Note also that venous return becomes zero when the right atrial pressure rises to equal the mean systemic filling pressure.

pressure rises to about +7 mm Hg. Such a slight rise in right atrial pressure causes a drastic decrease in venous return because any increase in back pressure causes blood to dam up in the systemic circulation instead of returning to the heart.

At the same time that the right atrial pressure is rising and causing venous stasis, pumping by the heart also approaches zero because of decreasing venous return. Both the arterial and venous pressures reach equilibrium when all flow in the systemic circulation ceases at a pressure of 7 mm Hg, which, by definition, is the *mean systemic filling pressure*.

Plateau in Venous Return Curve at Negative Atrial Pressures Caused By Collapse of the Large Veins. When the right atrial pressure falls *below* zero—that is, below atmospheric pressure—any further increase in venous return almost ceases, and by the time the right atrial pressure has fallen to about −2 mm Hg, the venous return reaches a plateau. It remains at this plateau level, even though the right atrial pressure falls to −20 mm Hg, −50 mm Hg or even further. This plateau is caused by *collapse of the veins* entering the chest. Negative pressure in the right atrium sucks the walls of the veins together where they enter the chest, which prevents any additional flow of blood from the peripheral veins. Consequently, even very negative pressures in the right atrium cannot increase venous return much above that which exists at a normal atrial pressure of 0 mm Hg.

Mean Circulatory Filling Pressure and Mean Systemic Filling Pressure—Effects on Venous Return

When heart pumping is stopped by shocking the heart with electricity to cause ventricular fibrillation or is stopped in any other way, flow of blood everywhere in the circulation ceases a few seconds later. Without blood flow, the pressures everywhere in the circulation become equal. This equilibrated pressure level is called the *mean circulatory filling pressure*.

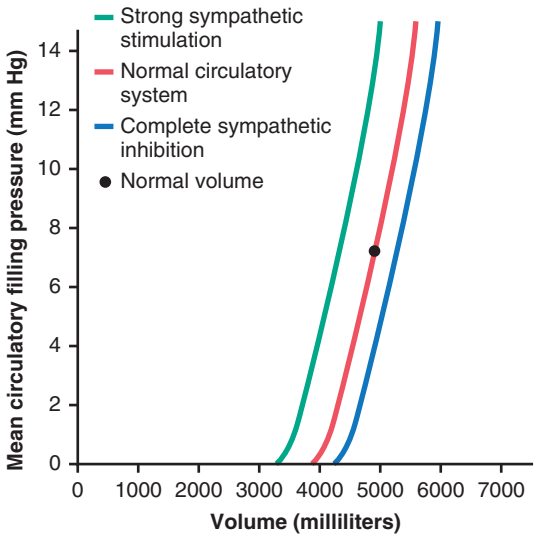

Figure 20.11 Effect of changes in total blood volume on the *mean circulatory filling pressure* (volume-pressure curve for the entire circulatory system). These curves also show the effects of strong sympathetic stimulation and complete sympathetic inhibition.

Increased Blood Volume Raises Mean Circulatory Filling Pressure. If all other factors are unchanged, the greater the volume of blood in the circulation, the greater is the mean circulatory filling pressure because extra blood volume stretches the walls of the vasculature. The *red curve* in **Fig. 20.11** shows the approximate normal effect of different levels of blood volume on the mean circulatory filling pressure. Note that at a blood volume of about 4000 mL the mean circulatory filling pressure is close to zero because this is the unstressed volume of the circulation, but at a volume of 5000 mL the filling pressure is the normal value of 7 mm Hg. Similarly, at still higher volumes, the mean circulatory filling pressure increases almost linearly.

Sympathetic Nervous Stimulation Increases Mean Circulatory Filling Pressure. The *green curve* and *blue curve* in **Fig. 20.11** show the effects, respectively, of high and low levels of sympathetic nervous activity on the mean circulatory filling pressure. Strong sympathetic stimulation constricts the systemic blood vessels, as well as the larger pulmonary blood vessels and even the chambers of the heart. Therefore, the capacity of the circulatory system decreases so that at each level of blood volume, the mean circulatory filling pressure is increased. At normal blood volume, maximal sympathetic stimulation increases the mean circulatory filling pressure from 7 mm Hg to about twice that value, or about 14 mm Hg.

Conversely, complete inhibition of the sympathetic nervous system relaxes both the blood vessels and heart, decreasing the mean circulatory filling pressure from the normal value of 7 mm Hg down to about 4 mm Hg. Note in **Fig. 20.11** how steep the curves are, which means that even slight changes in blood volume or capacity of the system caused by various levels of sympathetic activity can have large effects on the mean circulatory filling pressure.

Mean Systemic Filling Pressure and Relationship to Mean Circulatory Filling Pressure. The *mean systemic filling pressure* (Psf) is slightly different from the mean circulatory filling pressure. It is the pressure measured everywhere *in the systemic circulation* after blood flow has been stopped by clamping the large blood vessels at the heart, so the pressures in the systemic circulation can be measured independently from those in the pulmonary circulation. The *mean systemic filling pressure*, although almost impossible to measure in a live animal, *is almost always nearly equal to the mean circulatory filling pressure*, because the pulmonary circulation has less than one-eighth as much capacitance as the systemic circulation and only about one-tenth as much blood volume.

Effect on Venous Return Curve of Changes in Mean Systemic Filling Pressure. Fig. 20.12 shows the effects on the venous return curve caused by increasing or decreasing Psf. Note that the normal Psf is about 7 mm Hg. Then, for the uppermost curve in the figure, Psf has been increased to 14 mm Hg, and for the lowermost curve, it has decreased to 3.5 mm Hg. These curves demonstrate that the higher the Psf (which also means the greater the "tightness" with which the circulatory system is filled with blood), the more the venous return curve shifts *upward* and *to the right*. Conversely, the lower the Psf, the more the curve shifts *downward* and *to the left*.

Expressing this another way, the greater the degree to which the system is filled, the easier it is for blood to flow into the heart. The lesser the degree to which the system is filled, the more difficult it is for blood to flow into the heart. The degree to which the system is filled, in turn, is determined by the volume of blood in the vascular system and the vascular capacity.

When Pressure Gradient for Venous Return Is Zero There Is No Venous Return. When the right atrial pressure rises to equal the Psf, there is no longer any pressure difference between the peripheral vessels and right atrium. Consequently, there can no longer be any blood flow from peripheral vessels back to the right atrium. However, when the right atrial pressure falls progressively lower than the Psf, blood flow to the heart increases proportionately, as can be seen by studying any of the venous return curves in Fig. 20.12. That is, *the greater the difference between the Psf and right atrial pressure, the greater becomes the venous return*. Therefore, the difference between these two pressures is called the *pressure gradient for venous return*.

Resistance to Venous Return

In the same way that Psf represents a pressure pushing venous blood from the periphery toward the heart, there is also resistance to this venous flow of blood. This is called the *resistance to venous return*. Most of the resistance to venous return occurs in the veins, although some occurs in the arterioles and small arteries as well.

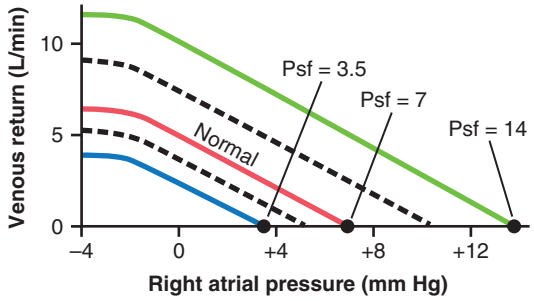

Figure 20.12 Venous return curves showing the normal curve when the mean *systemic filling pressure* (Psf) *is* 7 mm Hg and the effect of altering the Psf to 3.5, 7, or 14 mm Hg. *(Modified from Guyton AC, Jones CE, Coleman TG.* Circulatory Physiology: Cardiac Output and Its Regulation. *2nd ed. Philadelphia: WB Saunders; 1973.)*

Why is venous resistance so important in determining the resistance to venous return? The answer is that when the resistance in the veins increases, blood begins to be dammed up, mainly in the veins themselves. However, the venous pressure rises very little because the veins are highly distensible. Therefore, this rise in venous pressure is not very effective in overcoming the resistance, and blood flow into the right atrium decreases drastically. Conversely, when arteriolar and small artery resistances increase, blood accumulates in the arteries, which have a capacitance only one-thirtieth as great as that of the veins. Therefore, even slight accumulation of blood in the arteries raises the pressure greatly—30 times as much as in the veins—and this high pressure overcomes much of the increased resistance. Mathematically, it turns out that about two-thirds of the so-called resistance to venous return is determined by venous resistance, and about one-third is determined by the arteriolar and small artery resistance.

Venous return can be calculated by the following formula:

$$VR = \frac{Psf - PRA}{RVR}$$

in which VR is venous return, Psf is mean systemic filling pressure, PRA is right atrial pressure, and RVR is resistance to venous return. In the average healthy adult, the approximate values for these are as follows: venous return = 5 L/min, Psf = 7 mm Hg, right atrial pressure = 0 mm Hg, and resistance to venous return = 1.4 mm Hg/L/min of blood flow.

Effect of Resistance to Venous Return on the Venous Return Curve. Fig. 20.13 demonstrates the effect of different levels of resistance to venous return on the venous

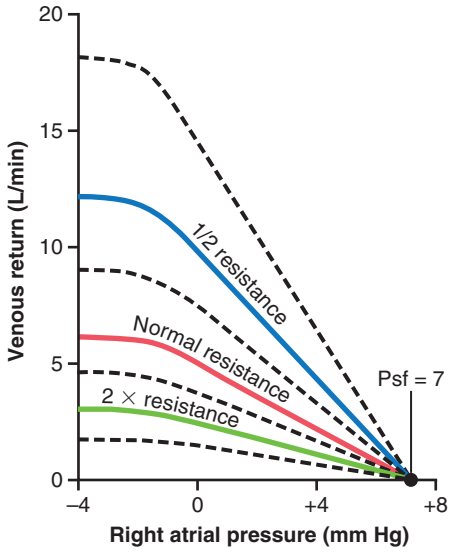

Figure 20.13 Venous return curves depicting the effect of altering the resistance to venous return. *Psf*, Mean systemic filling pressure. *(Modified from Guyton AC, Jones CE, Coleman TG.* Circulatory Physiology: Cardiac Output and Its Regulation. *2nd ed. Philadelphia: WB Saunders; 1973.)*

return curve, showing that a *decrease* in this resistance to half-normal allows twice as much flow of blood and, therefore, *rotates the curve upward* to twice as great a slope. Conversely, an *increase* in resistance to twice normal *rotates the curve downward* to half as great a slope.

Note also that when the right atrial pressure rises to equal the Psf, venous return becomes zero at all levels of resistance to venous return because there is no pressure gradient to cause flow of blood. Therefore, *the highest level to which the right atrial pressure can rise*, regardless of how much the heart might fail, is equal to the Psf.

Combinations of Venous Return Curve Patterns. **Fig. 20.14** shows the effects on the venous return curve caused by simultaneous changes in Psf and resistance to venous return, demonstrating that both these factors can operate simultaneously.

ANALYSIS OF CARDIAC OUTPUT AND RIGHT ATRIAL PRESSURE BY SIMULTANEOUS CARDIAC OUTPUT AND VENOUS RETURN CURVES

In the complete circulation, the heart and the systemic circulation must operate together. This requirement means that (1) the venous return from the systemic circulation must equal the cardiac output from the heart and (2) the right atrial pressure is the same for the heart and systemic circulation.

Therefore, one can predict the cardiac output and right atrial pressure in the following way:

1. Determine the momentary pumping ability of the heart, and depict this ability in the form of a cardiac output curve.
2. Determine the momentary state of flow from the systemic circulation into the heart, and depict this state of flow in the form of a venous return curve.

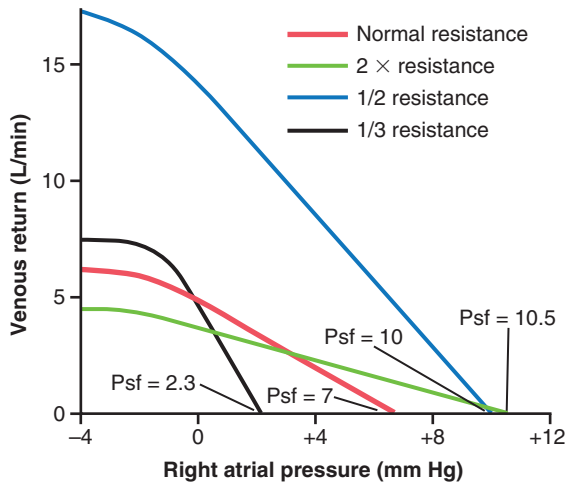

Figure 20.14 Combinations of the major patterns of venous return curves showing the effects of simultaneous changes in the mean systemic filling pressure (Psf) and in resistance to venous return. *(Modified from Guyton AC, Jones CE, Coleman TG.* Circulatory Physiology: Cardiac Output and Its Regulation. *2nd ed. Philadelphia: WB Saunders; 1973.)*

3. Equate these curves against each other, as shown in **Fig. 20.15**.

Two curves in the figure depict the *normal cardiac output curve* (red line) and the *normal venous return curve* (blue line). There is only one point on the graph, point A, at which the venous return equals the cardiac output and at which the right atrial pressure is the same for both the heart and systemic circulation. Therefore, in the normal circulation, the right atrial pressure, cardiac output, and venous return are all depicted by point A, called the *equilibrium point*, giving a normal value for cardiac output of 5 L/min and a right atrial pressure of 0 mm Hg.

Effect of Increased Blood Volume on Cardiac Output. A sudden increase in blood volume of about 20% increases the cardiac output to about 2.5 to 3 times normal. An analysis of this effect is shown in **Fig. 20.15**. After infusing the large quantity of extra blood, the increased filling of the system rapidly causes the Psf to increase to 16 mm Hg, which shifts the venous return curve to the right. At the same time, the increased blood volume distends the blood vessels, reducing their resistance and thereby reducing the resistance to venous return, which rotates the curve upward. As a result of these two effects, the venous return curve of **Fig. 20.15** is shifted to the right. This new curve equates with the cardiac output curve at point B, showing that the cardiac output and venous return increase 2.5 to 3 times and that the right atrial pressure rises to about +8 mm Hg.

Compensatory Effects Initiated in Response to Increased Blood Volume. The greatly increased cardiac output caused by increased blood volume lasts for only a few minutes because several compensatory effects rapidly begin to occur:

1. The increased cardiac output *increases the capillary pressure* so that fluid begins to transude out of the

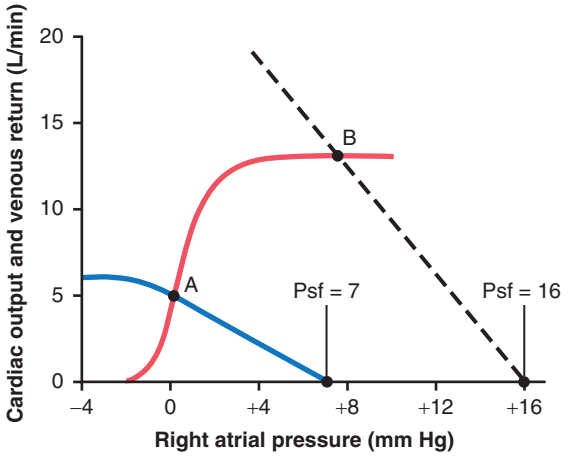

Figure 20.15 The two *solid curves* demonstrate an analysis of cardiac output and right atrial pressure when the cardiac output (*red line*) and venous return (*blue line*) curves are normal. Transfusion of blood equal to 20% of the blood volume causes the venous return curve to become the dashed curve. As a result, the cardiac output and right atrial pressure shift from point A to point B. *Psf*, Mean systemic filling pressure.

capillaries into the tissues, thereby returning the blood volume toward normal.

2. The increased pressure in the veins causes the veins to continue distending gradually by the mechanism called *stress-relaxation*, especially causing the venous blood reservoirs, such as the liver and spleen, to distend, thus *reducing the Psf.*
3. The excess blood flow through the peripheral tissues causes an autoregulatory increase in the peripheral vascular resistance, thus increasing the *resistance to venous return*.

These factors cause the Psf to return toward normal and the resistance vessels of the systemic circulation to constrict. Therefore, gradually, over a period of 10 to 40 minutes, the cardiac output returns almost to normal.

Effect of Sympathetic Stimulation on Cardiac Output. Sympathetic stimulation affects the heart and systemic circulation: (1) it *makes the heart a stronger pump*; and (2) in the systemic circulation, it *increases the Psf* because of contraction of the peripheral vessels, especially the veins, and it *increases the resistance to venous return*.

In **Fig. 20.16**, the *normal* cardiac output and venous return curves are depicted; these equate with each other at point A, which represents a normal venous return, cardiac output of 5 L/min. and right atrial pressure of 0 mm Hg. Note in the figure that maximal sympathetic stimulation (green curves) increases the Psf to 17 mm Hg (depicted by the point at which the venous return curve reaches the zero venous return level). Sympathetic stimulation also increases pumping effectiveness of the heart by nearly 100%. As a result, the cardiac output rises from the normal value at equilibrium point A to about double normal at equilibrium point D, and yet *the right atrial pressure hardly changes*. Thus, different degrees of sympathetic stimulation can increase the cardiac output progressively to about twice normal *for short periods*, until other compensatory effects occur within seconds or minutes to return cardiac output to nearly normal.

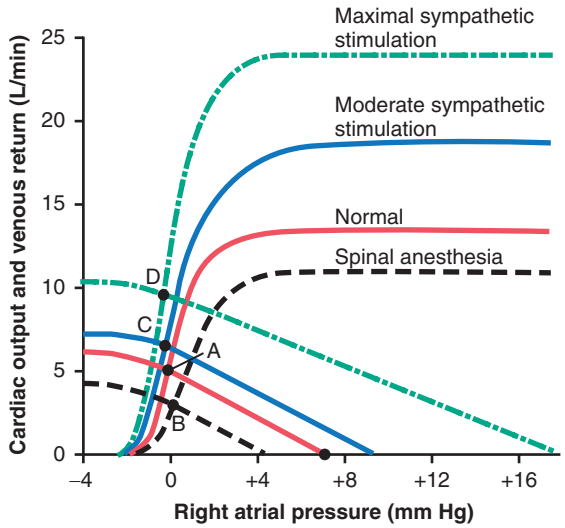

Figure 20.16 Analysis of the effect on cardiac output of (1) moderate sympathetic stimulation (from point A to point C), (2) maximal sympathetic stimulation (point D), and (3) sympathetic inhibition caused by total spinal anesthesia (point B). *(Modified from Guyton AC, Jones CE, Coleman TG.* Circulatory Physiology: Cardiac Output and Its Regulation. *2nd ed. Philadelphia: WB Saunders; 1973.)*

Effect of Sympathetic Inhibition on Cardiac Output. The sympathetic nervous system can be blocked by inducing *total spinal anesthesia* or by using a drug, such as *hexamethonium*, that blocks transmission of nerve signals through the autonomic ganglia. The lowermost curves in **Fig. 20.16** show the effect of sympathetic inhibition caused by total spinal anesthesia and demonstrate the following: (1) *the Psf falls to about 4 mm Hg;* and (2) *the effectiveness of the heart as a pump decreases to about 80% of normal*. The cardiac output falls from point A to point B, which is a decrease to about 60% of normal.

Effect of Opening a Large Arterial-Venous Fistula. **Fig. 20.17** shows various stages of circulatory changes that occur after opening a large A-V fistula—that is, after directly connecting a large artery and a large vein.

1. The two red curves crossing at point A show the normal condition.
2. The curves crossing at point B show the circulatory condition *immediately after opening the large fistula*. The principal effects are as follows: (a) a sudden and precipitous rotation of the venous return curve upward caused by the *large decrease in resistance to venous return* when blood is allowed to flow with almost no impediment directly from

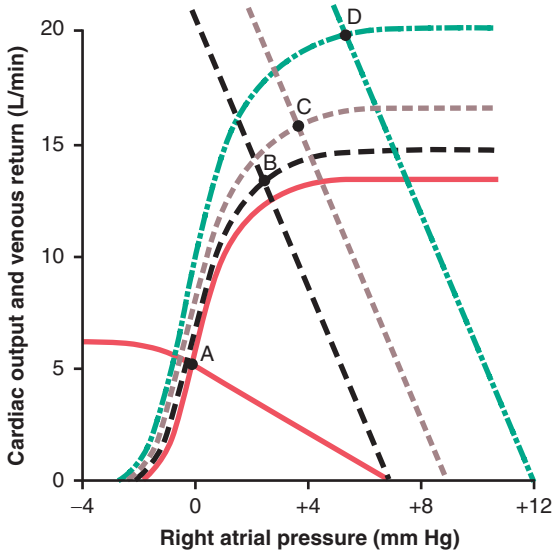

Figure 20.17 Analysis of successive changes in cardiac output and right atrial pressure in a human after a large arterial-venous (A-V) fistula is suddenly opened. The stages of the analysis, as shown by the equilibrium points, are as follows: A, normal conditions; B, immediately after opening the A-V fistula; C, 1 minute or so after the sympathetic reflexes have become active; and D, several weeks after the blood volume has increased and the heart has begun to hypertrophy. *(Modified from Guyton AC, Jones CE, Coleman TG.* Circulatory Physiology: Cardiac Output and Its Regulation. *2nd ed. Philadelphia: WB Saunders; 1973.)*

the large arteries into the venous system, bypassing most of the resistance elements of the peripheral circulation; and (b) a *slight increase in the level of the cardiac output curve* because opening the fistula decreases the peripheral resistance and allows an acute fall in arterial pressure against which the heart can pump more easily. The net result, depicted by point B, is an *increase in cardiac output from 5 L/min up to 13 L/min* and *an increase in right atrial pressure to about +3 mm Hg.*

3. Point C represents the effects about 1 minute later, after the sympathetic nerve reflexes have restored the arterial pressure almost to normal and caused two other effects: (a) an increase in the Psf (because of constriction of veins and arteries) from 7 to 9 mm Hg, thus shifting the venous return curve 2 mm Hg to the right; and (b) further elevation of the cardiac output curve because of sympathetic nervous excitation of the heart. The cardiac output now rises to almost 16 L/min, and the right atrial pressure rises to about 4 mm Hg.
4. Point D shows the effect after several more weeks. By this time, the blood volume has increased because the slight reduction in arterial pressure and the sympathetic stimulation have both transiently reduced the kidney output of urine, causing salt and water retention. The Psf has now risen to +12 mm Hg, shifting the venous return curve another 3 mm Hg to the right. Also, the prolonged increased workload on the heart has caused the heart muscle to hypertrophy slightly, raising the level of the cardiac output curve still further. Therefore, point D shows a cardiac output that is now almost 20 L/min and a right atrial pressure of about 6 mm Hg.

Other Analyses of Cardiac Output Regulation. In Chapter 21, analysis of cardiac output regulation during exercise is presented. In Chapter 22, analyses of cardiac output regulation at various stages of congestive heart failure are discussed.

METHODS FOR MEASURING CARDIAC OUTPUT

Accurate assessment of cardiac output is vitally important in critically ill patients or in high-risk patients undergoing surgery. In animal experiments, one can measure the cardiac output using an electromagnetic or ultrasonic flowmeter placed on the aorta or pulmonary artery to measure cardiac output. In humans, however, cardiac output is usually measured by indirect methods that do not require surgery.

Pulsatile Output of the Heart Measured By Electromagnetic or Ultrasonic Flowmeter

Fig. 20.18 shows a recording in a dog of blood flow in the root of the aorta; this recording was made using an electromagnetic flowmeter. It demonstrates that the blood flow rises rapidly to a peak during systole and then, at the end of systole, it reverses for a fraction of a second. This reverse flow causes the aortic valve to close and the flow to return to zero.

Measurement of Cardiac Output Using the Oxygen Fick Principle

The Fick principle is illustrated in **Fig. 20.19**, which shows 200 mL of oxygen being absorbed from the lungs into the pulmonary blood each minute. It also shows blood entering the right heart with an oxygen concentration of 160 mL/L of blood and blood leaving the left heart with an oxygen concentration of 200 mL/L of blood. From these data, one can calculate that each liter of blood passing through the lungs absorbs 40 mL of oxygen.

Because the total quantity of oxygen absorbed into the blood from the lungs each minute is 200 mL, dividing 200 by 40 calculates to a total of 5 liters of blood that must pass through the pulmonary circulation each minute to absorb this amount of oxygen. Therefore, the quantity of blood flowing through the lungs each minute is 5 liters, which is also a measure of the cardiac output. Thus, the cardiac output can be calculated by the following formula:

$$\text{Cardiac output (L/min)} = \frac{\text{O}_2 \text{ absorbed per minute by the lungs (mL/min)}}{\text{Arterial-venous O}_2 \text{ difference (mL/L of blood)}}$$

In applying this Fick procedure for measuring cardiac output in humans, *mixed venous blood* is usually obtained through a catheter inserted up the brachial vein of the

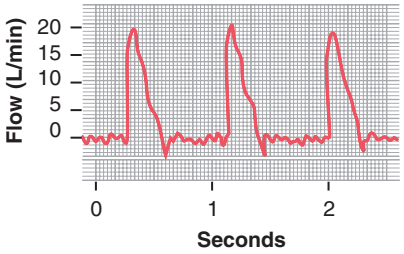

Figure 20.18 Pulsatile blood flow in the root of the aorta recorded using an electromagnetic flowmeter.

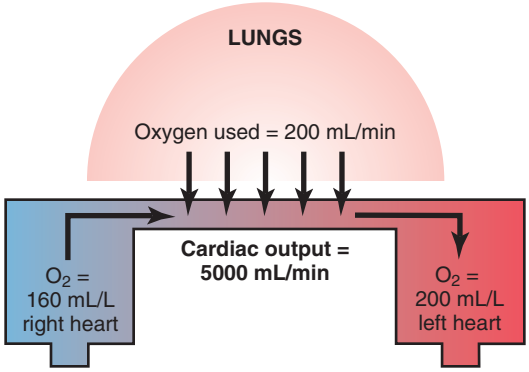

Figure 20.19 Fick principle for determining cardiac output.

forearm, through the subclavian vein, down to the right atrium and, finally, into the right ventricle or pulmonary artery. *Systemic arterial blood* can then be obtained from any systemic artery in the body. The *rate of oxygen absorption* by the lungs is measured by the rate of disappearance of oxygen from the respired air, using any type of oxygen meter.

Indicator Dilution Method

To measure cardiac output by the indicator dilution method, a small amount of indicator, such as a dye, is injected into a large systemic vein or, preferably, into the right atrium. This indicator passes rapidly through the right side of the heart, then through the blood vessels of the lungs, through the left side of the heart, and finally into the systemic arterial system. The concentration of the dye is recorded as the dye passes through one of the peripheral arteries, giving a curve as shown in **Fig. 20.20**. In each of these cases, 5 milligrams of Cardiogreen dye were injected at zero time. In the top recording, none of the dye passed into the arterial tree until about 3 seconds after the injection, but then the arterial concentration of the dye rose rapidly to a maximum in about 6 to 7 seconds. After that, the concentration fell rapidly, but before the concentration reached zero, some of the dye had already circulated all the way through some of the peripheral systemic vessels and returned through the heart for a second time. Consequently, the dye concentration in the artery began to rise again. For the purpose of calculation, it is necessary to *extrapolate* the early downslope of the curve to the zero point, as shown by the dashed portion of each curve. In this way, the *extrapolated time-concentration curve* of the dye in the systemic artery without recirculation can be measured in its first portion and estimated with reasonable accuracy in its latter portion.

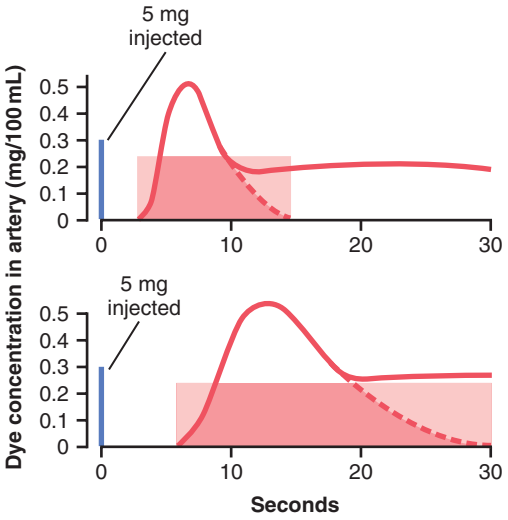

Figure 20.20 Extrapolated dye concentration curves used to calculate two separate cardiac outputs by the dilution method. The rectangular areas are the calculated average concentrations of dye in the arterial blood for the durations of the respective extrapolated curves.

Once the extrapolated time-concentration curve has been determined, the mean concentration of dye in the arterial blood for the duration of the curve can then be calculated. For example, in the top example of **Fig. 20.20**, this calculation was done by measuring the area under the entire initial and extrapolated curve and then averaging the concentration of dye for the duration of the curve. One can see from the shaded rectangle straddling the curve in the upper figure that the average concentration of dye was 0.25 mg/dL of blood and that the duration of this average value was 12 seconds. A total of 5 milligrams of dye had been injected at the beginning of the experiment. For blood carrying only 0.25 milligram of dye in each 100 milliliters to carry the entire 5 milligrams of dye through the heart and lungs in 12 seconds, a total of 20 portions, each with 100 milliliters of blood, would have passed through the heart during the 12 seconds, which would be the same as a cardiac output of 2 L/12 sec, or 10 L/min. We leave it to the reader to calculate the cardiac output from the bottom *extrapolated* curve of **Fig. 20.20**. To summarize, the cardiac output can be determined using the following formula:

$$\text{Cardiac output (mL/min)} = \frac{\text{Milligrams of dye injected} \times 60}{\left(\begin{array}{c}\text{Average concentration of dye}\\ \text{in each milliliter of blood}\\ \text{for the duration of the curve}\end{array}\right) \times \left(\begin{array}{c}\text{Duration of}\\ \text{the curve}\\ \text{in seconds}\end{array}\right)}$$

ECHOCARDIOGRAPHY

Cardiac output can also be estimated by *echocardiography*, a method that uses ultrasound waves from a transducer placed on the chest wall or passed into the patient's esophagus to measure the size of the heart's chambers and the velocity of blood flowing from the left ventricle into the aorta. Stroke volume is calculated from the velocity of blood flowing into the aorta, and the aorta cross-sectional area is determined from the aorta diameter measured by ultrasound imaging. Cardiac output is then calculated from the product of the stroke volume and heart rate.

Thoracic Electrical Bioimpedance Method

Impedance cardiography, also known as *thoracic electrical bioimpedance*, is a noninvasive technology used to measure changes in total electrical conductivity of the thorax as an indirect assessment of hemodynamic parameters such as cardiac output. This method detects the *impedance* changes caused by a high-frequency, low-magnitude current flowing through the thorax between a pair of electrodes located outside the segment where the current is delivered. Electrical impedance is the opposition that a circuit presents to current flow when a voltage is applied. With each heartbeat, blood volume and velocity in the aorta change, and the corresponding change in impedance and its timing are measured and used to estimate cardiac output.

Although some studies have suggested that impedance cardiography may provide reasonable assessments of cardiac output under some conditions, this method is also subject to several potential sources of error, including electrical interferences, motion artifacts, fluid accumulation around the heart and in the lungs, and arrhythmias. Studies have suggested that the average error with this method may be as high as 20% to 40%.

Accurate assessment of cardiac output provides insight into heart function and tissue perfusion because cardiac output represents the sum of blood flows to all the organs and tissues of the body. Thus, noninvasive methods for more accurate measurements of cardiac output are continuously being developed for managing patients with circulatory distress.

CHAPTER 21

Muscle Blood Flow and Cardiac Output During Exercise; The Coronary Circulation and Ischemic Heart Disease

In this chapter we consider the following: (1) blood flow to the skeletal muscles; and (2) coronary artery blood flow to the heart. Regulation of each of these types of blood flow is achieved mainly by local control of vascular resistance in response to muscle tissue metabolic needs.

We also discuss the physiology of related subjects, including the following: (1) cardiac output control during exercise; (2) characteristics of heart attacks; and (3) the pain of angina pectoris.

BLOOD FLOW REGULATION IN SKELETAL MUSCLE AT REST AND DURING EXERCISE

Strenuous exercise is one of the most stressful conditions that the normal circulatory system faces because exercising skeletal muscle requires large increases in blood flow to supply its metabolic needs. Cardiac output often must increase to four to five times normal in the nonathlete or to six to seven times normal in the well-trained athlete to satisfy the metabolic needs of the exercising muscles.

SKELETAL MUSCLE BLOOD FLOW RATE

During rest, skeletal muscle blood flow averages 3 to 4 mL/min/100 g of muscle. During extreme exercise in the well-conditioned athlete, this blood flow can increase 25- to 50-fold, rising to 100 to 200 mL/min/100 g of muscle. Peak blood flows as high as 400 mL/min/100 g of muscle have been reported for thigh muscles of endurance-trained athletes.

Muscle Blood Flow Increases During Contractions. Fig. 21.1 shows a record of blood flow changes in a calf muscle of a leg during strong rhythmic muscular exercise. Note that the flow increases and decreases with each muscle contraction. At the end of the contractions, the blood flow remains high for a few seconds but then returns to normal during the next few minutes.

The cause of the lower flow during the muscle contraction phase of exercise is compression of the blood vessels by the contracted muscle. During strong tetanic contraction, which causes sustained compression of the blood vessels, the blood flow can be almost stopped, but this also causes rapid weakening of the contraction.

Increased Blood Flow in Muscle Capillaries During Exercise. During rest, some muscle capillaries have little or no flowing blood, but during strenuous exercise, all the capillaries open. This opening of dormant capillaries diminishes the distance that oxygen and other nutrients must diffuse from the capillaries to the contracting muscle fibers; it sometimes contributes a 2-fold to 3-fold increased capillary surface area through which oxygen and nutrients can rapidly diffuse from the blood to the tissues.

CONTROL OF SKELETAL MUSCLE BLOOD FLOW

Decreased Oxygen in Muscle Greatly Enhances Blood Flow. The large increase in muscle blood flow that occurs during skeletal muscle activity is caused mainly by factors related to tissue metabolism that act directly on the muscle arterioles to cause dilation. One of the most important metabolic factors is reduction of the oxygen level in exercising muscle. When muscles are active, they use oxygen rapidly, thereby decreasing the oxygen concentration in the tissue fluids. This in turn causes local arteriolar vasodilation because low oxygen levels cause the blood vessels to relax and because oxygen deficiency causes release of vasodilator substances. *Adenosine* may

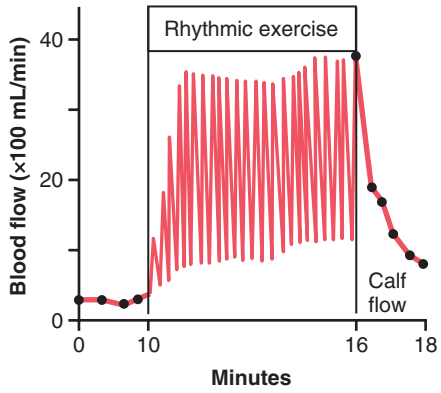

Figure 21.1 Effects of muscle exercise on blood flow in the calf of a leg during strong rhythmic contraction. The blood flow was much less during contractions than between contractions. *(Modified from Barcroft H, Dornhorst AC. The blood flow through the human calf during rhythmic exercise.* J Physiol. *1949;109:402.)*

be an important vasodilator substance, but experiments have shown that even large amounts of adenosine infused directly into a muscle artery cannot increase blood flow to the same extent as during intense exercise, and it cannot sustain vasodilation in skeletal muscle for more than about 2 hours.

Fortunately, even after sensitivity of the muscle blood vessels to the vasodilator effects of adenosine has decreased, other vasodilator factors continue to maintain increased capillary blood flow as long as the exercise continues. These factors include the following: (1) potassium ions; (2) adenosine triphosphate (ATP); (3) lactic acid; and (4) carbon dioxide. We still do not know quantitatively the role of each of these factors in increasing muscle blood flow during muscle activity; this subject was discussed in Chapter 17.

Nervous Control of Muscle Blood Flow. In addition to local tissue vasodilator mechanisms, skeletal muscles are provided with sympathetic vasoconstrictor nerves and, in some species of animals, sympathetic vasodilator nerves.

The sympathetic vasoconstrictor nerve fibers secrete norepinephrine at their nerve endings. When maximally activated, this mechanism can decrease blood flow through resting muscles to as little as one-half to one-third normal. This vasoconstriction is of physiological importance in attenuating decreases of arterial pressure in circulatory shock and during other periods of stress, when it may even be necessary to increase blood pressure.

In addition to the norepinephrine secreted at the sympathetic vasoconstrictor nerve endings, the medullae of the two adrenal glands also secrete increased amounts of norepinephrine plus even more epinephrine into the circulating blood during strenuous exercise. The circulating norepinephrine acts on the muscle vessels to cause vasoconstriction, similar to that caused by direct sympathetic nerve stimulation. The epinephrine, however, often has a slight vasodilator effect because epinephrine excites more of the beta-adrenergic receptors of the vessels, which are vasodilator receptors, in contrast to the alpha vasoconstrictor receptors excited especially by norepinephrine. These receptors are discussed in Chapter 61.

CIRCULATORY READJUSTMENTS DURING EXERCISE

Three major effects occur during exercise that are essential for the circulatory system to supply the tremendous blood flow required by the muscles: (1) sympathetic nervous system activation with consequent stimulatory effects on the circulation; (2) increase in arterial pressure; and (3) increase in cardiac output.

Effects of Sympathetic Activation

At the onset of exercise, signals are transmitted not only from the brain to the muscles to cause muscle contraction but also into the vasomotor center to initiate sympathetic discharge in many other tissues. Simultaneously, the parasympathetic signals to the heart are attenuated. Therefore, three major circulatory effects result:

1. The heart is stimulated to a greatly increased heart rate and increased pumping strength as a result of the sympathetic drive to the heart plus release of the heart from normal parasympathetic inhibition.
2. Many of the arterioles of the peripheral circulation are strongly contracted, except for the arterioles in the active muscles (including the heart), which are strongly vasodilated by the local vasodilator effects in the muscles, as noted earlier. Thus, the heart is stimulated to supply the increased blood flow required by the muscles, while at the same time blood flow through most nonmuscular areas of the body is temporarily reduced, thereby "lending" blood supply to the muscles. This process accounts for as much as 2 L/min of extra blood flow to the muscles, which is exceedingly important when considering a person running for their life, when even a fractional increase in running speed may make the difference between life and death. Two of the peripheral circulatory systems, the coronary and cerebral systems, are spared this vasoconstrictor effect because both these circulatory areas have poor vasoconstrictor innervation—fortunately so, because both the heart and brain are as essential to exercise as the skeletal muscles.
3. The muscle walls of the veins and other capacitative areas of the circulation are contracted powerfully, which greatly increases the mean systemic filling pressure. As we learned in Chapter 20, this effect is one of the most important factors in promoting increased venous return of blood to the heart and, therefore, increased cardiac output.

Sympathetic Stimulation May Increase Arterial Pressure During Exercise. An important effect of increased sympathetic stimulation in exercise is to increase arterial pressure through multiple stimulatory effects, including the following: (1) vasoconstriction of the arterioles and small arteries in most tissues of the body except the brain and active muscles, including the heart; (2) increased pumping activity by the heart; and (3) a great increase in mean systemic filling pressure caused mainly by venous contraction. These effects, working together, almost always increase the arterial pressure during exercise. This increase can be as little as 20 mm Hg or as much as 80 mm Hg, depending on the conditions under which the exercise is performed. When a person performs exercise under tense conditions but uses only a few muscles, the sympathetic nervous response still occurs. In the few active muscles, vasodilation occurs, but elsewhere in the body the effect is mainly vasoconstriction, often increasing the mean arterial pressure to as high as 170 mm Hg. Such a condition might occur in a person standing on a ladder and nailing with a hammer on the ceiling above. The tenseness of the situation is obvious.

Conversely, when a person performs massive whole-body exercise, such as running or swimming, the increase in arterial pressure is often only 20 to 40 mm Hg. This lack of a large increase in pressure results from the extreme vasodilation that occurs simultaneously in large masses of active muscle.

Why Is Increased Arterial Pressure During Exercise Important? When muscles are stimulated maximally in a laboratory experiment, but without allowing the arterial pressure to rise, muscle blood flow seldom rises more than about 8-fold. Yet, we know from studies of marathon runners that muscle blood flow can increase from as little as 1 L/min for the whole body during rest to more than 20 L/min during maximal activity. An important reason for this difference is that the arterial pressure rises during normal exercise. Let us assume, for example, that the arterial pressure rises by 30% during heavy exercise. This 30% increase causes 30% more force to push blood through the muscle tissue vessels. However, this is not the only important effect—the extra pressure also stretches the walls of the vessels, and this effect, along with the locally released vasodilators and higher blood pressure, may increase muscle total flow to more than 20 times normal.

Importance of Increased Cardiac Output During Exercise

Many different physiological effects occur at the same time during exercise to increase cardiac output approximately in proportion to the degree of exercise. In fact, the ability of the circulatory system to provide increased cardiac output for delivery of oxygen and other nutrients to the muscles during exercise is equally as important as the strength of the muscles themselves in setting the limit for continued muscle work. For example, marathon runners who can increase their cardiac outputs the most are generally the ones who have record-breaking running times.

Graphic Analysis of Changes in Cardiac Output During Heavy Exercise. Fig. 21.2 shows a graphic analysis of the large increase in cardiac output that occurs during heavy exercise. The cardiac output and venous return curves crossing at point A represent the normal circulation, and the curves crossing at point B represent heavy exercise. Note that the great increase in cardiac output requires significant changes in both the cardiac output curve and the venous return curve.

The increased level of the cardiac output curve results almost entirely from sympathetic stimulation of the heart, which causes the following: (1) increased heart rate, up to as high as 170 to 190 beats/min; and (2) increased strength of contraction of the heart to as much as twice normal. Without this increased level of cardiac function, the increase in cardiac output would be limited to the plateau level of the normal heart, which would be a maximum increase of cardiac output of only about 2.5-fold rather than the 4-fold increase that can commonly be achieved by the untrained runner and the 7-fold increase that can be achieved in some marathon runners.

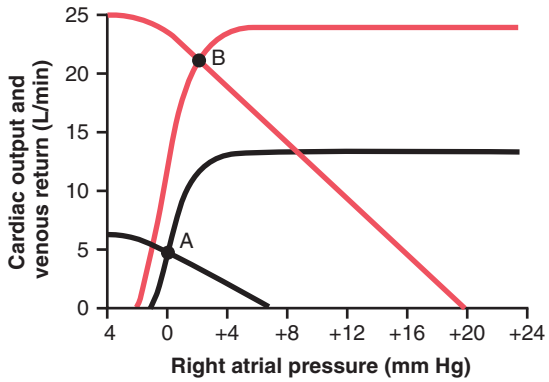

Figure 21.2 Graphic analysis of change in cardiac output, venous return, and right atrial pressure with the onset of strenuous exercise. *Black curves*, Normal circulation. *Red curves*, heavy exercise.

If no change occurred from the normal venous return curve, the cardiac output could hardly rise at all in exercise because the upper plateau level of the normal venous return curve is only 6 L/min. Yet, two important changes do occur:

1. The mean systemic filling pressure rises at the onset of heavy exercise. This effect results partly from the sympathetic stimulation that contracts the veins and other capacitative parts of the circulation. In addition, tensing of the abdominal and other skeletal muscles of the body compresses many of the internal vessels, thus causing more compression of the entire capacitative vascular system and a greater increase in the mean systemic filling pressure. During maximal exercise, these two effects together can increase the mean systemic filling pressure from a normal level of 7 mm Hg to as high as 30 mm Hg.
2. The slope of the venous return curve rotates upward. This upward rotation is caused by decreased resistance in virtually all the blood vessels in active muscle tissue, which also decreases resistance to venous return, thus increasing the upward slope of the venous return curve.

Therefore, the combination of increased mean systemic filling pressure and decreased resistance to venous return raises the entire level of the venous return curve.

In response to the changes in both the venous return curve and cardiac output curve, the new equilibrium point in Fig. 21.2 for cardiac output and right atrial pressure is now point B, in contrast to the normal level at point A. Note especially that the right atrial pressure has hardly changed, having risen only 1.5 mm Hg. In fact, in a person with a strong heart, the right atrial pressure often falls below normal during very heavy exercise because of the greatly increased sympathetic stimulation of the heart. In contrast, even a moderate level of exercise may cause marked increases in right atrial pressure in patients with weakened hearts.

CORONARY CIRCULATION

About one-third of all deaths in industrialized countries of the Western world result from coronary artery disease, and most older adults have at least some impairment of the coronary artery circulation. For this reason, understanding normal and pathological physiology of the coronary circulation is one of the most important subjects in medicine.

PHYSIOLOGICAL ANATOMY OF THE CORONARY BLOOD SUPPLY

Fig. 21.3 shows the heart and its coronary blood supply. Note that the main coronary arteries lie on the surface of the heart. Smaller arteries then penetrate from the surface into the cardiac muscle mass. It is almost entirely through these arteries that the heart receives its nutritive blood supply. Only the inner one-tenth millimeter of the endocardial surface can obtain significant nutrition directly from the blood inside the cardiac chambers, so this source of muscle nutrition is minuscule.

The *left coronary artery* supplies mainly the anterior and left lateral portions of the left ventricle, whereas the *right coronary artery* supplies most of the right ventricle, as well as the posterior part of the left ventricle in 80% to 90% of people.

About 75% of the total coronary venous blood flow from the left ventricular muscle returns to the right atrium of the heart by way of the *coronary sinus*. On the other hand, most of the coronary venous blood from the right ventricular muscle returns through small *anterior cardiac veins* that flow directly into the right atrium, not by way of the coronary sinus. A very small amount of coronary venous blood also flows back into the heart through minute *thebesian veins*, which empty directly into all chambers of the heart.

NORMAL CORONARY BLOOD FLOW AVERAGES 5% OF CARDIAC OUTPUT

The normal coronary blood flow in the resting person averages approximately 70 mL/min/100 g of heart weight, or about 225 mL/min, which is about 4% to 5% of the total cardiac output. Coronary blood flow per gram heart weight is typically higher in women than in men, although heart weight is generally smaller in women than in men even after indexing for body weight. However, there is considerable variation in heart weight and coronary blood flow, depending on body habitus and physical fitness.

During strenuous exercise, the heart in the young adult increases its cardiac output 4-fold to 7-fold and it pumps this blood against a higher than normal arterial pressure. Consequently, the work output of the heart under severe conditions may increase 6-fold to 9-fold. At the same time, the coronary blood flow increases 3-fold to 4-fold to supply the extra nutrients needed by the heart. This increase is not as much as the increase in workload, which means that the ratio of cardiac energy expenditure to coronary blood flow increases. Thus, the efficiency of cardiac utilization of energy increases to make up for the relative deficiency of coronary blood supply.

Cardiac Muscle Compression Causes Phasic Changes in Coronary Blood Flow During Systole and Diastole. **Fig. 21.4** shows the changes in blood flow through the nutrient capillaries of the left ventricular coronary system during systole and diastole, as extrapolated from studies in experimental animals. Note that the coronary capillary blood flow in the left ventricle muscle falls to a low value during systole, which is opposite to flow in vascular beds elsewhere in the body. This reduction of coronary blood flow is due to compression of the intramuscular blood vessels by the left ventricular muscle during systolic contraction.

During diastole, the cardiac muscle relaxes and no longer obstructs blood flow through the left ventricular muscle capillaries, so blood flows rapidly during all of diastole.

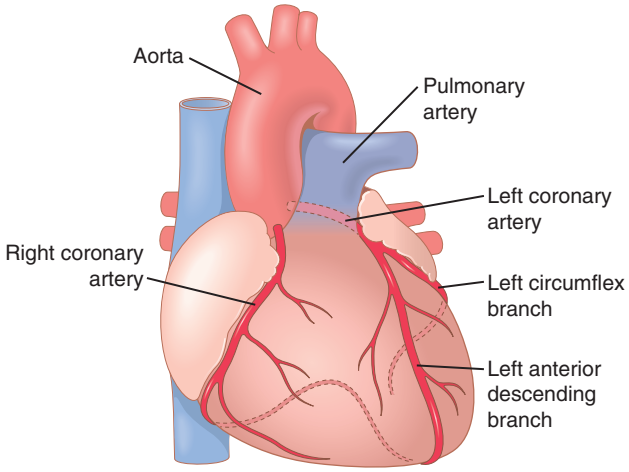

Figure 21.3 Coronary arteries.

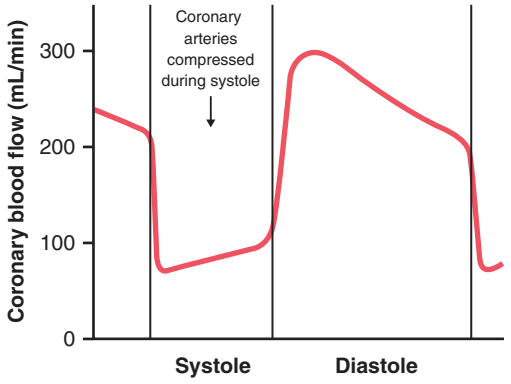

Figure 21.4 Phasic flow of blood through the coronary capillaries of the human left ventricle during cardiac systole and diastole (as extrapolated from measured flows in dogs).

Blood flow through the coronary capillaries of the right ventricle also undergoes phasic changes during the cardiac cycle, but because the force of contraction of the right ventricular muscle is far less than that of the left ventricular muscle, the inverse phasic changes are only partial, in contrast to those in the left ventricular muscle.

Epicardial Versus Subendocardial Coronary Blood Flow—Effect of Intramyocardial Pressure. Fig. 21.5 demonstrates the special arrangement of the coronary vessels at different depths in the heart muscle, showing on the outer surface *epicardial coronary arteries*, which supply most of the muscle. Smaller intramuscular arteries derived from the epicardial arteries penetrate the muscle, supplying the needed nutrients. Lying immediately beneath the endocardium is a plexus of *subendocardial arteries*. During systole, when the intramuscular coronary vessels are compressed greatly by ventricular muscle contraction, blood flow through the subendocardial plexus of the left ventricle tends to be reduced. However, the extra vessels of the subendocardial plexus normally compensate for this reduction. Later in the chapter, we explain how this peculiar difference between blood flow in the epicardial and subendocardial arteries plays an important role in certain types of coronary ischemia.

CONTROL OF CORONARY BLOOD FLOW

Local Muscle Metabolism Is the Primary Controller of Coronary Flow

Blood flow through the coronary system is regulated mostly by local arteriolar vasodilation in response to the metabolic needs of cardiac muscle. That is, whenever the vigor of cardiac contraction is increased, the rate of coronary blood flow also increases. Conversely, decreased heart activity is accompanied by decreased coronary flow. This local regulation of coronary blood flow is similar to that which occurs in many other tissues of the body, especially in the skeletal muscles.

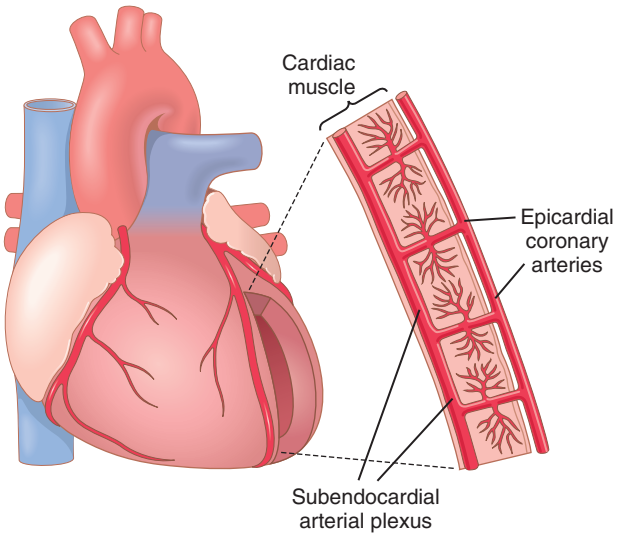

Figure 21.5 Diagram of the epicardial, intramuscular, and subendocardial coronary vasculature.

Oxygen Demand Is a Major Factor in Local Coronary Blood Flow Regulation. Blood flow in the coronary arteries usually is regulated in proportion to the need of the cardiac musculature for oxygen. Normally, about 70% of the oxygen in the coronary arterial blood is removed as the blood flows through the heart muscle. Because not much oxygen is left, little additional oxygen can be supplied to the heart musculature unless the coronary blood flow increases. Fortunately, the coronary blood flow increases almost in direct proportion to any additional metabolic consumption of oxygen by the heart.

The exact means whereby increased oxygen consumption causes coronary dilation is not fully understood. However, increased metabolic rate and decreased oxygen concentration in the heart may cause the muscle cells to release vasodilator substances that dilate the arterioles. A substance with great vasodilator propensity is adenosine. In the presence of very low concentrations of oxygen in the muscle cells, a large proportion of the cell's ATP degrades to adenosine monophosphate (AMP). Small portions of this substance are then further degraded and release adenosine to the tissue fluids of the heart muscle, with a resultant increase in local coronary blood flow. After adenosine causes vasodilation, much of it is reabsorbed into the cardiac cells to be reused for production of ATP.

Adenosine is not the only vasodilator product that has been identified; others include adenosine phosphate compounds, potassium ions, hydrogen ions, carbon dioxide, prostaglandins, and nitric oxide. The mechanisms of coronary vasodilation during increased cardiac activity have not been fully explained by adenosine. Pharmacological agents that block or partially block the vasodilator effect of adenosine do not completely prevent coronary vasodilation caused by increased heart muscle activity. Therefore, the other vasodilator mechanisms listed earlier should be remembered.

Nervous Control of Coronary Blood Flow

Stimulation of the autonomic nerves to the heart can affect coronary blood flow directly and indirectly. The direct effects result from action of the nervous transmitter substances acetylcholine from the vagus nerves and norepinephrine from the sympathetic nerves on the coronary vessels. The indirect effects result from secondary changes in coronary blood flow caused by increased or decreased activity of the heart.

The indirect effects, which are mostly opposite to the direct effects, play a far more important role in the normal control of coronary blood flow. Thus, sympathetic stimulation, which releases norepinephrine from the sympathetic nerves and epinephrine, as well as norepinephrine, from the adrenal medullae, increases both heart rate and heart contractility and increases the rate of metabolism of the heart. In turn, the increased metabolism of the heart

sets off local blood flow regulatory mechanisms for dilating the coronary vessels, and blood flow increases approximately in proportion to the metabolic needs of the heart muscle. In contrast, vagal stimulation, with its release of acetylcholine, slows the heart and has a slightly depressive effect on heart contractility. These effects decrease cardiac oxygen consumption and, therefore, indirectly constrict the coronary arteries.

Direct Effects of Nervous Stimuli on Coronary Vasculature. The distribution of parasympathetic (vagal) nerve fibers to the ventricular coronary system is not very great. However, the acetylcholine released by parasympathetic stimulation has a direct effect to dilate the coronary arteries.

Much more extensive sympathetic innervation of the coronary vessels occurs. In Chapter 61, we see that the sympathetic transmitter substances norepinephrine and epinephrine can have vascular constrictor or vascular dilator effects, depending on the presence or absence of constrictor or dilator receptors in the blood vessel walls. The receptors that cause vasoconstriction when activated are called *alpha receptors*, and the dilator receptors are called *beta receptors*. Both alpha and beta receptors exist in the coronary vessels. In general, the epicardial coronary vessels have a preponderance of alpha receptors, whereas the intramuscular arteries may have a preponderance of beta receptors. Therefore, sympathetic stimulation can, at least theoretically, cause slight overall coronary constriction or dilation, but usually constriction. In some people, the alpha vasoconstrictor effects seem to be disproportionately severe, causing vasospastic myocardial ischemia during periods of excess sympathetic drive, often with resultant anginal pain.

Metabolic factors, especially myocardial oxygen consumption, are the major controllers of myocardial blood flow. Whenever the direct effects of nervous stimulation tend to reduce coronary blood flow, the metabolic control of coronary flow usually overrides the vasoconstriction within seconds.

SPECIAL FEATURES OF CARDIAC MUSCLE METABOLISM

The basic principles of cellular metabolism, discussed in Chapters 68 through 73, apply to cardiac muscle, as well as for other tissues, but some quantitative differences exist. Most importantly, under resting conditions, cardiac muscle normally consumes more fatty acids than carbohydrates to supply its energy (~70% of the energy is derived from fatty acids). However, as is also true of other tissues, under anaerobic or ischemic conditions, cardiac metabolism must call on anaerobic glycolysis mechanisms for energy. However, glycolysis consumes large quantities of blood glucose and, at the same time, forms large amounts of lactic acid in the cardiac tissue. This is probably one of the causes of cardiac pain in cardiac ischemic conditions, as discussed later in this chapter.

As is true in other tissues, more than 95% of the metabolic energy liberated from foods is used to form ATP in the mitochondria. This ATP in turn acts as the conveyer of energy for cardiac muscular contraction and other cellular functions. In severe coronary ischemia, the ATP degrades first to adenosine diphosphate (ADP) and then to AMP and adenosine. Because the cardiac muscle cell membrane is slightly permeable to adenosine, much of this agent can diffuse from the muscle cells into the circulating blood.

The released adenosine is believed to be one of the substances that causes dilation of the coronary arterioles during coronary hypoxia, as discussed earlier. However, loss of adenosine also has a serious cellular consequence. Within as little as 30 minutes of severe coronary ischemia, as occurs after a myocardial infarct, about half of the adenine base can be lost from the affected cardiac muscle cells. Furthermore, this loss is replaced slowly by synthesis of new adenine at a rate of only 2%/hour. Therefore, once a serious bout of coronary ischemia has persisted for 30 minutes or longer, relief of the ischemia may be too late to prevent injury and death of the cardiac cells. This is almost certainly one of the major causes of cardiac cellular death during myocardial ischemia.

ISCHEMIC HEART DISEASE

The most common cause of death in men and women in Western countries is ischemic heart disease, which results from insufficient coronary blood flow. About 35% of people in the United States aged 65 years and older die of ischemic heart disease, which encompasses both obstructive and nonobstructive coronary artery disease. Some deaths occur suddenly as a result of acute coronary occlusion, coronary microvascular dysfunction, or fibrillation of the heart, whereas other deaths occur slowly over a period of weeks to years as a result of progressive weakening of the heart. In this chapter, we discuss acute coronary ischemia and myocardial infarction. In Chapter 22, we discuss congestive heart failure, which is frequently caused by slowly increasing coronary ischemia and weakening of the cardiac muscle.

Atherosclerosis Is a Major Cause of Ischemic Heart Disease. A frequent cause of diminished coronary blood flow is atherosclerosis. The atherosclerotic process is discussed in connection with lipid metabolism in Chapter 69. Briefly, in people who have a genetic predisposition to atherosclerosis, who are overweight or obese, who have a sedentary lifestyle, or have high blood pressure and damage to the endothelial cells of the coronary blood vessels, excess cholesterol gradually becomes deposited beneath the endothelium at many points in arteries throughout the body. Gradually, these areas of deposit are invaded by fibrous tissue and frequently become calcified. The net result is the development of atherosclerotic plaques, which protrude into the vessel lumens and block, or partially block, blood flow. A common site for development

of atherosclerotic plaques is the first few centimeters of the major coronary arteries.

Although women have a lower prevalence of obstructive coronary atherosclerosis than men, these sex differences in atherosclerotic plaque formation are attenuated in older adults, and ischemic heart disease remains the leading cause of death in women. Coronary microvascular dysfunction and coronary vasospasm are common causes of ischemic heart disease when no obstruction of the coronary arteries can be detected.

Acute Coronary Artery Occlusion

Acute occlusion of a coronary artery usually occurs in a person who already has underlying atherosclerotic coronary heart disease but rarely occurs in a person with a normal coronary circulation. Acute occlusion can have various causes, two of which are the following:

1. An atherosclerotic plaque can cause a local blood clot called a *thrombus* that occludes the artery. The thrombus usually occurs where the arteriosclerotic plaque has broken through the endothelium, thus coming into direct contact with the flowing blood. Because the plaque presents an unsmooth surface, blood platelets adhere to it, fibrin is deposited, and red blood cells become trapped to form a blood clot that grows until it occludes the vessel. Occasionally, the clot breaks away from its attachment on the atherosclerotic plaque and flows to a more peripheral branch of the coronary arterial tree, where it blocks the artery at that point. A thrombus that flows along the artery in this way and occludes the vessel more distally is called a *coronary embolus*.
2. Local muscular spasm of a coronary artery also can occur. The spasm might result from direct irritation of the smooth muscle of the arterial wall by the edges of an arteriosclerotic plaque, or it might result from local nervous reflexes that cause excess coronary vascular wall contraction. Other factors that may lead to coronary artery spasm in susceptible people include extreme emotional stress, stimulant drugs such as cocaine or amphetamines, tobacco use, and cold exposure. The spasm may then lead to *secondary thrombosis* of the vessel. Treatment of coronary artery spasms may include vasodilators such as *calcium channel blockers* or *nitrate drugs*, which relax the arteries.

Lifesaving Value of Collateral Circulation in the Heart. The degree of damage to the heart muscle caused by slowly developing atherosclerotic constriction of the coronary arteries or by sudden coronary occlusion is determined to a great extent by the degree of collateral circulation that has already developed or that can open within minutes after the occlusion. In a normal heart, almost no large communications exist among the larger coronary arteries. However, many anastomoses do exist among the smaller arteries of 20 to 250 micrometers in diameter, as shown in **Fig. 21.6**.

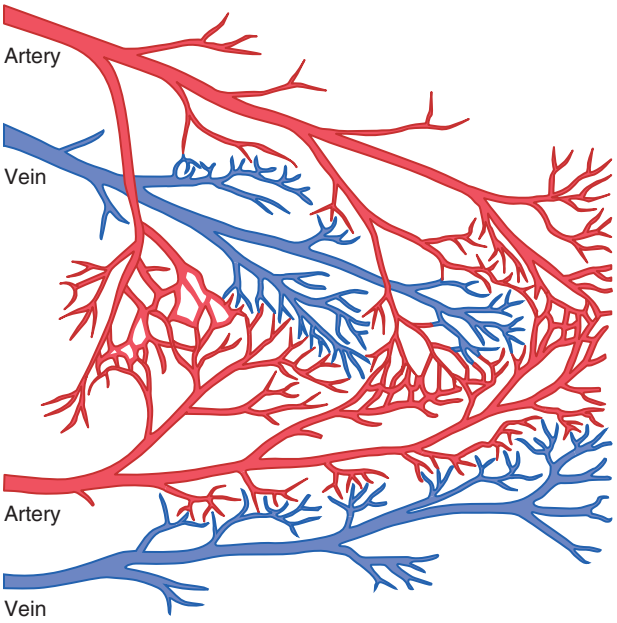

Figure 21.6 Minute anastomoses in the normal coronary arterial system.

When a sudden occlusion occurs in one of the larger coronary arteries, the small anastomoses begin to dilate within seconds. However, the blood flow through these minute collaterals is usually less than half of that needed to keep most of the cardiac muscle alive that they now supply. The diameters of the collateral vessels do not enlarge much more for the next 8 to 24 hours. Then, however, collateral flow begins to increase, doubling by the second or third day and often reaching normal or almost normal coronary flow within about 1 month. Because of these developing collateral channels, many patients recover almost completely from various degrees of coronary occlusion when the area of muscle involved is not too large.

When atherosclerosis constricts the coronary arteries slowly over a period of many years, rather than suddenly, collateral vessels can develop at the same time, while the atherosclerosis becomes more and more severe. Therefore, the person may never experience an acute episode of cardiac dysfunction. Eventually, however, the sclerotic process develops beyond the limits of the collateral blood supply to provide the needed blood flow, and sometimes, the collateral blood vessels themselves develop atherosclerosis. When this occurs, the heart muscle becomes severely limited in its work output, and the heart cannot pump even normally required amounts of blood flow. This is one of the most common causes of cardiac failure in older people.

Myocardial Infarction

Immediately after an acute coronary occlusion, blood flow ceases in the coronary vessels beyond the occlusion, except for small amounts of collateral flow from surrounding vessels. The area of muscle that has zero flow or

so little flow that it cannot sustain cardiac muscle function is said to be *infarcted*. The overall process is called a *myocardial infarction*.

Soon after the onset of the infarction, small amounts of collateral blood begin to infiltrate the infarcted area, which, combined with progressive dilation of local blood vessels, causes the area to become overfilled with stagnant blood. Simultaneously the muscle fibers use the last bits of the oxygen in the blood, causing the hemoglobin to become totally deoxygenated. Therefore, the infarcted area takes on a bluish-brown hue, and the blood vessels of the area appear to be engorged, despite lack of blood flow. In later stages, the vessel walls become highly permeable and leak fluid, the local muscle tissue becomes edematous, and the cardiac muscle cells begin to swell because of diminished cellular metabolism. Within a few hours of almost no blood supply, the cardiac muscle cells die.

Cardiac muscle requires about 1.3 mL of oxygen/100 g of muscle tissue/min just to remain alive. In comparison, about 8 mL oxygen/100 g are delivered to the normal resting left ventricle each minute. Therefore, if there is even 15% to 30% of normal resting coronary blood flow, the muscle will not die. In the central portion of a large infarct, however, where there is almost no collateral blood flow, the muscle does die.

Subendocardial Infarction. Infarction of the subendocardial muscle frequently occurs even when there is no evidence of infarction in the outer surface portions of the heart. The reason for this susceptibility of subendocardial muscle to infarction is that it has a higher oxygen consumption and extra difficulty obtaining adequate blood flow because the blood vessels in the subendocardium are intensely compressed by systolic contraction of the heart, as explained earlier. Therefore, any condition that compromises blood flow to any area of the heart usually causes damage first in the subendocardial regions, and the damage then spreads outward toward the epicardium.

CAUSES OF DEATH AFTER ACUTE CORONARY OCCLUSION

The most common causes of death after acute myocardial infarction are the following: (1) decreased cardiac output; (2) damming of blood in the pulmonary blood vessels and then death resulting from pulmonary edema; (3) fibrillation of the heart; and, occasionally (4) rupture of the heart.

Decreased Cardiac Output—Systolic Stretch and Cardiac Shock. When some of the cardiac muscle fibers are not functioning and others are too weak to contract with great force, the overall pumping ability of the affected ventricle is proportionately depressed. The pumping strength of the infarcted heart is often decreased more than one might expect because of a phenomenon called *systolic stretch*, shown in **Fig. 21.7**. That is, when the normal portions of the ventricular muscle contract, the ischemic portion of the muscle, whether it is dead or simply nonfunctional, instead of contracting is forced outward by the pressure that develops inside the ventricle. Therefore, much of the pumping force of the ventricle is dissipated by bulging of nonfunctional cardiac muscle.

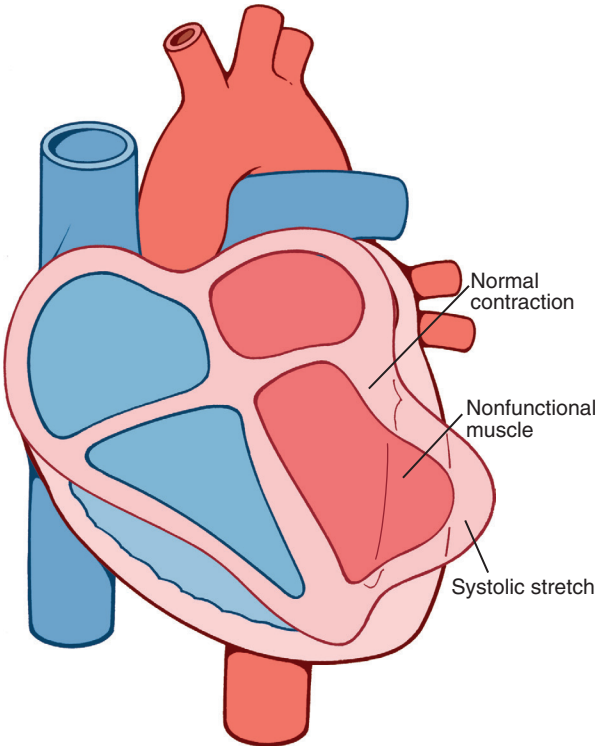

Figure 21.7 Systolic stretch in an area of ischemic cardiac muscle.

When the heart becomes incapable of contracting with sufficient force to pump enough blood into the peripheral arterial tree, cardiac failure and death of peripheral tissues ensue as a result of peripheral ischemia. This condition, called *coronary shock, cardiogenic shock, cardiac shock*, or *low cardiac output failure*, is discussed more fully in Chapter 22. Cardiac shock almost always occurs when more than 40% of the left ventricle is infarcted. Despite advances in treatment, short-term mortality is 40% to 50% of patients once cardiac shock develops.

Damming of Blood in the Body's Venous System. When the heart is not pumping blood forward, it must be damming blood in the atria and in the blood vessels of the lungs or in the systemic circulation. This leads to increased capillary pressures, particularly in the lungs.

Damming of blood in the veins may cause little difficulty during the first few hours after a myocardial infarction. However, symptoms develop a few days later because the acutely diminished cardiac output leads to diminished blood flow to the kidneys. Then, for reasons discussed in Chapter 22, the kidneys fail to excrete enough urine. This adds progressively to the total blood volume and, therefore, leads to congestive symptoms. Consequently, many patients who seemingly are getting along well during the first few days after the onset of heart failure will suddenly

experience acute pulmonary edema and often will die within a few hours after the appearance of the initial pulmonary symptoms.

Fibrillation of the Ventricles After Myocardial Infarction. In many people who die of coronary occlusion, death occurs because of sudden ventricular fibrillation. The tendency for fibrillation to develop is especially great after a large infarction, but fibrillation can sometimes occur after small occlusions as well. Some patients with chronic coronary insufficiency die suddenly of fibrillation without having any acute infarction.

Fibrillation is most likely to occur during two especially dangerous periods after coronary infarction. The first period occurs within 10 minutes after the infarction. Then, there is a short period of relative safety, followed by a second period of cardiac irritability beginning 1 hour or so later and lasting for another few hours. Fibrillation can also occur many days after the infarct but is less likely to occur then.

At least four factors are involved in the tendency for the heart to fibrillate, as follows:

1. Acute loss of blood supply to the cardiac muscle causes rapid loss of potassium from the ischemic muscle fibers. This also increases the potassium concentration in the extracellular fluids surrounding the cardiac muscle fibers. An elevated extracellular potassium concentration increases the irritability of the cardiac musculature and, therefore, its likelihood of fibrillating.
2. Ischemia of the muscle causes an *injury current*, described in Chapter 12 in relation to electrocardiograms in patients with acute myocardial infarction. That is, the ischemic musculature often cannot completely repolarize its membranes after a heartbeat, and thus the external surface of this muscle remains negative with respect to normal cardiac muscle membrane potential elsewhere in the heart. Therefore, electric current flows from this ischemic area of the heart to the normal area and can elicit abnormal impulses, which can cause fibrillation.
3. Powerful sympathetic reflexes often develop after massive infarction, principally because the heart does not pump an adequate volume of blood into the arterial tree, which leads to reduced blood pressure and activation of baroreceptor reflexes, as discussed in Chapter 18. The sympathetic stimulation also increases irritability of the cardiac muscle and thereby predisposes to fibrillation.
4. Cardiac muscle weakness caused by the myocardial infarction often causes the ventricle to dilate excessively. This excessive dilation increases the pathway length for impulse conduction in the heart and frequently causes abnormal conduction pathways all the way around the infarcted area of the cardiac muscle. Both of these effects predispose to the development of *circus movements*. As discussed in Chapter 13, excess prolongation of conduction pathways in the ventricles allows impulses to reenter muscle that is already recovering from refractoriness, thereby initiating a circus movement cycle of new excitation and resulting in continuation of the process.

Rupture of Infarcted Area. During the first day or so after an acute infarct, there is little danger of rupture of the ischemic portion of the heart, but a few days later, the dead muscle fibers begin to degenerate, and the heart wall becomes stretched very thin. When this happens, the dead muscle bulges outward to a severe degree with each heart contraction, and this systolic stretch becomes greater and greater until finally the heart ruptures. One of the methods used to assess the progress of severe myocardial infarction is to record by cardiac imaging, with echocardiography, magnetic resonance imaging (MRI), or computed tomography (CT), whether the degree of systolic stretch is worsening.

When a ventricle does rupture, loss of blood into the pericardial space causes rapid development of *cardiac tamponade*—that is, compression of the heart from the outside by blood collecting in the pericardial cavity. Because of this compression of the heart, blood cannot flow into the right atrium, and the patient dies of suddenly decreased cardiac output.

STAGES OF RECOVERY FROM ACUTE MYOCARDIAL INFARCTION

The upper left part of **Fig. 21.8** shows the effects of acute coronary occlusion in a patient with a small area of muscle ischemia; to the right is shown a heart with a large area of ischemia. When the area of ischemia is small, little or no death of the muscle cells may occur, but part of the muscle often does become temporarily nonfunctional because of inadequate nutrition to support muscle contraction.

When the area of ischemia is large, some of the muscle fibers in the center of the area die rapidly, within 1 to 3 hours, where there is total cessation of coronary blood supply. Immediately around the dead area is a nonfunctional area, with failure of contraction and usually failure of impulse conduction. Then, extending circumferentially around the nonfunctional area, is an area that is still contracting but only weakly because of mild ischemia.

Replacement of Dead Muscle By Scar Tissue. In the lower part of **Fig. 21.8**, the various stages of recovery after a large myocardial infarction are shown. Shortly after the occlusion, the muscle fibers in the center of the ischemic area die. Then, during the ensuing days, this area of dead fibers enlarges because many of the marginal fibers finally succumb to the prolonged ischemia. At the same time, because of the enlargement of collateral arterial channels supplying the outer rim of the infarcted area, some of

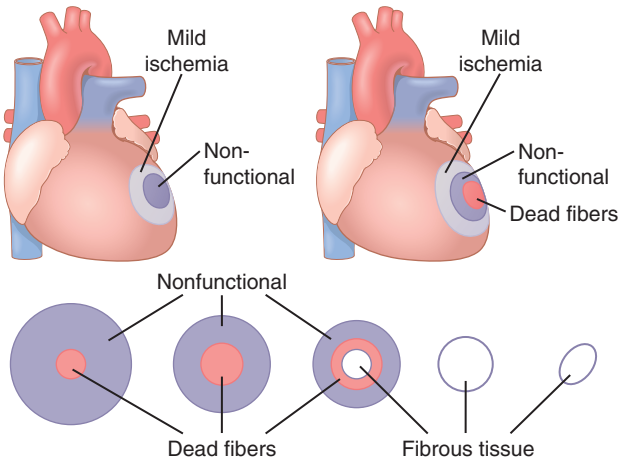

Figure 21.8 *Top*, Small and large areas of coronary ischemia. *Bottom*, Stages of recovery from myocardial infarction.

the nonfunctional muscle recovers. After a few days to 3 weeks, most of the nonfunctional muscle becomes functional again or dies. In the meantime, fibrous tissue begins developing among the dead fibers because ischemia can stimulate growth of fibroblasts and promote development of greater than normal quantities of fibrous tissue. Therefore, the dead muscle tissue is gradually replaced by fibrous tissue. Then, because it is a general property of fibrous tissue to undergo progressive contraction and dissolution, the fibrous scar may grow smaller over a period of several months to a year.

Finally, the normal areas of the heart gradually hypertrophy to compensate, at least partially, for the lost dead cardiac musculature. By these means, the heart recovers partially or almost completely within a few months, depending on the severity of the infarction and cardiac tissue death.

Value of Rest for Recovery Following Myocardial Infarction. The degree of cardiac cellular death is determined by the degree of ischemia and workload on the heart muscle. When the workload is greatly increased, such as during exercise or in severe emotional strain, the heart needs increased oxygen and other nutrients for sustaining its life. Furthermore, anastomotic blood vessels that supply blood to ischemic areas of the heart must also still supply the areas of the heart that they normally supply. When the heart becomes excessively active, the vessels of the normal musculature become greatly dilated. This dilation allows most of the blood flowing into the coronary vessels to flow through the normal muscle tissue, thus leaving little blood to flow through the small anastomotic channels into the ischemic area. As a result, the ischemic condition worsens, a condition called the *coronary steal syndrome*. Consequently, an important factor in the treatment of a patient with myocardial infarction is observance of absolute body rest during the initial acute phase of recovery.

Importance of Increased Physical Activity for Cardiac Rehabilitation After Myocardial Infarction. Although body rest is essential for reducing the workload on the heart immediately following myocardial infarction, clinical studies have shown that increased physical activity, beginning after medical therapy has been started and the clinical status of the patient is stable, is associated with a lower risk of subsequent death. Current programs for cardiac rehabilitation after myocardial infarction therefore generally include prescribed aerobic exercise as a core component although exercise intervention should be initiated after an appropriate recovery time and under the guidance of a physician. Exercise training has several favorable effects on the heart, including improved endothelial function in coronary arteries, reduced inflammation, and improved contractile function of surviving cardiomyocytes.

HEART FUNCTION AFTER RECOVERY FROM MYOCARDIAL INFARCTION

Occasionally, a heart that has recovered from a large myocardial infarction returns almost to full functional capability, but more frequently, its pumping capability is permanently decreased below that of a healthy heart. This does not mean that the person is necessarily a cardiac invalid or that the resting cardiac output is depressed below normal because the normal heart is capable of pumping 300% to 400% more blood per minute than the body requires during rest—that is, a normal person has a *cardiac reserve* of 300% to 400%. Even when the cardiac reserve is reduced to as little as 100%, the person can still perform most normal daily activities although the ability to increase cardiac output during strenuous exercise is reduced. Yet, a cardiac rehabilitation program that includes exercise training often permits at least partial recovery of cardiac reserve and improved exercise tolerance.

CARDIAC PAIN IN CORONARY HEART DISEASE

Normally, a person cannot "feel" the heart, but ischemic cardiac muscle often does cause a pain sensation that is sometimes severe. Exactly what causes this pain is not known, but it is believed that ischemia causes the muscle to release acidic substances such as lactic acid or other pain-promoting products, such as histamine, kinins, or cellular proteolytic enzymes, which are not removed rapidly enough by the slowly moving coronary blood flow. The high concentrations of these abnormal products then stimulate pain nerve endings in the cardiac muscle, sending pain impulses through sensory afferent nerve fibers into the central nervous system.

Angina Pectoris. In most people who sustain progressive constriction of their coronary arteries, cardiac pain, called *angina pectoris*, begins to appear whenever the metabolic demands on the heart become too great in

relation to the available coronary blood flow. This pain is usually felt beneath the upper sternum over the heart. In addition, the pain is often referred to distant surface areas of the body, usually to the left arm and left shoulder but also frequently to the neck and even to the side of the face. The reason for this distribution of pain is that during embryonic life, the heart originates in the neck, as do the arms. Therefore, both the heart and these surface areas of the body receive pain nerve fibers from the same spinal cord segments.

Most people who have chronic angina pectoris feel pain when they exercise or when they experience emotions that increase metabolism of the heart or temporarily constrict the coronary vessels because of sympathetic vasoconstrictor nerve signals. Anginal pain is also exacerbated by cold temperatures or by having a full stomach, both of which increase the workload of the heart. The pain usually lasts for only a few minutes. However, some patients have such severe and lasting ischemia that the pain is present all the time. The pain is frequently described as hot, pressing, and constricting and is of such quality that it usually makes the patient stop all unnecessary body activity.

Drug Treatment for Angina Pectoris. Several vasodilator drugs, when administered during an acute anginal attack, can often provide immediate relief from the pain. Commonly used short-acting vasodilators are *nitroglycerin* and other *nitrate drugs*. Other drugs, such as angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, calcium channel blockers, and *ranolazine*, may be beneficial in treating chronic stable angina pectoris.

Another class of drugs used for the prolonged treatment of angina pectoris is the *beta blockers*, such as *propranolol*. These drugs block sympathetic beta-adrenergic receptors, which attenuates sympathetic enhancement of heart rate and cardiac metabolism during exercise or emotional episodes. Therefore, therapy with a beta blocker decreases the need of the heart for extra metabolic oxygen during stressful conditions. For obvious reasons, this therapy can also reduce the number of anginal attacks, as well as their severity.

SURGICAL TREATMENT OF CORONARY ARTERY DISEASE

Aortic-Coronary Bypass Surgery. In many patients with coronary ischemia, the constricted areas of the coronary arteries are located at only a few discrete points blocked by atherosclerotic disease, and the coronary vessels elsewhere are normal or almost normal. In the 1960s, a surgical procedure called *aortic-coronary bypass* or *coronary artery bypass grafting* (CABG) was developed, in which a section of a subcutaneous vein is removed from an arm or leg and then grafted from the root of the aorta to the side of a peripheral coronary artery beyond the atherosclerotic blockage point (**Fig. 21.9A**). One to five such grafts are usually performed, each of which supplies a peripheral coronary artery beyond a block.

Anginal pain is relieved in most patients after coronary bypass surgery. Also, in patients whose hearts have not become too severely damaged before the operation, the coronary bypass procedure may provide the patient with normal life expectancy. If the heart has already been severely damaged, however, the bypass procedure may be of little value.

Coronary Angioplasty. Since the 1980s, a procedure has been used to open partially blocked coronary vessels before they become totally occluded. This procedure, called *coronary artery angioplasty*, is performed as follows. A small balloon-tipped catheter, about 1 millimeter in diameter, is passed under radiographic guidance into the coronary system and pushed through the partially occluded artery until the balloon portion of the catheter straddles the partially occluded point (**Fig. 21.9B**). The balloon is then inflated with high pressure, which stretches the diseased artery markedly. After

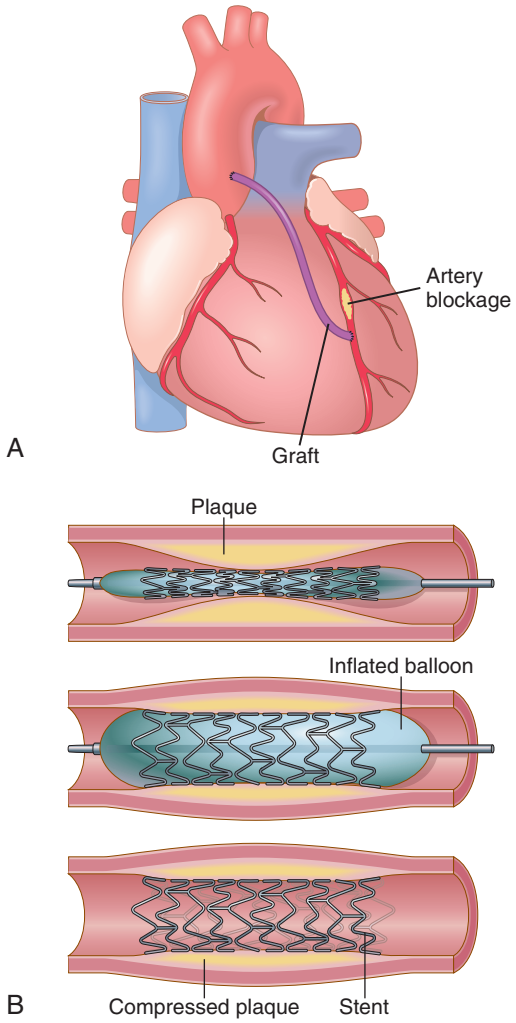

Figure 21.9 (A) Aortic-coronary artery bypass procedure. (B) Angioplasty procedure with a stent.

this procedure is performed, the blood flow through the vessel often increases 3-fold to 4-fold, and more than 75% of patients who undergo the procedure are relieved of the coronary ischemic symptoms for at least several years, although many of the patients still eventually require coronary bypass surgery.

Small stainless steel mesh tubes called *stents* are sometimes placed inside a coronary artery dilated by angioplasty to hold the artery open, thus preventing its restenosis. Within a few weeks after the stent is placed in the coronary artery, the endothelium usually grows over the metal surface of the stent, allowing blood to flow smoothly through the stent. However, reclosure (restenosis) of the blocked coronary artery occurs in about 25% to 40% of patients treated with angioplasty, often within 6 months of the initial procedure. Restenosis is usually due to excessive formation of scar tissue that develops underneath the healthy new endothelium that has grown over the stent. Stents that slowly release drugs (drug-eluting stents) may help prevent the excessive growth of scar tissue.

Newer procedures for opening atherosclerotic coronary arteries are constantly in experimental development. One of these procedures uses a laser beam from the tip of a coronary artery catheter aimed at the atherosclerotic lesion. The laser literally dissolves the lesion without substantially damaging the remainder of the arterial wall.

Heart Failure

One of the most common diseases treated by the clinician is heart failure. This clinical syndrome can result from any condition that reduces the ability of the heart to pump enough blood to meet the body's hemodynamic and metabolic needs. A common cause of heart failure is decreased contractility of the myocardium resulting from diminished coronary blood flow and myocardial ischemia. However, several other conditions may also cause heart failure (**Table 22.1**).

In the first part of this chapter, we mainly discuss heart failure caused by ischemic heart disease resulting from partial blockage of the coronary blood vessels, which is the most common cause of heart failure. Later, we discuss the different types of heart failure. In Chapter 23, we discuss valvular and congenital heart disease.

Table 22.1 Some Conditions Associated With Heart Failure

Damage to the myocardium
• Myocardial ischemia or infarction
• Inflammation or injury from infection (myocarditis)
• Drug toxicity (stimulants, chemotherapy)
• Excessive alcohol use
Increased arterial pressure or heart afterload
• Hypertension
• Aortic stenosis
Increased body fluid volume or preload
• Valvular regurgitation
• Intracardiac shunts
Metabolic abnormalities
• Excess adiposity
• Diabetes mellitus
• Severe anemia
Autoimmune disorders
Genetic or congenital heart disease
Cardiac arrhythmias (tachycardia)
Infiltrative myocardial diseases (amyloidosis, sarcoidosis)

CIRCULATORY DYNAMICS IN HEART FAILURE

ACUTE EFFECTS OF HEART FAILURE

If the heart suddenly becomes severely damaged, such as by myocardial infarction, the pumping ability of the heart is immediately depressed. As a result, two main effects occur: (1) reduced cardiac output; and (2) damming of blood in the veins, resulting in increased venous pressure.

The progressive changes in heart pumping effectiveness at different times after an acute myocardial infarction are shown graphically in **Fig. 22.1**. The top curve of this figure shows a normal cardiac output curve. Point A on this curve is the normal operating point, showing a normal cardiac output under resting conditions of 5 L/min and a right atrial pressure of 0 mm Hg.

Immediately after the heart becomes damaged, the cardiac output curve is greatly depressed, falling to the lowest curve at the bottom of the graph. Within a few seconds, a new circulatory state is established at point B, illustrating that the cardiac output has fallen to 2 L/min,

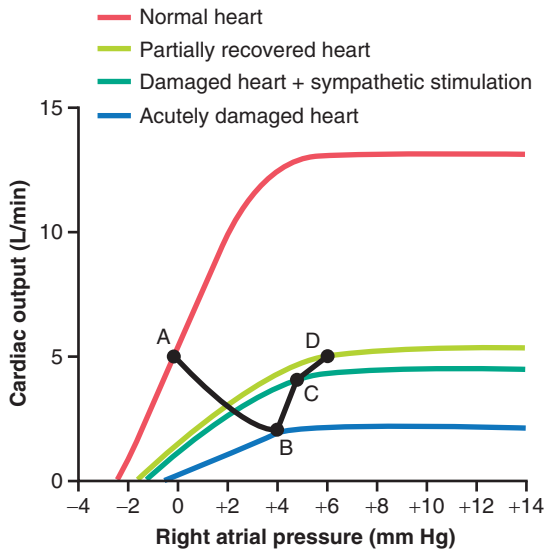

Figure 22.1 Progressive changes in the cardiac output curve after acute myocardial infarction. Both the cardiac output and right atrial pressure change progressively from point A to point D (illustrated by the *black line*) over a period of seconds, minutes, days, and weeks.

about two-fifths normal, whereas the right atrial pressure has risen to +4 mm Hg because venous blood returning to the heart from the body is dammed up in the right atrium. This low cardiac output is still sufficient to sustain life, but it is likely to be associated with symptoms such as dizziness or fainting, fatigue, and shortness of breath with activity. Fortunately, this acute stage usually is transient because sympathetic nervous reflexes occur almost immediately and compensate, to a great extent, for the damaged heart, as follows.

Compensation for Acute Heart Failure By Sympathetic Nervous Reflexes. When the cardiac output falls very low, many of the circulatory reflexes discussed in Chapter 18 are rapidly activated. The best known of these is the *baroreceptor reflex*, which is activated by diminished arterial pressure. The *chemoreceptor reflex*, the *central nervous system ischemic response*, and even *reflexes that originate in the damaged heart* also likely contribute to activation of the sympathetic nervous system. The sympathetic nervous system therefore becomes strongly stimulated within a few seconds, and the parasympathetic nervous signals to the heart become inhibited at the same time.

Strong sympathetic stimulation has major effects on the heart and peripheral blood vessels. If all the ventricular musculature is diffusely damaged but is still functional, sympathetic stimulation strengthens this damaged musculature. If part of the muscle is nonfunctional and part of it is still normal, the normal muscle is strongly stimulated by sympathetic stimulation, in this way partially compensating for the nonfunctional muscle. Thus, *the heart becomes a stronger pump* as a result of sympathetic stimulation. This effect is illustrated in **Fig. 22.1**, which shows about a 2-fold elevation of the very low cardiac output curve after sympathetic compensation.

Sympathetic stimulation also increases venous return because it increases the tone of most of the blood vessels of the circulation, especially the veins, *raising the mean systemic filling pressure* to 12 to 14 mm Hg, almost 100% above normal. As discussed in Chapter 20, this increased filling pressure greatly increases the tendency for blood to flow from the veins back into the heart. Therefore, the damaged heart becomes primed with more inflowing blood than usual, and the right atrial pressure rises still further, which helps the heart pump still larger quantities of blood. Thus, in **Fig. 22.1**, the new circulatory state is depicted by point C, showing a cardiac output of 4.2 L/min and a right atrial pressure of 5 mm Hg.

The sympathetic reflexes become maximally developed in about 30 seconds. Therefore, a person who has a sudden, mild or moderate heart attack might experience nothing more than cardiac pain. Shortly thereafter, with the aid of the sympathetic reflex compensations, the cardiac output may return to a level adequate to sustain the person if they remain quiet, although the pain might persist.

CHRONIC STAGE OF HEART FAILURE—FLUID RETENTION AND COMPENSATED CARDIAC OUTPUT

After the first few minutes of an acute myocardial infarction (heart attack), a prolonged semichronic state begins, characterized mainly by two events: (1) retention of fluid by the kidneys; and (2) varying degrees of recovery of the heart over a period of weeks to months, as illustrated by the light green curve in **Fig. 22.1**. This topic was also discussed in Chapter 21.

Renal Retention of Fluid and Increase in Blood Volume Occur for Hours to Days

A low cardiac output has a profound effect on kidney function, sometimes causing anuria when the cardiac output falls to 50% to 60% of normal. In general, the urine output remains below normal as long as the cardiac output and arterial pressure remain significantly less than normal; urine output usually does not return all the way to normal after an acute heart attack until the cardiac output and arterial pressure rise almost to normal levels.

Moderate Fluid Retention in Heart Failure Can Be Beneficial. Many clinicians have considered fluid retention to have a detrimental effect in heart failure. However, a moderate increase in body fluid and blood volume is an important factor in helping to compensate for the diminished pumping ability of the heart by increasing the venous return. The increased blood volume increases venous return in two ways. First, it increases the mean systemic filling pressure, which *increases the pressure gradient for causing venous flow of blood toward the heart*. Second, it distends the veins, which *reduces the venous resistance* and allows even more ease of flow of blood to the heart.

If the heart is not damaged too severely, this increased venous return can almost fully compensate for the heart's diminished pumping ability—enough so that even when the heart's pumping ability is reduced to as low as 40% to 50% of normal, the increased venous return can often cause nearly normal cardiac output as long as the person remains in a quiet resting state.

When the heart's pumping capability is reduced further, blood flow to the kidneys finally becomes too low for the kidneys to excrete enough salt and water to equal salt and water intake. Therefore, fluid retention begins and continues indefinitely unless major therapeutic procedures are used to prevent this outcome. Furthermore, because the heart is already pumping at its maximum capacity, *this excess fluid no longer has a beneficial effect* on the circulation. Instead, the fluid retention increases the workload on the already damaged heart, and severe edema develops throughout the body, which can be very detrimental and can lead to death.

Detrimental Effects of Excess Fluid Retention in Severe Heart Failure. In contrast to the beneficial effects of moderate fluid retention in mild or moderate heart failure, in severe heart failure, extreme excesses of fluid can have serious physiological consequences. These include

the following: (1) increasing the workload on the damaged heart; (2) overstretching of the heart, which further weakens the heart; (3) filtration of fluid into the lungs, causing pulmonary edema and consequent deoxygenation of the blood; and (4) development of extensive edema in most parts of the body. These detrimental effects of excessive fluid are discussed in later sections of this chapter.

Recovery of the Heart After Myocardial Infarction

After a heart becomes suddenly damaged as a result of myocardial infarction, the natural reparative processes of the body begin to help restore normal cardiac function. For example, a new collateral blood supply begins to penetrate the peripheral portions of the infarcted area of the heart, often causing some of the heart muscle in the fringe areas to become functional again. Also, the undamaged portion of the heart musculature hypertrophies, offsetting some of the cardiac damage.

The degree of recovery, which depends on the type and severity of cardiac damage, varies from no recovery to almost complete recovery. After an acute myocardial infarction, the heart ordinarily recovers rapidly during the first few days and weeks and achieves most of its final state of recovery within 5 to 7 weeks, although mild degrees of additional recovery can continue for months.

Cardiac Output Curve After Partial Recovery. Fig. 22.1 shows function of the partially recovered heart a week or so after an acute myocardial infarction. By this time, considerable fluid has been retained in the body, and the tendency for venous return has increased markedly as well; therefore, the right atrial pressure has risen even more. As a result, the state of the circulation is now changed from point C to point D, which shows a normal cardiac output of 5 L/min but right atrial pressure increased to 6 mm Hg.

Because the cardiac output has returned to normal, renal output of fluid also returns to normal, and no further fluid retention occurs, except that *the retention of fluid that has already occurred continues to maintain moderate excesses of fluid*. Therefore, except for the high right atrial pressure represented by point D in this figure, the person now has essentially normal cardiovascular dynamics *as long as they remain at rest*.

If the heart recovers to a significant extent, and if adequate fluid volume has been retained, the cardiac output increases toward normal and sympathetic stimulation gradually abates toward normal. As the heart recovers, the fast pulse rate, cold skin, and pallor resulting from sympathetic stimulation in the acute stage of heart failure gradually disappear.

SUMMARY OF CHANGES AFTER ACUTE HEART FAILURE—COMPENSATED HEART FAILURE

To summarize the events discussed in the past few sections describing the dynamics of circulatory changes after an acute, mild or moderate heart attack, we can divide the stages into the following: (1) the instantaneous effect of the cardiac damage; (2) compensation by the sympathetic nervous system, which occurs mainly within the first 30 to 60 seconds; and (3) chronic compensations resulting from partial heart recovery and renal retention of fluid. All these changes are shown graphically by the black line in Fig. 22.1. The progression of this line shows the normal state of the circulation (point A), the state a few seconds after the heart attack but before sympathetic reflexes have occurred (point B), the rise in cardiac output toward normal caused by sympathetic stimulation (point C), and final return of the cardiac output to almost normal after several days to several weeks of partial cardiac recovery and fluid retention (point D). This final state is called *compensated heart failure*.

Compensated Heart Failure. Note especially in Fig. 22.1 that the maximum pumping ability of the partly recovered heart, as depicted by the plateau level of the light green curve, is still depressed to less than half-normal. This demonstrates that an increase in right atrial pressure can maintain the cardiac output at a normal level, despite continued weakness of the heart. Thus, many people, especially older adults, have normal resting cardiac outputs but mildly to moderately elevated right atrial pressures because of various degrees of compensated heart failure. They may not know that they have cardiac damage because the damage often has occurred a little at a time, and the compensation has occurred concurrently with the progressive stages of damage.

When a person is in a state of compensated heart failure, attempts to perform heavy exercise often cause return of the symptoms of acute heart failure because the heart is not able to increase its pumping capacity to the levels required for the exercise. Therefore, the *cardiac reserve* is reduced in compensated heart failure. This concept of cardiac reserve is discussed later in the chapter.

DECOMPENSATED HEART FAILURE

If the heart becomes severely damaged, no amount of compensation by sympathetic nervous reflexes or fluid retention can make the excessively weakened heart pump a normal cardiac output. As a consequence, the cardiac output cannot rise high enough to make the kidneys excrete normal quantities of fluid. Therefore, fluid continues to be retained, the person develops more and more edema, and this state of events eventually leads to circulatory collapse and death. This condition is called *decompensated heart failure*. Thus, a major cause of decompensated heart failure is failure of the heart to pump sufficient blood to make the kidneys excrete the necessary amounts of fluid every day.

Graphic Analysis of Decompensated Heart Failure. Fig. 22.2 shows greatly depressed cardiac output at different times (points A to F) after the heart has become

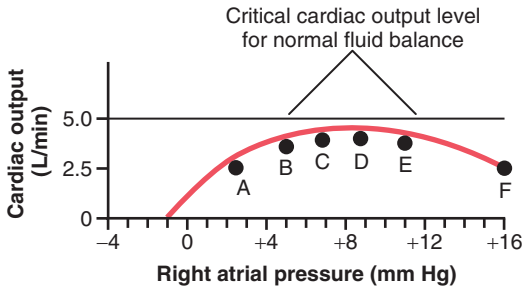

Figure 22.2 Greatly depressed cardiac output that indicates decompensated heart disease. Progressive fluid retention raises the right atrial pressure over a period of days, and the cardiac output progresses from point A to point F until death occurs.

severely weakened. Point A on this curve represents the approximate state of the circulation before any compensation has occurred, and point B represents the state a few minutes later, after sympathetic stimulation has compensated as much as it can but before fluid retention has begun. At this time, the cardiac output has risen to 4 L/min and the right atrial pressure has risen to 5 mm Hg. The person appears to be in reasonably good condition, but this state will not remain stable because the cardiac output has not risen high enough to cause adequate kidney excretion of fluid; therefore, fluid retention continues and can eventually be the cause of death. These events can be explained quantitatively in the following way.

Note the straight line in **Fig. 22.2**, at a cardiac output level of 5 L/min. This level is approximately the critical cardiac output level that is required in the average adult person to make the kidneys reestablish normal fluid balance—that is, for the output of salt and water to be as high as the intake of these substances. At cardiac outputs below this level, the fluid-retaining mechanisms discussed in the earlier section remain in play, and the body fluid volume increases progressively. Because of this progressive increase in fluid volume, the mean systemic filling pressure of the circulation continues to rise, which forces progressively increasing quantities of blood from the person's peripheral veins into the right atrium, thus increasing the right atrial pressure. After 1 day or so, the state of the circulation changes in **Fig. 22.2** from point B to point C, with the right atrial pressure rising to 7 mm Hg and the cardiac output rising to 4.2 L/min. Note again that the cardiac output is still not high enough to cause normal renal output of fluid; therefore, fluid continues to be retained. After another day or so, the right atrial pressure rises to 9 mm Hg, and the circulatory state becomes that depicted by point D. Still, the cardiac output is not enough to establish normal fluid balance.

After another few days of fluid retention, the right atrial pressure has risen further but, by now, cardiac function is beginning to decline toward a lower level. This decline is caused by overstretch of the heart, edema of the heart muscle, and other factors that diminish the heart's pumping performance. It is now clear that further retention of fluid will be more detrimental than beneficial to the circulation. Yet, the cardiac output still is not high enough to bring about normal renal function, so fluid retention not only continues but accelerates because of the falling cardiac output (and the falling arterial pressure that also occurs). Consequently, within a few days, the state of the circulation has reached point F on the curve, with the cardiac output now less than 2.5 L/min and the right atrial pressure 16 mm Hg. This state has approached or reached incompatibility with life, and the patient will die unless this chain of events can be arrested. This state of heart failure in which the failure continues to worsen is called *decompensated heart failure*.

Thus, one can see from this analysis that failure of the cardiac output (and arterial pressure) to rise to the critical level required for normal renal function results in the following: (1) progressive retention of more and more fluid; (2) progressive elevation of the mean systemic filling pressure; and (3) progressive elevation of the intracardiac pressures until, finally, the heart is so overstretched or so edematous that it cannot pump even moderate quantities of blood and, therefore, fails completely. Clinically, one detects this serious condition of decompensation principally by the progressing edema, especially edema of the lungs, which leads to *rales* (a crackling sound) in the lungs and to *dyspnea* (air hunger). Lack of appropriate therapy at this stage rapidly leads to death.

Treatment of Decompensation. The decompensation process can often be attenuated or stopped by (1) strengthening the heart in any one of several ways, especially by administering an inotropic drug (e.g., dobutamine, milrinone, or digitalis) that increases the force of cardiac pumping so that the heart can pump adequate quantities of blood to make the kidneys function normally again; or (2) administering diuretic drugs to increase renal salt and water excretion while at the same time reducing water and salt intake, which results in a balance between fluid intake and output, despite low cardiac output.

Both methods stop the decompensation process by reestablishing normal fluid balance so that at least as much fluid leaves the body as enters it.

Mechanism of Action of Inotropic Drugs. Inotropic drugs, such as digitalis, when administered to a person with a healthy heart, have little effect on increasing the contractile strength (positive inotropy) of the cardiac muscle. However, when administered to someone with a failing heart, the same drugs can sometimes increase the strength of the failing myocardium by as much as 50% to 100%.

Inotropic drugs strengthen heart contractile force by ultimately increasing the quantity of calcium ions in cardiac muscle fibers. The effect of digitalis is likely due to inhibition of Na^+-K^+ ATPase in cardiac cell membranes. Inhibition of the sodium-potassium pump increases the intracellular sodium concentration and slows the sodium-calcium exchange pump, which extrudes calcium from the cell in exchange for sodium. Because the sodium-calcium

exchange pump relies on a high sodium gradient across the cell membrane, accumulation of sodium inside the cell reduces its activity.

In the failing heart muscle, the sarcoplasmic reticulum fails to accumulate normal quantities of calcium and, therefore, cannot release enough calcium ions into the free fluid compartment of the muscle fibers to cause full contraction of the muscle. The effect of digitalis to depress the sodium-calcium exchange pump and raise calcium ion concentration in cardiac muscle provides the extra calcium needed to increase the muscle contractile force. Therefore, it is usually beneficial to depress the calcium pumping mechanism by a moderate amount using digitalis, allowing the muscle fiber intracellular calcium level to rise slightly.

Milrinone, a phosphodiesterase III inhibitor, works in the sarcoplasmic reticulum by preventing the breakdown of cyclic AMP, which phosphorylates calcium channels and increases calcium ion availability in the sarcomere for increasing cardiac contractile force. *Dobutamine* activates beta$_1$-adrenergic receptors to increase cardiac contractile force and heart rate, which both augment cardiac output.

UNILATERAL LEFT HEART FAILURE

Thus far we have considered failure of the heart as a whole. Yet, in a large number of patients, especially those with early acute heart failure, left-sided failure predominates over right-sided failure and, in rare cases, the right side fails without significant failure of the left side.

When the left side of the heart fails without concomitant failure of the right side, blood continues to be pumped into the lungs with usual right heart vigor, whereas it is not pumped adequately out of the lungs by the left heart into the systemic circulation. As a result, the *mean pulmonary filling pressure* rises because of the shift of large volumes of blood from the systemic circulation into the pulmonary circulation.

As the volume of blood in the lungs increases, the pulmonary capillary pressure increases, and if this pressure rises above a value approximately equal to the colloid osmotic pressure of the plasma (about 28 mm Hg), fluid begins to filter out of the capillaries into the lung interstitial spaces and alveoli, resulting in pulmonary edema.

Thus, the most important problems of left heart failure include *pulmonary vascular congestion* and *pulmonary edema*. In severe cases of acute left heart failure, pulmonary edema occasionally occurs so rapidly that it can cause death by suffocation in 20 to 30 minutes, discussed later in this chapter.

LOW-OUTPUT CARDIAC FAILURE—CARDIOGENIC SHOCK

In some cases after severe acute heart attacks, and often after prolonged periods of slow, progressive cardiac deterioration, the heart becomes incapable of pumping even the minimal amount of blood flow required to keep the body alive. Consequently, the body tissues begin to suffer and even to deteriorate, often leading to death within a few hours to a few days. The picture, then, is one of circulatory shock, as explained in Chapter 24. Even the cardiovascular system suffers from lack of nutrition and deteriorates, along with the remainder of the body, thus hastening death. This circulatory shock syndrome caused by inadequate cardiac pumping is called *cardiogenic shock*. Once cardiogenic shock develops, the survival rate is often less than 30%, even with appropriate medical care.

Vicious Cycle of Cardiac Deterioration in Cardiogenic Shock. The discussion of circulatory shock in Chapter 24 emphasizes the tendency for the heart to become progressively more damaged when its coronary blood supply is reduced during the course of the shock. That is, the low arterial pressure that occurs during shock reduces the coronary blood supply even more. This reduction further weakens the heart, which makes the arterial pressure fall further, which makes the shock progressively worse; the process eventually becomes a vicious cycle of cardiac deterioration.

In cardiogenic shock caused by myocardial infarction, this problem is greatly compounded by already existing coronary vessel blockage. For example, in a healthy heart, the arterial pressure usually must be reduced below about 45 mm Hg before cardiac deterioration sets in. However, in a heart that already has a blocked major coronary vessel, deterioration begins when the coronary arterial pressure falls below 80 to 90 mm Hg. In other words, even a small decrease in arterial pressure can now set off a vicious cycle of cardiac deterioration. For this reason, in treating myocardial infarction, it is extremely important to prevent even short periods of hypotension.

Cardiogenic Shock Treatment. In severe cases, a patient dies of cardiogenic shock before the various compensatory processes can return the cardiac output (and arterial pressure) to a life-sustaining level. Therefore, treatment of this condition is one of the most important challenges in the management of acute heart attacks.

Drugs that increase cardiac contractile strength (positive inotropes) are often administered immediately to strengthen the heart if the ventricular muscle shows signs of deterioration and there are signs of weakened peripheral circulation. Also, infusion of blood pressure–raising drugs (vasopressors) is used to sustain the arterial pressure.

In patients with cardiogenic shock who are refractory to medical therapies, mechanical circulatory support devices can increase cardiac output, thus increasing coronary and peripheral blood flow and oxygenation. *Intra-aortic balloon pumps* can be placed in the descending thoracic aorta and inflated during diastole, thereby increasing coronary blood flow, and rapidly deflated in systole to create a suction effect in the proximal aorta to increase cardiac output. *Continuous or pulsatile flow devices with pumping motors* can be placed in the left

ventricle, directing blood through a cannula into the aorta to increase cardiac output. Some of these devices are temporary, but some ventricular assist devices can sustain increased cardiac output for many months with an external pump. If the arterial pressure can be elevated to a high enough level, the coronary blood flow often will increase enough to prevent the vicious cycle of deterioration. This process allows enough time for appropriate compensatory mechanisms in the circulatory system to correct the shock.

Some success has also been achieved in saving the lives of patients in ischemic cardiogenic shock by using one of the following procedures: (1) performing coronary angiography through a peripheral artery and inflating a small balloon-mounted metallic stent in the blocked coronary segment (percutaneous coronary intervention) (see **Fig. 21.9**); (2) surgically bypassing the clotted segment in the coronary artery with a coronary artery bypass graft (see **Fig. 21.9**); or (3) infusing thrombolytic agents (*tissue-type plasminogen activator* enzymes) or anticoagulants that cause dissolution of the clot. The results are occasionally astounding when one of these procedures is instituted within the first 90 minutes of an acute heart attack, but their beneficial effects on heart function are attenuated over time.

EDEMA IN PATIENTS WITH HEART FAILURE

Acute Heart Failure Does Not Cause Immediate Peripheral Edema. Acute *left* heart failure can cause rapid congestion of the lungs, with the development of *pulmonary edema* and even death within minutes to hours in severe cases. However, left or right heart failure is slow to cause *peripheral edema*. This situation can best be explained by referring to **Fig. 22.3**. When a previously healthy heart acutely fails as a pump, the aortic pressure falls, and the right atrial pressure rises. As the cardiac output approaches zero, these two pressures approach each other at an equilibrium value of about 13 mm Hg. Capillary pressure also falls from its normal value of 17 mm Hg to the new equilibrium pressure of 13 mm Hg. Thus, *severe acute heart failure often causes a fall rather than a rise in peripheral capillary pressure*. Therefore, acute heart failure almost never causes immediate development of peripheral edema.

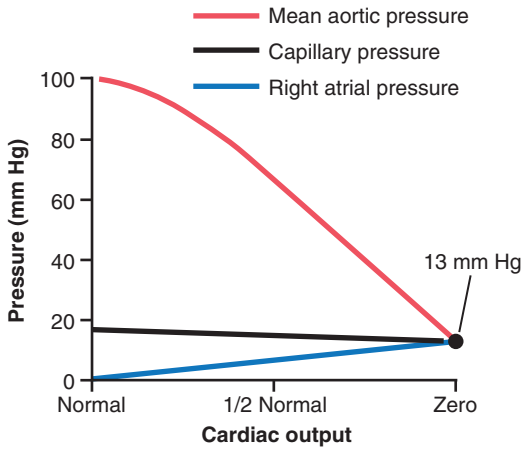

Figure 22.3 Progressive changes in mean aortic pressure, peripheral tissue capillary pressure, and right atrial pressure as the cardiac output falls from normal to zero.

LONG-TERM FLUID RETENTION BY THE KIDNEYS CAUSES PERIPHERAL EDEMA IN CHRONIC HEART FAILURE

After the first day or so of overall heart failure or right ventricular heart failure, peripheral edema begins to occur, principally *because of fluid retention by the kidneys*. The retention of fluid increases the mean systemic filling pressure, resulting in an increased tendency for blood to return to the heart. This further elevates the right atrial pressure and returns the arterial pressure back toward normal. Therefore, *the capillary pressure now also rises markedly*, thus causing loss of fluid into the tissues and the development of edema.

Reduced renal output of urine during heart failure has several known causes.

1. **Decreased glomerular filtration rate**. A decrease in cardiac output tends to reduce the glomerular pressure in the kidneys because of the following: (a) *reduced arterial pressure*; and (b) *intense sympathetic constriction of the afferent arterioles of the kidney*. As a consequence, except in the mildest degrees of heart failure, the glomerular filtration rate is reduced. It is clear from the discussion of kidney function in Chapters 27 through 30 that *a decrease in glomerular filtration often markedly decreases urine output*. A fall in the cardiac output to about half-normal can result in almost complete anuria.
2. **Activation of renin-angiotensin system and increased reabsorption of water and salt by renal tubules**. The reduced blood flow to the kidneys causes a marked increase in *renin secretion* by the kidneys, which in turn increases the *formation of angiotensin II*, as described in Chapter 19. Angiotensin II, in turn, has a direct effect on the arterioles of the kidneys to decrease blood flow through the kidneys further, which reduces the pressure in the peritubular capillaries surrounding the renal tubules, promoting greatly increased reabsorption of water and sodium from the tubules. Angiotensin II also acts directly on the renal tubular epithelial cells to stimulate reabsorption of sodium and water. Therefore, loss of water and sodium into the urine decreases greatly, and large quantities of sodium and water accumulate in the blood and interstitial fluids throughout the body.
3. **Increased aldosterone secretion**. In the chronic stage of heart failure, large quantities of aldosterone

are secreted by the adrenal cortex. This secretion results mainly from the effect of angiotensin II to stimulate aldosterone secretion by the adrenal cortex. However, some of the increase in aldosterone secretion often results from increased plasma potassium concentration. Excess potassium is one of the most powerful stimuli known for aldosterone secretion, and the potassium concentration rises in response to reduced renal function in those with heart failure. The elevated aldosterone level further increases reabsorption of sodium from the renal tubules, which in turn leads to a secondary increase in water reabsorption, as discussed in Chapter 28.

4. **Increased antidiuretic hormone secretion**. In advanced heart failure, increased secretion of *antidiuretic hormone* (ADH) may contribute to excessive water reabsorption by the renal tubules. As discussed in Chapters 28 and 29, ADH is secreted by the hypothalamic–posterior pituitary gland system in response to increased extracellular fluid osmolarity, as well as nonosmotic stimuli from low-pressure (e.g., left atrial) and high-pressure (e.g., carotid sinus) baroreceptors. In severe heart failure, the nonosmotic effects of reductions in cardiac output and arterial pressure may predominate to stimulate secretion of ADH, which in turn causes excess water retention and *hyponatremia* (low plasma sodium concentration). Inappropriately high levels of ADH and hyponatremia are predictors for worsening outcomes in patients with heart failure.
5. **Activation of sympathetic nervous system**. As discussed previously, heart failure causes marked activation of the sympathetic nervous system, which in turn has several effects that lead to salt and water retention by the kidneys: (a) constriction of renal afferent arterioles, which reduces the glomerular filtration rate; (b) stimulation of renal tubular reabsorption of salt and water by activation of alpha-adrenergic receptors on tubular epithelial cells; (c) stimulation of renin release and angiotensin II formation, which increases renal tubular reabsorption; and (d) stimulation of ADH release from the posterior pituitary, which then increases water reabsorption by the renal tubules. These effects of sympathetic stimulation are discussed in Chapters 27 and 28.

Role of Natriuretic Peptides in Delaying Onset of Cardiac Decompensation. *Natriuretic peptides* are hormones released by the heart when it becomes stretched. Atrial natriuretic peptide (ANP) is primarily released by distension of the atrial walls, and brain natriuretic peptide (BNP) is released by the ventricular walls. Because heart failure almost always increases the atrial and ventricular pressures that stretch the walls of these chambers, circulating levels of ANP and BNP in the blood may increase severalfold in severe heart failure. These natriuretic peptides, in turn, have a direct effect on the kidneys to increase their excretion of salt and water greatly. Therefore, the natriuretic peptides play a natural role to help prevent extreme congestive symptoms during heart failure. Because the half-life of BNP is significantly longer than that of ANP and can be easily measured in the bloodstream, it is often used to diagnose heart failure or to monitor volume status in patients with established heart failure. The renal effects of ANP are discussed in Chapters 28 and 30.

Acute Pulmonary Edema in Late-Stage Heart Failure—Another Lethal Vicious Cycle

A frequent cause of death is *acute pulmonary edema* in patients who have already had heart failure for a long time. When acute pulmonary edema occurs in a person without new cardiac damage, it usually is set off by some temporary overload of the heart, such as that which might result from a bout of heavy exercise, an emotional experience, or even a severe cold. The acute pulmonary edema is believed to result from the following vicious cycle:

1. A temporarily increased load on the already weak left ventricle initiates the vicious cycle. Because of limited pumping capacity of the left heart, blood begins to dam up in the lungs.
2. The increased blood in the lungs increases the pulmonary capillary pressure, and a small amount of fluid begins to transude into the lung tissues and alveoli.
3. The increased fluid in the lungs diminishes the degree of oxygenation of the blood.
4. The decreased oxygen in the blood further stresses and weakens the heart and also causes peripheral vasodilation.
5. The peripheral vasodilation further increases venous return of blood from the peripheral circulation.
6. The increased venous return further increases damming of the blood in the lungs, leading to more transudation of fluid, more arterial oxygen desaturation, and more venous return. Thus, a vicious cycle has been established.

Once this vicious cycle has proceeded beyond a certain critical point, it will continue until the patient dies, unless successful therapeutic measures are initiated. The types of measures that can reverse the process and save the patient's life include the following:

1. Administering a rapidly acting diuretic, such as the loop diuretic furosemide, to cause rapid loss of fluid from the body
2. Giving the patient pure oxygen to breathe to reverse the blood oxygen desaturation, heart deterioration, and peripheral vasodilation
3. Administering a rapidly acting cardiotonic drug, such as dobutamine or digitalis, to strengthen the force of heart contraction

This vicious cycle of acute pulmonary edema can proceed so rapidly that death can occur in 20 to 60 minutes in severe cases. Therefore, any procedure that is to be successful must be instituted immediately.

CARDIAC RESERVE

The maximum percentage that the cardiac output can increase above normal is called the *cardiac reserve*. Thus, in the healthy young adult, the cardiac reserve is 300% to 400%. In athletically trained persons, it is 500% to 600% or more. However, in persons with severe heart failure, there is no cardiac reserve. As an example of normal reserve, the cardiac output of a healthy young adult during vigorous exercise can rise to about five times normal, which is an increase above normal of 400%—that is, *a cardiac reserve of 400%*.

Any factor that prevents the heart from pumping blood satisfactorily will decrease the cardiac reserve. A decrease in cardiac reserve can result from disorders such as ischemic heart disease, primary myocardial disease, vitamin deficiency that affects cardiac muscle, physical damage to the myocardium, valvular heart disease, and other factors, some of which are shown in **Fig. 22.4**.

Diagnosis of Low Cardiac Reserve—Exercise Test. As long as persons with low cardiac reserve remain in a state of rest, they usually will not experience major symptoms of heart disease. However, a diagnosis of low cardiac reserve usually can be made by requiring the person to exercise on a treadmill or by walking up and down steps, either of which requires greatly increased cardiac output. The increased load on the heart rapidly uses up the small amount of reserve that is available, and the cardiac output soon fails to rise high enough to sustain the body's new level of activity. The acute effects are as follows:

1. Immediate and sometimes extreme shortness of breath (*dyspnea*) resulting from failure of the heart to pump sufficient blood to the tissues, thereby causing tissue ischemia and creating a sensation of air hunger
2. Extreme muscle fatigue resulting from muscle ischemia, thus limiting the person's ability to continue with the exercise
3. Excessive increase in heart rate because the nervous reflexes to the heart overreact in an attempt to overcome the inadequate cardiac output

Exercise tests are part of the armamentarium of the cardiologist. These tests take the place of cardiac output measurements that cannot easily be made in most clinical settings.

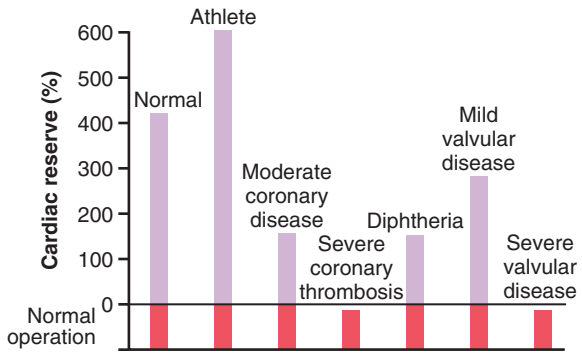

Figure 22.4 Cardiac reserve in different conditions, showing less than zero reserve for two of the conditions.

QUANTITATIVE GRAPHIC ANALYSIS OF CARDIAC FAILURE

Although it is possible to understand most general principles of heart failure using mainly qualitative logic, as we have done thus far in this chapter, one can grasp the importance of the different factors in heart failure in greater depth by using more quantitative approaches. One such approach is the graphic method for analysis of cardiac output regulation introduced in Chapter 20. In the rest of this chapter, we will use this graphic technique to analyze several aspects of heart failure.

Graphic Analysis of Acute Heart Failure and Chronic Compensation

Fig. 22.5 shows *cardiac output* and *venous return curves* for different states of the heart and peripheral circulation. The two curves passing through point A are (1) the *normal cardiac output curve* and (2) the *normal venous return curve*. As indicated in Chapter 20, there is only one point on each of these two curves at which the circulatory system can operate—point A, where the two curves cross. Therefore, the normal state of the circulation is a cardiac output and venous return of 5 L/min and a right atrial pressure of 0 mm Hg.

Myocardial Infarction Reduces the Cardiac Output Curve. During the first few seconds after a moderately severe myocardial infarction, the cardiac output curve falls to the *lowermost blue curve*. During these few seconds, the venous return curve still has not changed because the peripheral circulatory system is still operating normally. Therefore, the new state of the circulation is depicted by point B, where the new cardiac output curve crosses the normal venous return curve. Thus, the right atrial pressure rises immediately to 4 mm Hg, whereas the cardiac output falls to 2 L/min.

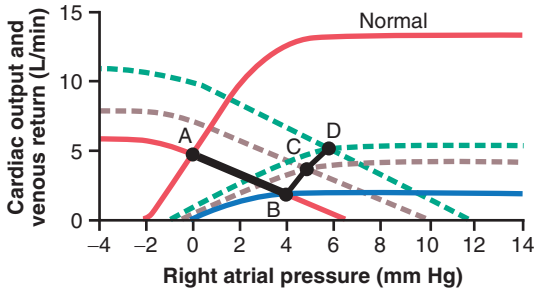

Figure 22.5 Progressive changes in cardiac output, venous return, and right atrial pressure during different stages of cardiac failure.

Sympathetic Reflexes Raise Cardiac Output and Venous Return Curves. Within the next 30 seconds, the sympathetic reflexes are activated. They raise the cardiac output and venous return curves (*brown dashed curves*). Sympathetic stimulation can increase the plateau level of the cardiac output curve by as much as 30% to 100%. It can also increase the mean systemic filling pressure (depicted by the point where the venous return curve crosses the zero venous return axis) by several millimeters of mercury—in this figure, from a normal value of 7 mm Hg up to 10 mm Hg. This increase in mean systemic filling pressure shifts the entire venous return curve to the right and upward. The new cardiac output and venous return curves now equilibrate at point C—that is, at a right atrial pressure of +5 mm Hg and a cardiac output of 4 L/min.

Compensation During the Next Few Days Further Increases Cardiac Output and Venous Return Curves. During the ensuing week, the cardiac output and venous return curves rise further (*green dashed curves*) because of the following: (1) some recovery of the heart; and (2) renal retention of salt and water, which raises the mean systemic filling pressure still further—this time up to +12 mm Hg. The two new curves now equilibrate at point D. Thus, the cardiac output has now returned to normal. The right atrial pressure, however, has risen still further, to +6 mm Hg. Because the cardiac output is now normal, renal output is also normal, so a new state of equilibrated fluid balance has been achieved. The circulatory system will continue to function at point D and remain stable, with a normal cardiac output and an elevated right atrial pressure, until some additional extrinsic factor changes the cardiac output curve or venous return curve.

Using this technique for analysis, one can especially see the importance of moderate fluid retention and how it eventually leads to a new stable state of the circulation in mild to moderate heart failure. The interrelationship between mean systemic filling pressure and cardiac pumping at various degrees of heart failure can also be seen.

Note that the events described in **Fig. 22.5** are the same as those presented in **Fig. 22.1**, although in a more quantitative manner.

Graphic Analysis of Decompensated Heart Failure

The black cardiac output curve in **Fig. 22.6** is the same as the curve shown in **Fig. 22.2**—a greatly depressed curve that has already reached a degree of recovery as much as this heart can achieve. In this figure, we have added venous return curves that occur during successive days after the acute fall of the cardiac output curve to this low level. At point A, the curve at time zero equates with the normal venous return curve to give a cardiac output of about 3 L/min. However, stimulation of the sympathetic nervous system, caused by this low cardiac output, increases the mean systemic filling pressure within 30 seconds from 7 to 10.5 mm Hg. This effect shifts the venous return curve upward and to the right to produce the curve labeled "autonomic compensation." Thus, the new venous return curve equates with the cardiac output curve at point B. The cardiac output has been improved to a level of 4 L/min but at the expense of an additional rise in right atrial pressure to 5 mm Hg.

The cardiac output of 4 L/min is still too low for the kidneys to function normally. Therefore, fluid continues to be retained and the mean systemic filling pressure rises from 10.5 to almost 13 mm Hg. Now the venous return curve is labeled "2nd day" and equilibrates with the cardiac output curve at point C. The cardiac output rises to 4.2 L/min, and the right atrial pressure rises to 7 mm Hg.

During the succeeding days, the cardiac output never rises high enough to reestablish normal renal function. Fluid continues to be retained, the mean systemic filling pressure continues to rise, the venous return curve continues to shift to the right, and the equilibrium point between the venous return curve and cardiac output curve also shifts progressively to point D, point E, and finally point F. The equilibration process is now on the downslope of the cardiac output curve, and thus further fluid retention causes even more severe cardiac edema and a detrimental effect on cardiac output. The condition accelerates downhill until death occurs.

Thus, *decompensation* results from the fact that the cardiac output curve never rises to the critical level of 5 L/min needed to reestablish the normal renal excretion of fluid required to result in a balance between fluid input and output.

Treatment of Decompensated Heart Failure With Digitalis. Assume that the stage of decompensation has already reached point E in **Fig. 22.6**, and then proceed to the same point E in **Fig. 22.7**. At this time, digitalis is given to strengthen the heart. This intervention raises the cardiac output curve to the level shown in **Fig. 22.7**, but there is no immediate change in the venous return curve. Therefore, the new cardiac output curve equates with the venous return curve at point G. The cardiac output is now

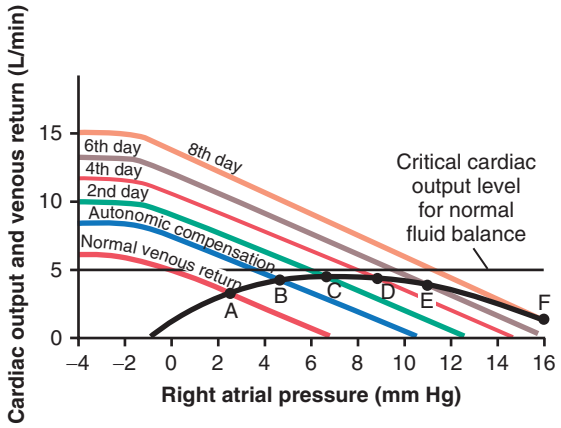

Figure 22.6 Graphic analysis of decompensated heart disease showing progressive shift of the venous return curve to the right and increasing right atrial pressure as a result of continued fluid retention.

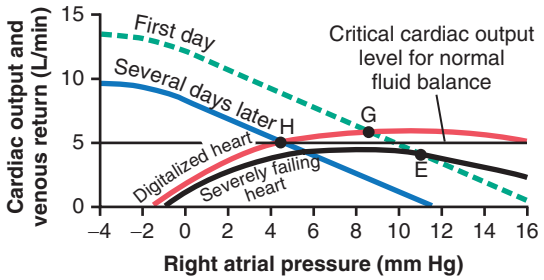

Figure 22.7 Treatment of decompensated heart disease showing the effect of digitalis in elevating the cardiac output curve, with this in turn causing increased urine output, progressive shift of the venous return curve to the left, and decreased right atrial pressure.

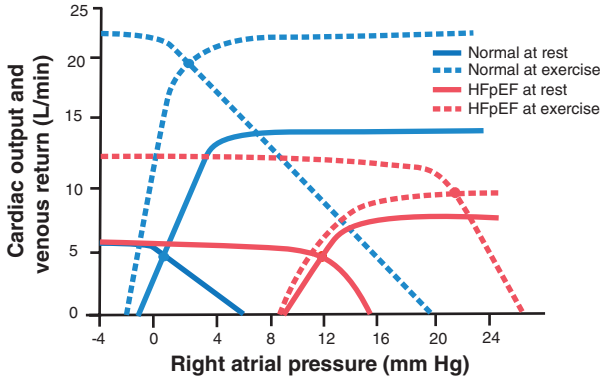

Figure 22.8 Maximal cardiac output during exercise is reduced in patients with heart failure with preserved ejection fraction and comes at the cost of significantly increased cardiac filling pressures.

5.7 L/min, a value higher than the critical level of 5 liters required to make the kidneys excrete normal amounts of urine. The increased cardiac output, along with the well-known diuretic effect of digitalis, permits the kidneys to eliminate some of the excess fluid.

The progressive loss of fluid over several days reduces mean systemic filling pressure down to 11.5 mm Hg, and the new venous return curve becomes the curve labeled "Several days later." This curve equates with the cardiac output curve of the digitalized heart at point H, at an output of 5 L/min and a right atrial pressure of 4.6 mm Hg. This cardiac output is precisely that required for normal fluid balance. Therefore, no additional fluid will be lost, and none will be gained. Consequently, the circulatory system has now stabilized or, in other words, the decompensation of the heart failure has been compensated. To state this another way, the final steady-state condition of the circulation is defined by the crossing point of three curves—the cardiac output curve, venous return curve, and the critical level for normal fluid balance. The compensatory mechanisms automatically stabilize the circulation when all three curves cross at the same point.

HEART FAILURE WITH PRESERVED EJECTION FRACTION

Our discussion thus far has focused mainly on heart failure due to decreased contractility of the myocardium following a myocardial infarction or impaired coronary blood flow. However, as discussed earlier in the chapter, heart failure can occur from any condition that decreases the heart's ability to pump enough blood to meet the body's needs. Heart failure associated with impaired cardiac contractility is often referred to as *systolic heart failure* or *heart failure with reduced ejection fraction* (HFrEF). As discussed in Chapter 9, the ejection fraction (EF), often assessed by echocardiography, is the fraction of the end-diastolic volume of the left ventricle that is ejected with each contraction. An EF of 0.6 means that 60% of the end-diastolic volume ventricle is pumped with each heartbeat. Normal values for EF are considered to be from 50% to 70%. When the heart muscle is weakened, as a result of a myocardial infarction or impaired coronary blood flow, the EF is usually reduced, with values below 40% considered to be indicative of HFrEF.

Heart failure can also be associated with normal EF if the heart muscle becomes thickened and stiff (*concentric hypertrophy*), so that filling of the ventricles is impaired, and the ventricles hold a smaller than usual volume of blood. Under these conditions, the total amount of blood pumped by the heart may not be enough to meet the body's needs, even though the heart is pumping with a normal or even increased EF. This condition is often referred to as *heart failure with preserved ejection fraction (HFpEF)*.

Many patients with HFpEF are obese and have higher cardiac afterload (increased blood pressure and vascular stiffness) and increased preload (total blood volume). It is often challenging to discern which symptoms are related to obesity and whether HFpEF is present. Even though patients with HFpEF may have normal cardiac filling pressures (right atrial pressure) while they are resting, they will experience increases in filling pressures and symptoms with exercise (**Fig. 22.8**).

Most patients with HFpEF also have hypertension, which leads to concentric left ventricular hypertrophy. This thickening of the left ventricular walls can lead to a smaller left ventricular chamber size and reductions in left ventricular stroke volume (**Fig. 22.9**). Left ventricular contractility (represented in the figure by end systolic pressure volume relationship, ESPVR) may be slightly increased, but left ventricular end diastolic pressure (LVEDP) is often increased compared to normal. This is in contrast to HFrEF, in which left ventricular contractility is significantly reduced while left ventricular end diastolic pressure is increased.

During the last 30 to 40 years, a growing proportion of patients with heart failure have presented with HFpEF. Currently, over 50% of patients with heart failure have a normal EF. HFpEF occurs more commonly in women and older adults and especially in those who have obesity, diabetes mellitus, and hypertension, a constellation

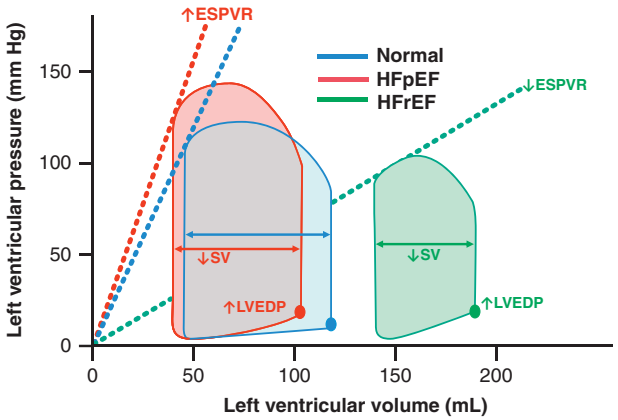

Figure 22.9 The volume-pressure diagrams of heart failure with preserved ejection fraction (HFpEF) and heart failure with reduced ejection fraction (HFrEF) compared to normal. Note that contractility represented by the end systolic pressure volume relationship (ESPVR) is slightly higher in patients with HFpEF and significantly lower in patients with HFrEF. The ESPVR represents the maximal pressure developed by the left ventricle at any given volume and is a measure of cardiac contractility. Left ventricular end diastolic pressure (LVEDP) is higher in patients with HFpEF and HFrEF compared to normal.

of disorders often called the *cardiometabolic syndrome*. In these individuals, diastolic dysfunction is characterized by impairment in the rate of ventricular filling, slowed relaxation of cardiomyocytes, increased thickness of the ventricular wall, proliferation of extracellular matrix, and fibrosis, which contribute to a stiffer left ventricle.

Although clinicians often classify patients into the categories of HFpEF or HFrEF using the EF threshold of 50%, most patients with advanced heart failure exhibit abnormalities of ventricular filling, as well as impaired contractility and impaired systolic function. Most of the neurohumoral changes in heart failure that have been discussed, including activation of the sympathetic and renin-angiotensin system, as well as excessive fluid retention by the kidneys, occur regardless of whether there is normal or reduced EF. Heart failure is a heterogeneous syndrome, rather than a specific disease, and occurs whenever the heart is unable to pump enough blood to meet the needs of the body.

Thus, measurements of EF, although useful, do not always provide an accurate assessment of cardiac function. A small thick heart with impaired diastolic filling may be unable to pump the appropriate stroke volume and cardiac output to meet the body's needs but could have a normal or elevated EF. This example illustrates the limitations of left ventricular EF as a marker of left ventricular function and as a means of categorizing patients with heart failure of different causes.

HIGH-OUTPUT HEART FAILURE

Fig. 22.10 provides an analysis of two types of high-output cardiac failure. One is caused by an arterial-venous (A-V) fistula that overloads the heart because of excessive venous return, even though the pumping capability of the heart

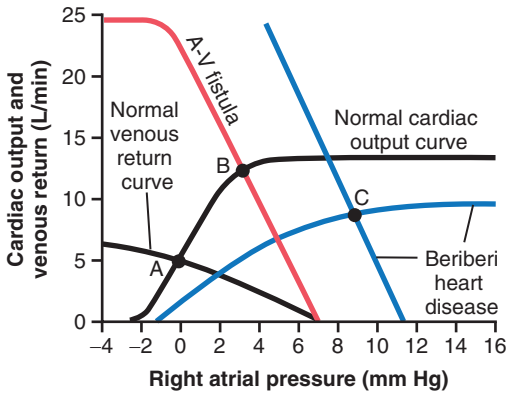

Figure 22.10 Graphic analysis of two types of conditions that can cause high-output cardiac failure—arterial-venous (A-V) fistula and beriberi heart disease.

is not depressed. The other type is caused by beriberi, in which the venous return is greatly increased because of diminished systemic vascular resistance but, at the same time, the pumping capability of the heart is depressed.

Arterial-Venous Fistula Increases Venous Return. The normal black curves of **Fig. 22.10** depict the normal cardiac output and normal venous return curves. These curves equate with each other at point A, which depicts a normal cardiac output of 5 L/min and a normal right atrial pressure of 0 mm Hg.

Now let us assume that the systemic vascular resistance (the *total peripheral vascular resistance*) becomes greatly decreased because of the opening of a large A-V fistula (a direct opening between a large artery and large vein). The venous return curve rotates upward to produce the curve labeled "A-V fistula." This venous return curve equates with the normal cardiac output curve at point B, with a cardiac output of 12.5 L/min and a right atrial pressure of 3 mm Hg. Thus, the cardiac output has become greatly elevated, the right atrial pressure is slightly elevated, and there are mild signs of peripheral congestion. If the person attempts to exercise, they will have little cardiac reserve because the heart is already at near-maximum capacity to pump the extra blood through the A-V fistula. This condition resembles a failure condition and is called *high-output failure*, but in reality the heart is overloaded by excess venous return.

Beriberi Weakens the Heart, Causes Fluid Retention By the Kidneys, and Increases Venous Return. **Fig. 22.10** also shows the approximate changes in the cardiac output and venous return curves caused by *beriberi*. The decreased level of the cardiac output curve is caused by weakening of the heart because of the avitaminosis (mainly lack of thiamine) that causes the beriberi syndrome. The weakening of the heart has decreased the blood flow to the kidneys. Therefore, the kidneys have retained a large amount of fluid, which in turn has increased the mean systemic filling pressure (represented by the point where the venous return curve now intersects the zero cardiac output level) from the

normal value of 7 mm Hg up to 11 mm Hg. This has shifted the venous return curve to the right. Finally, the venous return curve has rotated upward from the normal curve because the avitaminosis has dilated the peripheral blood vessels, as explained in Chapter 17.

The two blue curves (cardiac output curve and venous return curve) intersect with each other at point C, which describes the circulatory condition in beriberi, with a right atrial pressure in this case of 9 mm Hg and a cardiac output about 65% above normal. This high cardiac output occurs despite the weak heart, as demonstrated by the depressed plateau level of the cardiac output curve.

Treatment of Chronic Heart Failure

Medical therapies that target the compensatory responses to reduced cardiac output may decrease excessive fluid retention and some of the chronic heart failure symptoms and mortality related to HFrEF. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers block the effects of angiotensin II on the kidneys, leading to reduced salt and water reabsorption and ultimately reducing the cardiac afterload. Angiotensin receptor neprilysin inhibitors combine the effects of angiotensin receptor blockers with a neprilysin inhibitor that prevents the breakdown of natriuretic peptides, thereby increasing natriuresis and diuresis. Mineralocorticoid receptor antagonists block the effects of aldosterone, reducing kidney sodium reabsorption and preventing fibrosis of the kidneys and heart. Beta-adrenergic receptor antagonists ultimately reduce myocardial oxygen consumption and workload; however, they should not be used in patients with decompensated heart failure where higher heart rate and greater contractile force are necessary to maintain adequate cardiac output. Sodium-glucose cotransporter-2 (SGLT2) inhibitors have been demonstrated to be beneficial by reducing decompensated heart failure episodes. While these drugs were initially developed to reduce blood glucose levels, they have several potential effects that are beneficial in patients with heart failure, including antifibrotic effects, augmentation of natriuresis and diuresis, and improvement of myocardial metabolism and kidney perfusion.

Although several effective therapies exist that improve outcomes in patients with HFrEF, only recently have clinical trials demonstrated effectiveness of medications in patients with HFpEF. SGLT2 inhibitors and mineralocorticoid receptor antagonists reduce heart failure hospitalizations in patients with HFpEF, and angiotensin receptor neprilysin inhibitors may also have benefits to reduce heart failure symptoms.

CHAPTER 23

Heart Valves and Heart Sounds; Valvular and Congenital Heart Defects

Function of the heart valves was discussed in Chapter 9, where we pointed out that *closing* of the valves causes audible sounds. Ordinarily, no audible sounds occur when the valves open. In this chapter, we first discuss the factors that cause the sounds in the heart under normal and abnormal conditions. Then we discuss the overall circulatory changes that occur when valvular or congenital heart defects are present.

HEART SOUNDS

NORMAL HEART SOUNDS

When listening to a normal heart with a stethoscope, one hears a sound usually described as "lub, dub, lub, dub." The "lub" is associated with closure of the atrioventricular (AV) valves at the beginning of systole, and the "dub" is associated with closure of the semilunar (aortic and pulmonary) valves at the end of systole. The "lub" sound is called the *first heart sound*, and the "dub" is called the *second heart sound*, because the normal pumping cycle of the heart is considered to start when the AV valves close at the onset of ventricular systole (**Audio 23.1**).

The First Heart Sound Is Associated With Closure of the Mitral and Tricuspid Valves. The main cause of the first heart sound (S1) is vibration of the taut valves immediately after closure, along with vibration of the adjacent walls of the heart and major vessels around the heart. That is, in generating the first heart sound, contraction of the ventricles first causes sudden backflow of blood against the AV valves (tricuspid and mitral valves), causing them to close and bulge toward the atria until the chordae tendineae abruptly stop the back bulging. The elastic tautness of the chordae tendineae and valves then causes the backsurging blood to bounce forward again into each respective ventricle. This mechanism causes the blood and the ventricular walls, as well as the taut valves, to vibrate and causes vibrating turbulence in the blood. The vibrations travel through the adjacent tissues to the chest wall, where they can be heard as sound by using the stethoscope.

The Second Heart Sound Is Associated With Closure of the Aortic and Pulmonary Valves. The second heart sound (S2) results from sudden closure of the semilunar valves (aortic and pulmonary valves) at the end of systole. When the semilunar valves close, they bulge backward toward the ventricles, and their elastic stretch recoils the blood back into the arteries, which causes a short period of reverberation of blood back and forth between the walls of the arteries and the semilunar valves, as well as between these valves and the ventricular walls. The vibrations occurring in the arterial walls are then transmitted mainly along the arteries. When the vibrations of the vessels or ventricles come into contact with a sounding board, such as the chest wall, they create sound that can be heard using a stethoscope.

Duration and Pitch of First and Second Heart Sounds. The duration of each of the heart sounds is slightly more than 0.10 second, with the first sound about 0.14 second and the second about 0.11 second. The reason for the shorter second sound is that the semilunar valves are tauter than the AV valves, so they vibrate for a shorter time than do the AV valves.

The audible range of frequency (pitch) in the first and second heart sounds, as shown in **Fig. 23.1**, begins at the lowest frequency the ear can detect, about 40 cycles/sec, and goes up above 500 cycles/sec. When a special electronic apparatus is used to record these sounds, a larger proportion of the recorded sound is at frequencies and sound levels below the audible range, going down to 3 to 4 cycles/sec and peaking at about 20 cycles/sec, as illustrated by the lower shaded area in **Fig. 23.1**. For this reason, major portions of the heart sounds can be recorded electronically by phonocardiography, even though they cannot be heard with a stethoscope.

The second heart sound normally has a higher frequency than the first heart sound for two reasons: (1) the tautness of the semilunar valves in comparison with the much less taut AV valves; and (2) the greater elastic coefficient of the taut arterial walls, which provide the principal vibrating chambers for the second sound, in comparison with the much looser, less elastic ventricular chambers, which provide the vibrating system for the first heart sound. The clinician uses these differences to distinguish special characteristics of the two respective sounds.

The Third Heart Sound Occurs at the Beginning of the Middle Third of Diastole. Occasionally, a weak, rumbling third heart sound (often called an S3 gallop) is

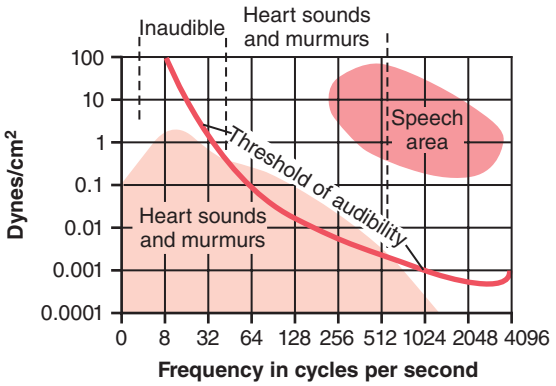

Figure 23.1 Amplitude of different frequency vibrations in the heart sounds and heart murmurs in relationship to the threshold of audibility, showing that the range of sounds that can be heard is between 40 and 520 cycles/sec. *(Modified from Butterworth JS, Chassin JL, McGrath JJ.* Cardiac Auscultation*, 2nd ed. New York: Grune & Stratton; 1960.)*

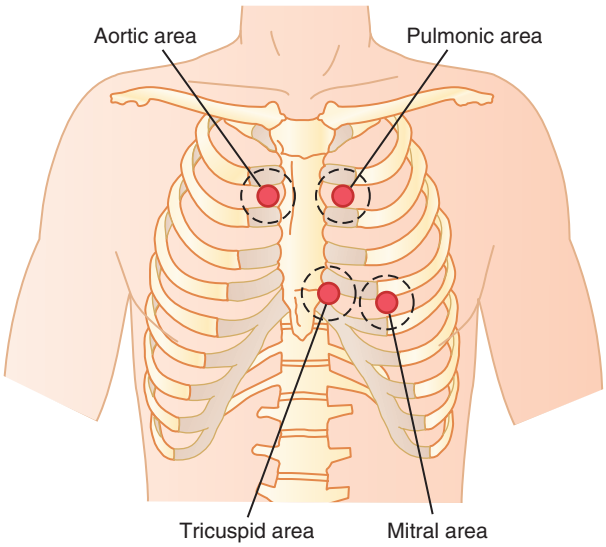

Figure 23.2 Chest areas from which sounds from each valve are heard best.

heard at the beginning of the *middle third of diastole*. A logical but unproved explanation of this sound is oscillation of blood back and forth between the walls of the ventricles, initiated by inrushing blood from the atria. This is analogous to running water from a faucet into a paper sack, with the inrushing water reverberating back and forth between the walls of the sack to cause vibrations in its walls. The reason the third heart sound does not occur until the middle third of diastole is believed to be that in the early part of diastole, the ventricles are not filled sufficiently to create even the small amount of elastic tension necessary for reverberation. The frequency of this sound is usually so low that the ear cannot hear it, yet it can often be recorded in the phonocardiogram. The third heart sound may be normally present in children, adolescents, and young adults but generally indicates systolic heart failure in older adults.

Atrial Contraction—Fourth Heart Sound. An atrial heart sound can sometimes be recorded in the phonocardiogram, but it can rarely be heard with a stethoscope because of its weakness and very low frequency—usually 20 cycles/sec or less. This sound occurs when the atria contract, and presumably, it is caused by the inrush of blood into the ventricles, which initiates vibrations similar to those of the third heart sound. A fourth heart sound (S4) is common in persons who derive benefit from atrial contraction for ventricular filling as a result of decreased ventricular wall compliance and increased resistance to ventricular filling. For example, a fourth heart sound, commonly called an S4 gallop, is often heard in older patients with left ventricular hypertrophy.

Chest Surface Areas for Auscultation of Normal Heart Sounds. Listening to the sounds of the body, usually with the aid of a stethoscope, is called *auscultation*. **Fig. 23.2** shows the areas of the chest wall from which the different heart valvular sounds can best be distinguished. Although the sounds from all the valves can be heard from all these areas, the cardiologist distinguishes the sounds from the different valves by a process of elimination. That is, the cardiologist moves the stethoscope from one area to another, noting the loudness of the sounds in different areas and gradually picking out the sound components from each valve.

The areas for listening to the different heart sounds are not directly over the valves themselves. The aortic area is upward along the aorta because of sound transmission up the aorta, and the pulmonic area is upward along the pulmonary artery. The tricuspid area is over the right ventricle, and the mitral area is over the apex of the left ventricle, which is the portion of the heart nearest the surface of the chest; the heart is rotated so that the remainder of the left ventricle lies more posteriorly.

Phonocardiogram. If a microphone specially designed to detect low-frequency sound is placed on the chest, the heart sounds can be amplified and recorded by a high-speed recording apparatus. The recording is called a *phonocardiogram*, and the heart sounds appear as waves, as shown schematically in **Fig. 23.3**. Recording A is an example of normal heart sounds, showing the vibrations of the first, second, and third heart sounds and even the very weak atrial sound. Note specifically that the third and atrial heart sounds are each a very low rumble. The third heart sound can be recorded in only one-third to one-half of people, and the atrial heart sound can be recorded in perhaps one-fourth of people.

VALVULAR LESIONS

Rheumatic Valvular Lesions

Rheumatic fever is an autoimmune disease in which the heart valves are likely to be damaged or destroyed. The sequence of events almost always begins with a streptococcal infection caused specifically by group A hemolytic

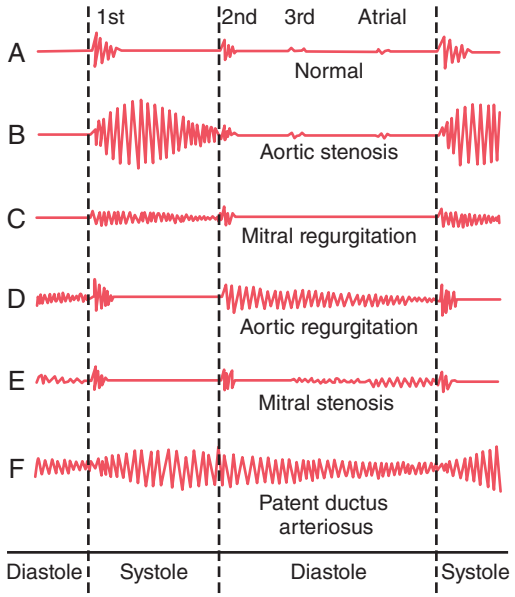

Figure 23.3 (A–F) Phonocardiograms from normal and abnormal hearts.

streptococci. These bacteria initially cause a sore throat, scarlet fever, or middle ear infection. However, the streptococci also release several different proteins, against which the person's reticuloendothelial system produces *antibodies*. The antibodies react not only with the streptococcal protein but also with other protein tissues of the body, often causing severe immunological damage. These reactions continue to take place as long as the antibodies persist in the blood—1 year or more.

Rheumatic fever particularly causes damage in certain susceptible areas, such as the heart valves. The degree of heart valve damage is directly correlated with the concentration and persistence of the antibodies. The principles of immunity that relate to this type of reaction are discussed in Chapter 35, and it is noted in Chapter 32 that acute glomerular nephritis of the kidneys has a similar immunological basis.

In persons with rheumatic fever, large hemorrhagic, fibrinous, bulbous lesions grow along the inflamed edges of the heart valves. Because the mitral valve undergoes more trauma during valvular action than any of the other valves, it is the one most often seriously damaged, and the aortic valve is the second most frequently damaged. The right heart valves—that is, the tricuspid and pulmonary valves—are usually affected much less severely, probably because the low-pressure stresses that act on these valves are slight compared with the high-pressure stresses that act on the left heart valves.

The lesions of acute rheumatic fever frequently occur on adjacent valve leaflets simultaneously, so the edges of the leaflets become stuck together. Then, weeks, months, or years later, the lesions become scar tissue, permanently fusing portions of adjacent valve leaflets. Also, the free edges of the leaflets, which are normally filmy and free-flapping, often become solid scarred masses.

A valve in which the leaflets adhere to one another so extensively that blood cannot flow through it normally is said to be *stenotic*. Conversely, when the valve edges are so destroyed by scar tissue that they cannot close as the ventricles contract, *regurgitation* (backflow) of blood occurs when the valve should be closed. Stenosis usually does not occur without the coexistence of at least some degree of regurgitation, and vice versa.

Aortic Valve Stenosis

With aging, the aortic valve often thickens, becomes calcified and stiffer, and may partially obstruct outflow from the left ventricle. With increased life expectancy and aging of the population, *aortic valve stenosis* has become the most common heart valve disease.

Stenosis of a previously normal aortic valve, often called *senile calcific aortic valve stenosis*, is characterized by valve calcium deposition and ossification, which lead to narrowing of the aortic valve orifice. As a compensatory response to the increased workload imposed on the heart by the stenotic aortic valve, the left ventricle undergoes *concentric* hypertrophy. This type of hypertrophy is associated with increased left ventricular wall thickness, which permits the heart to pump with greater vigor against the partially obstructed outflow. An increasing pressure gradient then develops across the calcified valve, reaching 75 to 100 mm Hg in severe cases of aortic valve stenosis.

The hypertrophied left ventricle also becomes more fibrotic and tends to be ischemic because of impaired microcirculatory perfusion, although some patients may also have atherosclerosis of the coronary arteries. The ejection fraction may be normal or even higher due to the smaller left ventricular chamber size, and the patient may be able to maintain adequate cardiac output under resting conditions, but with even moderate exercise, symptoms of heart failure may appear. As the stenosis progressively worsens, there are reductions in systolic heart function and inability of the left ventricle to develop enough pressure to pump effectively against the load imposed by the partially obstructed aortic valve. Consequently, symptoms of congestive heart failure appear, with reductions in stroke volume and cardiac output.

Calcific aortic valve stenosis usually does not become severe enough to draw clinical attention until after age 70. Important symptoms of aortic valve stenosis are exertion-related angina, reduced exercise tolerance, and congestive heart failure. In severe cases of aortic stenosis, fainting (*syncope*) can occur due to reductions in cardiac output and blood flow to the brain. Shortness of breath (*dyspnea*) is due to increased left ventricular filling pressure or inability to increase cardiac output adequately with exercise. Early recognition and management of aortic stenosis are important because untreated symptomatic aortic valve stenosis is progressive and will ultimately be fatal.

The normal aortic valve consists of three leaflets, although some people are born with only two aortic valve

leaflets, a defect known as a *bicuspid aortic valve*. Bicuspid aortic valves are more prone to stenosis and regurgitation, and patients with bicuspid aortic valves often present with symptoms earlier in life, typically around 50 to 60 years of age, compared to patients with senile aortic stenosis. This genetic condition is also associated with abnormalities in the aortic wall, called an *aortopathy*, and these patients are at risk for aortic dilation and dissection or "tearing" of the aorta.

The development of *transcatheter aortic valve replacement (TAVR)* technologies has provided new therapeutic opportunities, especially for older patients, in whom traditional surgical procedures cannot be performed or are associated with high risk.

Heart Murmurs Caused By Valvular Lesions

As shown by the phonocardiograms in **Fig. 23.3**, many abnormal heart sounds, known as *heart murmurs*, occur when abnormalities of the valves are present, as discussed here.

Systolic Murmur of Aortic Stenosis. In persons with aortic stenosis, blood is ejected from the left ventricle through only a small fibrous opening of the aortic valve. Because of the resistance to ejection, the blood pressure in the left ventricle sometimes rises as high as 300 mm Hg; the pressure in the aorta is still normal. Thus, a nozzle effect is created *during systole*, with blood jetting at tremendous velocity through the small opening of the valve. This phenomenon causes *severe turbulence* of the blood in the root of the aorta. The turbulent blood impinging against the aortic walls causes intense vibration, and a loud murmur occurs during systole (see recording B, **Fig. 23.3**; **Audio 23.2**) and is transmitted throughout the superior thoracic aorta and even into the large arteries of the neck. This sound is harsh, and in persons with severe stenosis it may be so loud that it can be heard several feet away from the patient. Also, the sound vibrations can often be felt with the hand on the upper chest and lower neck, a phenomenon known as a *thrill*.

Diastolic Murmur of Aortic Regurgitation. In aortic regurgitation, no abnormal sound is heard during systole, but *during diastole*, blood flows backward from the high-pressure aorta into the left ventricle, causing a "blowing" murmur of relatively high pitch, with a swishing quality heard maximally over the left ventricle (see recording D, **Fig. 23.3**; **Audio 23.3**). This murmur results from the *turbulence* of blood jetting backward into the blood already in the low diastolic pressure left ventricle.

Systolic Murmur of Mitral Regurgitation. In people with mitral regurgitation, blood flows backward through the mitral valve into the left atrium *during systole*. This backward flow also causes a high-frequency blowing, swishing sound (see recording C, **Fig. 23.3**; **Audio 23.4**) similar to that of aortic regurgitation but occurring during systole rather than diastole. It is transmitted most strongly into the left atrium. However, the left atrium is so deep within the chest that it is difficult to hear this sound directly over the atrium. As a result, the sound of mitral regurgitation is transmitted to the chest wall mainly through the left ventricle to the apex of the heart.

Mitral valve regurgitation is common in patients with heart failure with reduced ejection fraction. As the left ventricle dilates in heart failure, the papillary muscles, which are tethered to the chordae tendineae, are displaced, pulling the mitral valve leaflets apart. This often results in centrally directed regurgitation into the left atrium, usually referred to as *functional* mitral regurgitation. Sometimes functional mitral regurgitation can be corrected with heart failure medications that reduce the left ventricular chamber size and increase cardiac systolic function; however, mitral valve surgery or a percutaneous procedure to clip the mitral valve leaflets can attenuate mitral regurgitation and heart failure symptoms.

Diastolic Murmur of Mitral Stenosis. In people with mitral stenosis, blood passes with difficulty through the stenotic mitral valve from the left atrium into the left ventricle, and because the pressure in the left atrium seldom rises above 30 mm Hg, a large pressure differential forcing blood from the left atrium into the left ventricle does not develop. Consequently, the abnormal sounds heard in mitral stenosis (see recording E, **Fig. 23.3**; **Audio 23.5**) are usually weak and of very low frequency, so most of the sound spectrum is below the low-frequency end of human hearing.

During the early part of diastole, a left ventricle with a stenotic mitral valve has so little blood in it, and its walls are so flabby, that blood does not reverberate back and forth between the walls of the ventricle. For this reason, even in persons with severe mitral stenosis, no murmur may be heard during the first third of diastole. Then, after partial filling, the ventricle has stretched enough for blood to reverberate, and a low rumbling murmur begins.

Murmurs From Right Heart Valves. In people with pulmonary or tricuspid valve lesions, the timing and sounds of stenotic and regurgitant lesions can have some similar qualities as the aortic and tricuspid valve murmurs; however, right heart valvular murmurs have more variation with breathing. As a person inspires, there is increased venous return to the right side of the heart, typically increasing the intensity of the right heart murmur.

Phonocardiograms of Valvular Murmurs. Phonocardiograms B, C, D, and E of **Fig. 23.3** show, respectively, idealized records obtained from patients with aortic stenosis, mitral regurgitation, aortic regurgitation, and mitral stenosis. It is obvious from these phonocardiograms that the aortic stenotic lesion causes the loudest murmur and that the mitral stenotic lesion causes the weakest murmur. The phonocardiograms show how the intensity of the

murmurs varies during different portions of systole and diastole, and the relative timing of each murmur is also evident. Note especially that the murmurs of aortic stenosis and mitral regurgitation occur only during systole, whereas the murmurs of aortic regurgitation and mitral stenosis occur only during diastole.

ABNORMAL CIRCULATORY DYNAMICS IN VALVULAR HEART DISEASE

CIRCULATORY DYNAMICS IN AORTIC STENOSIS AND AORTIC REGURGITATION

In *aortic stenosis*, the contracting left ventricle fails to empty adequately, whereas in *aortic regurgitation*, blood flows backward into the ventricle from the aorta after the ventricle has just pumped the blood into the aorta. Therefore, in both cases, the *net stroke volume output* of the heart is reduced.

Several important compensations take place that can ameliorate the severity of the circulatory defects. Some of these compensations are described in the following sections.

Left Ventricular Hypertrophy. In aortic stenosis and aortic regurgitation, the left ventricular musculature hypertrophies because of the increased ventricular workload. In *regurgitation*, the left ventricular chamber also enlarges to hold all the regurgitant blood from the aorta. This type of hypertrophy, with enlargement of the ventricular chamber, is often referred to as *eccentric hypertrophy* (**Fig. 23.4**). Sometimes, the left ventricular muscle mass increases 4-fold to 5-fold, creating a tremendously large left side of the heart.

When the aortic valve is seriously *stenosed*, the hypertrophied muscle may allow the left ventricle to develop as much as 400 mm Hg of intraventricular pressure at systolic peak. This type of *concentric* hypertrophy is associated with thickened ventricular walls and a smaller ventricular chamber (see **Fig. 23.4**) and also occurs in other circumstances in which afterload of the heart is increased, such as in chronic hypertension.

In persons with severe aortic regurgitation, sometimes the enlarged left ventricle can pump a stroke volume output as great as 250 mL, although as much as 75% of this blood returns to the ventricle during diastole, and only 25% flows through the aorta to the body.

Increase in Blood Volume. Another effect that helps compensate for the diminished net pumping by the left ventricle is increased blood volume. This increased volume results from the following: (1) an initial slight decrease in arterial pressure; (2) nervous reflexes and hormonal changes induced by the decrease in pressure. These mechanisms together diminish renal output of urine, causing blood volume to increase and the mean arterial pressure to return to normal. Also, red blood cell mass eventually increases because of a slight degree of tissue hypoxia.

The increase in blood volume tends to increase venous return to the heart, which, in turn, causes the left ventricle to pump with the extra power required to overcome the abnormal pumping dynamics.

Increase in Heart Rate. In aortic stenosis, cardiac output can be significantly reduced due to severe impairment of the ejection of blood into the aorta through the stenotic valve. As discussed in Chapter 20, cardiac output is a product of stroke volume and heart rate. In aortic stenosis, the stroke volume through the aortic valve is reduced and heart rate often increases as a compensatory mechanism to maintain adequate cardiac output. Therefore, it is important for clinicians to be cautious when using medications that lower heart rate, such as beta receptor antagonists in patients with severe aortic stenosis.

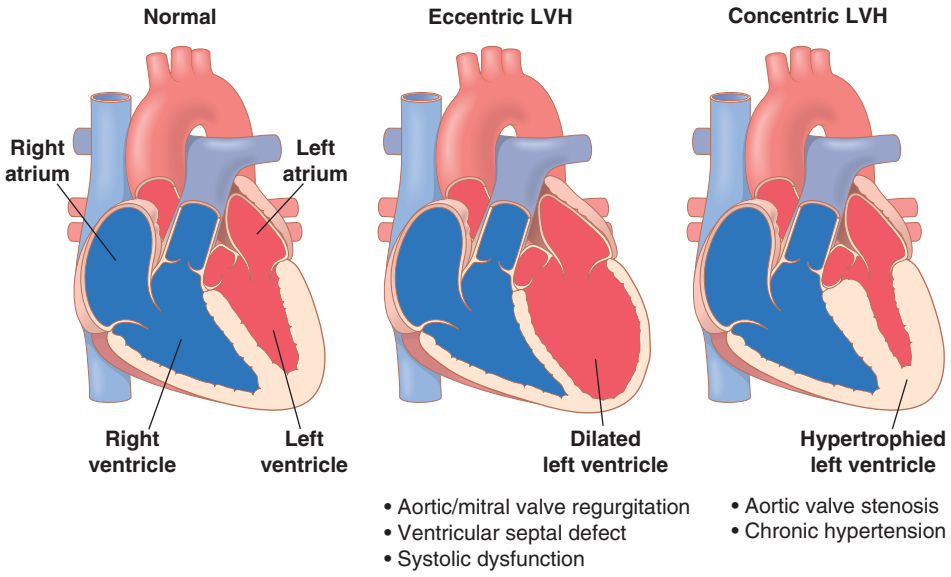

Figure 23.4 Comparison of the left ventricle in a normal heart, a heart with *eccentric* left ventricular hypertrophy (LVH), and a heart with *concentric* LVH. Left ventricular mass increases in eccentric and concentric LVH, but there is an increase in left ventricular cavity size in eccentric LVH, whereas wall thickness increases in concentric LVH.

Aortic Valvular Lesions May Be Associated With Inadequate Coronary Blood Flow. When a person has stenosis of the aortic valve, the ventricular muscle must develop a high tension to create the high intraventricular pressure needed to force blood through the stenosed valve. This action increases the workload and oxygen consumption of the ventricle, necessitating increased coronary blood flow to deliver this oxygen. The high wall tension of the ventricle, however, causes marked decreases in coronary flow during systole, particularly in the subendocardial vessels. Intraventricular diastolic pressure is also increased when there is aortic valve stenosis, and this increased pressure may cause compression of the inner layers of the heart muscle and reduced coronary blood flow. Thus, severe aortic valve stenosis often causes ischemia of the heart muscle.

With aortic regurgitation, the intraventricular diastolic pressure also increases, compressing the inner layer of the heart muscle and decreasing coronary blood flow. Aortic diastolic pressure decreases during aortic regurgitation, which can also decrease coronary blood flow and cause ischemia of the heart muscle.

Eventual Failure of Left Ventricle and Development of Pulmonary Edema. In the early stages of aortic stenosis or aortic regurgitation, the intrinsic ability of the left ventricle to adapt to increasing loads prevents significant abnormalities in circulatory function in the person during rest, other than the increased work output required of the left ventricle. Therefore, considerable degrees of aortic stenosis or aortic regurgitation often occur before the person knows that they have serious heart disease (e.g., a resting left ventricular systolic pressure as high as 200 mm Hg in persons with aortic stenosis or a left ventricular stroke volume output as high as twice normal in persons with aortic regurgitation).

Beyond a critical stage in these aortic valve lesions, the left ventricle finally cannot keep up with the work demand. As a consequence, the left ventricle dilates and cardiac output begins to fall; blood simultaneously dams up in the left atrium and in the lungs behind the failing left ventricle. The left atrial pressure rises progressively, and at mean left atrial pressures above 25 to 40 mm Hg, serious edema appears in the lungs, as discussed in detail in Chapter 39.

DYNAMICS OF MITRAL STENOSIS AND MITRAL REGURGITATION

In persons with mitral stenosis, blood flow from the left atrium into the left ventricle is impeded and, in persons with mitral regurgitation, much of the blood that has flowed into the left ventricle during diastole leaks back into the left atrium during systole rather than being pumped into the aorta. Therefore, either of these conditions reduces net movement of blood from the left atrium into the left ventricle.

Pulmonary Edema in Mitral Valvular Disease. The buildup of blood in the left atrium causes a progressive increase in left atrial pressure. If significant, this will eventually result in development of pulmonary edema. Ordinarily, lethal edema does not occur until the mean left atrial pressure rises above 25 mm Hg, and sometimes as high as 40 mm Hg, because the lung lymphatic vessels enlarge many times and can carry fluid rapidly away from the lung tissues.

Enlarged Left Atrium and Atrial Fibrillation. The high left atrial pressure in mitral valvular disease causes progressive enlargement of the left atrium, which increases the distance that the cardiac electrical excitatory impulse must travel in the atrial wall. This pathway may eventually become so long that it predisposes to the development of excitatory signal *circus movements*, as discussed in Chapter 13. Therefore, in late stages of mitral valvular disease, especially in mitral stenosis, atrial fibrillation often occurs. This development further reduces the pumping effectiveness of the heart and causes further cardiac debility.

Compensation in Early Mitral Valvular Disease. As also occurs in aortic valvular disease and in many types of congenital heart disease, the blood volume increases in mitral valvular disease principally because of diminished excretion of water and salt by the kidneys. This increased blood volume increases venous return to the heart, thereby helping overcome the effect of the cardiac debility. Therefore, after compensation, cardiac output may fall only minimally until the late stages of mitral valvular disease, even though the left atrial pressure is rising.

As the left atrial pressure rises, blood begins to dam up in the lungs, eventually all the way back to the pulmonary artery. In addition, incipient edema of the lungs causes pulmonary arteriolar constriction. These two effects together increase systolic pulmonary arterial pressure and also right ventricular pressure, sometimes to as high as 60 mm Hg, which is more than double normal. This increased pressure, in turn, causes hypertrophy of the right side of the heart, which partially compensates for its increased workload.

CIRCULATORY DYNAMICS DURING EXERCISE IN PATIENTS WITH VALVULAR LESIONS

During exercise, increased blood flow is required to provide additional oxygen and nutrients to the exercising muscles and remove waste products of increased metabolism. Consequently, increased quantities of venous blood are returned to the heart from the peripheral circulation. Therefore, all the dynamic abnormalities that occur in the different types of valvular heart disease become exacerbated. Even in persons with mild valvular heart disease, in which the symptoms may be unrecognizable at rest, severe symptoms often develop during heavy exercise. For example, in patients with aortic valvular lesions,

exercise can cause acute left ventricular failure followed by *acute pulmonary edema*. Also, in patients with mitral disease, exercise can cause so much damming of blood in the lungs that serious or even lethal pulmonary edema may ensue in as little as 10 minutes.

Even in mild to moderate cases of valvular disease, the patient's *cardiac reserve* diminishes in proportion to the severity of the valvular dysfunction. That is, the cardiac output does not increase as much as it should during exercise. Therefore, the muscles of the body fatigue rapidly because of too little increase in muscle blood flow.

ABNORMAL CIRCULATORY DYNAMICS IN CONGENITAL HEART DEFECTS

Occasionally, the heart or its associated blood vessels are malformed during fetal life; the defect is called a *congenital anomaly*. There are three major types of congenital anomalies of the heart and its associated vessels: (1) *stenosis* of the channel of blood flow at some point in the heart or in a closely allied major blood vessel; (2) an anomaly that allows blood to flow backward from the left side of the heart or aorta to the right side of the heart or pulmonary artery, thus failing to flow through the systemic circulation, called a *left-to-right shunt*; and (3) an anomaly that allows blood to flow directly from the right side of the heart into the left side of the heart, thus failing to flow through the lungs, called a *right-to-left shunt*.

The effects of the different stenotic lesions are easily understood. For instance, *congenital aortic valve stenosis* results in the same dynamic effects as aortic valve stenosis caused by other valvular lesions, namely, cardiac hypertrophy, heart muscle ischemia, reduced cardiac output, and a tendency to develop serious pulmonary edema.

Another type of congenital stenosis is *coarctation of the aorta*, most commonly in the proximal descending thoracic aorta above the level of the diaphragm. This stenosis causes the arterial pressure in the upper part of the body (above the level of the coarctation) to be much greater than the pressure in the lower body because of the great resistance to blood flow through the coarctation to the lower body; part of the blood may go around the coarctation through small collateral arteries, as discussed in Chapter 19.

PATENT DUCTUS ARTERIOSUS—A LEFT-TO-RIGHT SHUNT

During fetal life, the lungs are collapsed, and the elastic compression of the lungs that keeps the alveoli collapsed keeps most of the lung blood vessels collapsed as well. Therefore, resistance to blood flow through the lungs is so great that the pulmonary arterial pressure is high in the fetus. Also, because of low resistance to blood flow from the aorta through the large vessels of the placenta, the pressure in the aorta of the fetus is lower than normal—in fact, lower than in the pulmonary artery. This phenomenon causes almost all the pulmonary arterial blood to flow through a special artery present in the fetus that connects the pulmonary artery with the aorta (**Fig. 23.5**), the *ductus arteriosus*, thus bypassing the lungs. This mechanism allows immediate recirculation of the blood through the systemic arteries of the fetus without the blood going through the lungs. This lack of blood flow through the lungs is not detrimental to the fetus because the blood is oxygenated by the placenta.

Closure of Ductus Arteriosus After Birth. As soon as a baby is born and begins to breathe, the lungs inflate. Not only do the alveoli fill with air, but also the resistance to blood flow through the pulmonary vascular tree decreases tremendously, allowing the pulmonary arterial pressure to fall. Simultaneously, the aortic pressure rises because of sudden cessation of blood flow from the aorta through the placenta. Thus, the pressure in the pulmonary artery falls, while that in the aorta rises. As a result, forward blood flow through the ductus arteriosus ceases suddenly at birth and, in fact, blood begins to flow backward through the ductus, from the aorta into the pulmonary artery. This new state of backward blood flow causes the ductus arteriosus to become occluded within a few hours to a few days in most babies, so blood flow through the ductus does not persist. The ductus is believed to close because the oxygen concentration of the aortic blood now flowing through it is about twice as high as that of the blood flowing from the pulmonary artery into the ductus during fetal life. The oxygen presumably constricts the

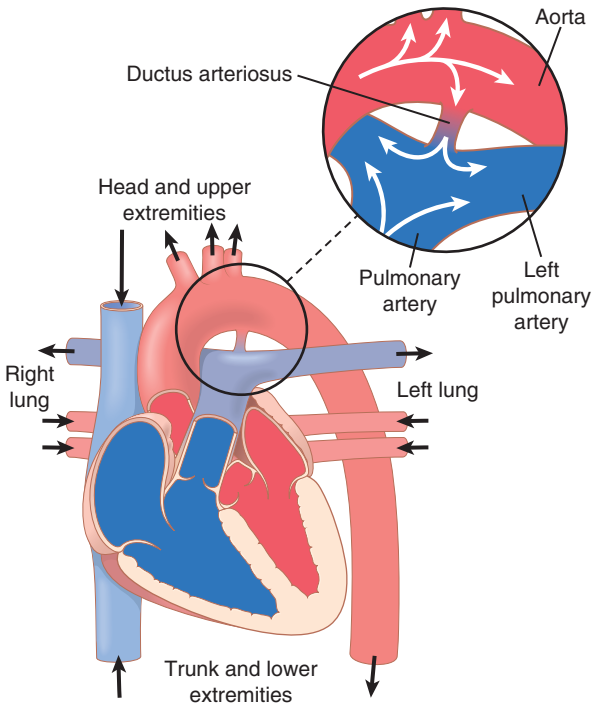

Figure 23.5 Patent ductus arteriosus, showing by the *blue color* that venous blood changes into oxygenated blood at different points in the circulation. *Inset*, Backflow of blood from the aorta into the pulmonary artery and then through the lungs for a second time.

muscle in the ductus wall. This phenomenon is discussed further in Chapter 84.

Unfortunately, in about 1 of every 5500 babies, the ductus does not close, causing the condition known as *patent ductus arteriosus (PDA)*, which is shown in **Fig. 23.5**.

Dynamics of the Circulation With a Persistent Patent Ductus Arteriosus

During the early months of an infant's life, PDA usually does not cause severely abnormal function. However, as the child grows older, the differential between the high pressure in the aorta and the lower pressure in the pulmonary artery progressively increases, with a corresponding increase in the backward flow of blood from the aorta into the pulmonary artery. Also, the high aortic blood pressure usually causes the diameter of the partially open ductus to increase with time, making the condition even worse.

Recirculation Through the Lungs. In an older child with PDA, one-half to two-thirds of the aortic blood flows backward through the ductus into the pulmonary artery, then through the lungs, and finally back into the left ventricle and aorta, passing through the lungs and left side of the heart two or more times for every one time that it passes through the systemic circulation. People with this condition *do not show cyanosis until later in life, when the heart fails or the lungs become congested*. Indeed, early in life, the arterial blood is often better oxygenated than normal because of the extra times that it passes through the lungs.

Diminished Cardiac and Respiratory Reserve. The major effects of PDA on the patient are decreased cardiac and respiratory reserve. The left ventricle is pumping about two or more times the normal cardiac output, and the maximum that it can pump after hypertrophy of the heart has occurred is about four to seven times normal. Therefore, during exercise, the net blood flow through the remainder of the body can never increase to the levels required for strenuous activity. With even moderately strenuous exercise, the person is likely to become weak and may even faint from momentary heart failure.

The high pressures in the pulmonary vessels caused by excess flow through the lungs may also lead to pulmonary congestion and pulmonary edema. As a result of the excessive load on the heart, and especially because the pulmonary congestion becomes progressively more severe with age, most patients with uncorrected PDA die from heart disease between the ages of 20 and 40 years.

Heart Sounds: Machinery Murmur

In a newborn infant with PDA, occasionally no abnormal heart sounds are heard because the quantity of reverse blood flow through the ductus may be insufficient to cause a heart murmur. However, as the baby grows older, to 1 to 3 years of age, a harsh blowing murmur begins to be heard in the pulmonary artery area of the chest, as shown in recording F, **Fig. 23.3**. This sound is much more intense during systole, when the aortic pressure is high, and much less intense during diastole, when the aortic pressure falls low, so that the murmur waxes and wanes with each beat of the heart, creating the so-called *machinery murmur*.

Surgical Treatment

Surgical treatment of PDA is simple; one need only ligate the patent ductus or divide it and then close the two ends. This procedure was one of the first successful heart surgeries ever performed. Catheter-based devices often are used to close PDAs in infants or children who are large enough to have the procedure. A small metal coil or other occlusion device is passed up through the catheter and placed in the PDA to block blood flow through the vessel.

TETRALOGY OF FALLOT—A RIGHT-TO-LEFT SHUNT

Tetralogy of Fallot is shown in **Fig. 23.6**; it is the most common cause of *blue baby*. Most of the blood bypasses the lungs, so the aortic blood is mainly unoxygenated venous blood. In this condition, four abnormalities of the heart occur simultaneously:

1. The aorta originates from the right ventricle rather than the left, or it overrides a hole in the septum, as shown in **Fig. 23.6**, receiving blood from both ventricles.
2. Because the pulmonary artery is stenotic, much lower than normal amounts of blood pass from the right ventricle into the lungs; instead, most of the blood passes directly into the aorta, thus bypassing the lungs.

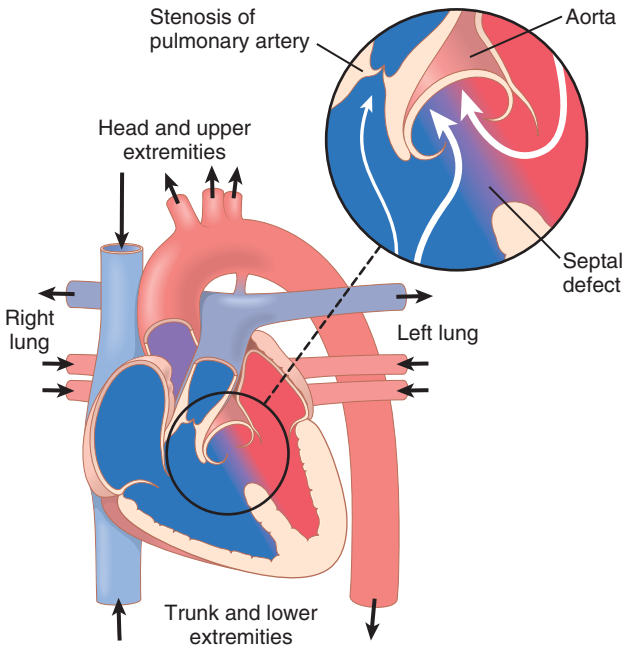

Figure 23.6 Tetralogy of Fallot, showing by the *blue color* that most of the venous blood is shunted from the right ventricle into the aorta without passing through the lungs.

3. Blood from the left ventricle flows through a ventricular septal defect into the right ventricle and then into the aorta or directly into the aorta that overrides this hole.
4. Because the right side of the heart must pump large quantities of blood against the high pressure in the aorta, its musculature is highly developed, causing an enlarged right ventricle.

Abnormal Circulatory Dynamics. It is readily apparent that the major physiological difficulty caused by tetralogy of Fallot is the shunting of blood past the lungs without becoming oxygenated. As much as 75% of the venous blood returning to the heart passes directly from the right ventricle into the aorta without becoming oxygenated. This can lead to *cyanosis* (blue coloration) of the baby's skin. Other signs include high right ventricular pressures, right ventricular enlargement, and a left-to-right shunt through the interventricular septum, which can be visualized by echocardiography. Ultimately, if not repaired, the pulmonary pressure will increase higher than systemic pressure and the left-to-right shunt will become a right-to-left shunt in the late stages. This leads to significant hypoxemia and cyanosis. This reversal of blood shunting from left to right in patients with congenital heart diseases is called *Eisenmenger syndrome*.

Surgical Correction of Tetralogy of Fallot. Tetralogy of Fallot can often be treated successfully with surgery. The usual procedure is to open the pulmonary stenosis, close the septal defect, and reconstruct the flow pathway into the aorta. When surgery is successful, the average life expectancy increases from only 3 to 4 years to 50 or more years.

CAUSES OF CONGENITAL ANOMALIES

Congenital heart disease is not uncommon, occurring in about 8 of every 1000 live births. One of the most common causes of congenital heart defects is a viral infection in the mother during the first trimester of pregnancy, when the fetal heart is being formed. Defects are particularly prone to develop when the expectant mother contracts German measles (rubella) during the first trimester of pregnancy. Other factors that increase the risk for heart defects in the developing fetus are the use of certain medications, such as angiotensin-converting enzyme (ACE) inhibitors and acne medications (e.g., isotretinoin), during pregnancy or the abuse of alcohol or drugs.

Some congenital defects of the heart are hereditary because the same defect has been known to occur in identical twins, as well as in succeeding generations. Children of patients surgically treated for congenital heart disease have about a 10 times greater chance of having congenital heart disease than other children. Congenital defects of the heart are also frequently associated with other congenital defects of the baby's body.

USE OF EXTRACORPOREAL CIRCULATION DURING CARDIAC SURGERY

It is almost impossible to repair intracardiac defects surgically while the heart is still pumping. Therefore, many types of artificial *heart-lung machines* have been developed to take the place of the heart and lungs during the course of an operation. Such a system is called *extracorporeal circulation*. The system consists principally of a pump and an oxygenating device. Almost any type of pump that does not cause hemolysis of the blood seems to be suitable.

Methods used for oxygenating blood include the following: (1) bubbling oxygen through the blood and removing the bubbles from the blood before passing it back into the patient; (2) dripping the blood downward over the surfaces of plastic sheets in the presence of oxygen; (3) passing the blood over surfaces of rotating discs; and (4) passing the blood between thin membranes or through thin tubes that are permeable to oxygen and carbon dioxide.

HYPERTROPHY OF THE HEART IN VALVULAR AND CONGENITAL HEART DISEASE

Hypertrophy of cardiac muscle is one of the most important mechanisms whereby the heart adapts to increased workloads whether these loads are caused by increased pressure against which the heart muscle must contract or by increased cardiac output that must be pumped. One can calculate approximately how much hypertrophy will occur in each chamber of the heart by multiplying the ventricular output by the pressure against which the ventricle must work, with an emphasis on pressure. Thus, hypertrophy occurs in most types of valvular and congenital disease, sometimes causing the heart to weigh as much as 800 grams instead of the normal 300 grams.

Hypertrophic Cardiomyopathy. Congenital hypertrophic cardiomyopathy is caused by abnormal genes that cause thickening of the walls of the heart. Many of the common genetic mutations associated with hypertrophic cardiomyopathy affect the sarcomere. In hypertrophic cardiomyopathy, there is often asymmetric hypertrophy of the left ventricular septum, typically affecting the base of the heart. In *obstructive* hypertrophic cardiomyopathy, the hypertrophied basal septum can reduce or "obstruct" blood flow being ejected through the left ventricular outflow tract into the aorta. People with obstructive hypertrophic cardiomyopathy can have symptoms such as shortness of breath, chest pain, and lightheadedness or syncope if the obstruction is severe. Hypertrophic cardiomyopathy is also associated with arrhythmias and increased risk for sudden cardiac death.

Detrimental Effects of Late Stages of Cardiac Hypertrophy. Although the most common cause of cardiac hypertrophy is hypertension, almost all forms of cardiac

diseases, including valvular and congenital disease, can stimulate enlargement of the heart.

So-called *physiological cardiac hypertrophy* is generally considered to be a compensatory response of the heart to increased workload and is usually beneficial for maintaining cardiac output in the presence of abnormalities that impair the heart's effectiveness as a pump. Physiological cardiac hypertrophy is often observed in well-trained athletes and regresses after cessation of exercise. However, extreme degrees of hypertrophy can lead to heart failure. One reason for this is that the coronary vasculature typically does not increase to the same extent as the mass of cardiac muscle increases. The second reason is that fibrosis often develops in the muscle, especially in the subendocardial muscle where the coronary blood flow is poor, with fibrous tissue replacing degenerating muscle fibers. Because of the disproportionate increase in muscle mass relative to coronary blood flow, relative ischemia may develop as the cardiac muscle hypertrophies, and coronary blood flow insufficiency may ensue. Anginal pain is therefore a frequent accompaniment of cardiac hypertrophy associated with valvular and congenital heart disease. Enlargement of the heart is also associated with a greater risk for developing arrhythmias, which in turn can lead to further impairment of cardiac function and sudden death because of fibrillation.

CHAPTER 24

Circulatory Shock and Its Treatment

Circulatory shock means generalized inadequate blood flow through the body to the extent that the body tissues are damaged, especially because too little oxygen and other nutrients are delivered to the tissue cells. Even the cardiovascular system itself—the heart musculature, walls of the blood vessels, vasomotor system, and other circulatory parts—begins to deteriorate, so the shock, once begun, is prone to become progressively worse.

Circulatory shock can occur with or without decreased cardiac output and is often classified into four main categories: 1) cardiogenic shock, 2) hypovolemic shock, 3) distributive (vasodilatory) shock, or 4) obstructive shock.

PHYSIOLOGICAL CAUSES OF SHOCK

CIRCULATORY SHOCK CAUSED BY DECREASED CARDIAC OUTPUT

Shock often results from inadequate cardiac output. Therefore, any condition that reduces cardiac output far below normal may lead to circulatory shock. Two types of factors can severely reduce cardiac output:

1. *Cardiac abnormalities that decrease the ability of the heart to pump blood.* These abnormalities include in particular myocardial infarction but also toxic states of the heart, severe inflammation of the heart muscle (myocarditis), severe heart valve dysfunction, heart arrhythmias, and other conditions. The circulatory shock that results from diminished cardiac pumping ability is called *cardiogenic shock*. This condition is discussed in Chapter 22, where it is noted that as many as 70% of people who experience cardiogenic shock do not survive.
2. *Factors that decrease venous return* also decrease cardiac output because the heart cannot pump blood that does not flow into it. The most common cause of decreased venous return is *diminished blood volume*, but venous return can also be reduced as a result of *decreased vascular tone*, especially of the venous blood reservoirs, or *obstruction to blood flow* at some point in the circulation, especially in the venous return pathway to the heart.

CIRCULATORY SHOCK WITHOUT DIMINISHED CARDIAC OUTPUT

Occasionally, cardiac output is normal or even higher than normal, yet the person is in a state of circulatory shock. This situation can result from the following: (1) *excessive metabolic rate, so even a normal cardiac output is inadequate*; or (2) *abnormal tissue perfusion, so most of the cardiac output is passing through blood vessels besides those that supply the local tissues with nutrition.*

The specific causes of shock are discussed later in this chapter. For the present, it is important to note that all of them lead to *inadequate delivery of nutrients to critical tissues and organs, as well as inadequate removal of cellular waste products from the tissues.*

WHAT HAPPENS TO THE ARTERIAL PRESSURE IN CIRCULATORY SHOCK?

In the minds of many clinicians, the arterial pressure is the principal measure of adequacy of circulatory function. However, the arterial pressure can often be seriously misleading. At times, a person may be in severe shock and still have an almost normal arterial pressure because of powerful nervous reflexes that keep the pressure from falling. At other times, the arterial pressure can fall to half of normal, but the person still has normal tissue perfusion and is not in shock.

In most types of shock, especially shock caused by severe blood loss, the arterial blood pressure decreases at the same time the cardiac output decreases, although usually not as much.

TISSUE DETERIORATION IS THE END RESULT OF CIRCULATORY SHOCK

Once circulatory shock reaches a critical state of severity, regardless of its initiating cause, *the shock itself leads to more shock*. That is, the inadequate blood flow causes the body tissues to begin deteriorating, including the heart and circulatory system. This deterioration causes even greater decreases in cardiac output, and a vicious cycle ensues, with progressively increasing circulatory shock, less adequate tissue perfusion, and more shock until death

occurs. It is with this late stage of circulatory shock that we are especially concerned because appropriate physiological treatment can often reverse the rapid slide to death.

STAGES OF SHOCK

Because the characteristics of circulatory shock change with different degrees of severity, shock is often divided into the following three major stages:

1. A *nonprogressive stage* (sometimes called the *compensated stage*), in which the normal circulatory compensatory mechanisms eventually cause full recovery without help from outside therapy.
2. A *progressive stage*, in which, without therapy, the shock becomes steadily worse until death occurs.
3. An *irreversible stage*, in which the shock has progressed to such an extent that all forms of known therapy are inadequate to save the person's life even though, for the moment, the person is still alive.

We will now discuss the stages of circulatory shock caused by decreased blood volume, which illustrate the basic principles. Then we will consider special characteristics of shock initiated by other causes.

HYPOVOLEMIC SHOCK DUE TO HEMORRHAGE

Hypovolemia means diminished blood volume. Hemorrhage is the most common cause of hypovolemic shock. Hemorrhage *decreases the filling pressure of the circulation* and, as a consequence, decreases venous return. As a result, the cardiac output falls below normal, and shock may ensue.

Relationship of Bleeding Volume to Cardiac Output and Arterial Pressure

Fig. 24.1 shows the approximate effects on cardiac output and arterial pressure of removing blood from the circulatory system over a period of about 30 minutes. About 10% of the total blood volume can be removed with almost no effect on arterial pressure or cardiac output, but greater blood loss usually diminishes the cardiac output first and later the arterial pressure, both of which fall to zero when about 40% to 45% of the total blood volume has been removed.

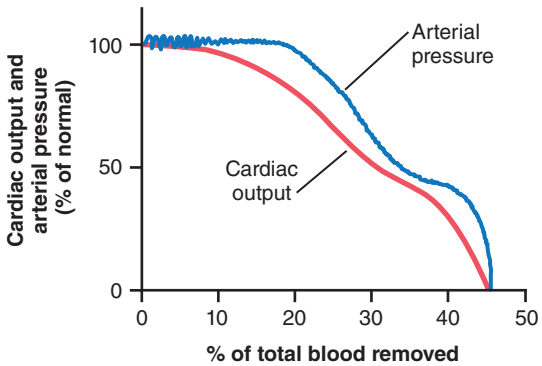

Figure 24.1 Effect of hemorrhage on cardiac output and arterial pressure.

Sympathetic Reflex Compensations in Shock—Their Special Value to Maintain Arterial Pressure. The decrease in arterial pressure after hemorrhage, as well as decreases in pressures in the pulmonary arteries and veins in the thorax, cause powerful sympathetic reflexes (initiated mainly by the arterial baroreceptors and other vascular stretch receptors, as explained in Chapter 18). These reflexes stimulate the sympathetic vasoconstrictor system in most tissues of the body, resulting in three important effects:

1. The arterioles constrict in most parts of the systemic circulation, thereby increasing total peripheral resistance.
2. The veins and venous reservoirs constrict, thereby helping maintain adequate venous return, despite diminished blood volume.
3. Heart activity increases markedly, sometimes increasing the heart rate from the normal value of 72 beats/min to as high as 160 to 180 beats/min.

In the absence of these sympathetic reflexes, only 15% to 20% of the blood volume can be removed over a period of 30 minutes before a person dies; in contrast, a person can sustain a 30% to 40% loss of blood volume when the reflexes are intact. Therefore, these reflexes extend the amount of blood loss that can occur without causing death to about twice that which is possible in their absence.

Sympathetic Nervous Reflexes Have a Greater Effect in Maintaining Arterial Pressure Than in Maintaining Cardiac Output. Referring again to **Fig. 24.1**, note that the arterial pressure is maintained at or near normal levels in the hemorrhaging person longer than is the cardiac output. The reason for this difference is that the sympathetic reflexes are geared more for maintaining arterial pressure than for maintaining cardiac output. They increase the arterial pressure mainly by increasing the total peripheral resistance, which has no beneficial effect on cardiac output. However, *sympathetic constriction of the veins is important to keep venous return and cardiac output from falling too much*, in addition to their role in maintaining arterial pressure.

Especially interesting is the second plateau occurring at about 50 mm Hg in the arterial pressure curve of **Fig. 24.1**. This second plateau results from activation of the central nervous system ischemic response, which causes extreme stimulation of the sympathetic nervous system when the brain begins to experience lack of oxygen or excess buildup of carbon dioxide, as discussed in Chapter 18. This effect of the central nervous system ischemic response can be called the "last stand" of the sympathetic reflexes in their attempt to keep the arterial pressure from falling too low.

Coronary and Cerebral Blood Flows Are Protected By Sympathetic Reflexes. A special value of maintaining normal arterial pressure, even in the presence of decreasing cardiac output, is protection of blood flow through the coronary and cerebral circulations. Sympathetic stimulation does not cause significant constriction of the cerebral or cardiac vessels. In addition, in both vascular beds, local blood flow autoregulation is excellent, which prevents moderate decreases in arterial pressure from significantly decreasing their blood flows. Therefore, blood flow through the heart and brain is maintained essentially at normal levels as long as the mean arterial pressure does not fall below about 70 mm Hg, despite the fact that blood flow in some other areas of the body might be decreased to as little as one-third to one-quarter normal by this time because of vasoconstriction.

PROGRESSIVE AND NONPROGRESSIVE HEMORRHAGIC SHOCK

Fig. 24.2 shows an experiment that demonstrates the effects of different degrees of sudden acute hemorrhage on the subsequent course of arterial pressure. The animals in this experiment were anesthetized and bled rapidly until their arterial pressures fell to different levels. The animals whose pressures fell immediately to no lower than 45 mm Hg (groups I, II, and III) all eventually recovered; the recovery occurred rapidly if the pressure fell only slightly (group I) but occurred slowly if it fell almost to the level of 45 mm Hg (group III). When the arterial pressure fell below 45 mm Hg (groups IV, V, and VI), all the animals died, although many of them hovered between life and death for hours before the circulatory system deteriorated to the stage of death.

This experiment demonstrates that the circulatory system can recover as long as the degree of hemorrhage is no greater than a certain critical amount. Crossing this critical threshold by even a few milliliters of blood loss makes the eventual difference between life and death. Thus, hemorrhage beyond a certain critical level causes shock to become *progressive*. That is, *the shock itself causes still more shock*, and the condition becomes a vicious cycle that eventually leads to deterioration of the circulation and to death.

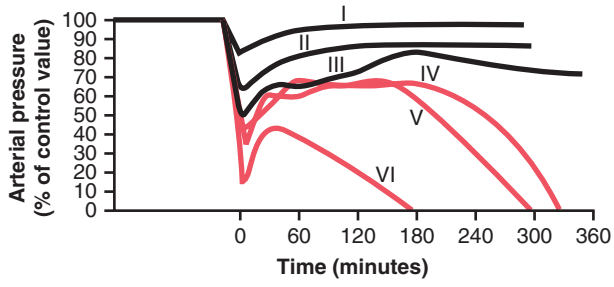

Figure 24.2 Time course of arterial pressure in dogs after different degrees of acute hemorrhage. Each curve represents average results from six dogs (curves I–VI).

Nonprogressive Shock—Compensated Shock

If shock is not severe enough to cause its own progression, the person eventually recovers. Therefore, shock of this lesser degree is called *nonprogressive shock* or *compensated shock*, meaning that the sympathetic reflexes and other factors compensate enough to prevent further deterioration of the circulation.

The factors that cause a person to recover from moderate degrees of shock are the negative feedback control mechanisms of the circulation that attempt to return cardiac output and arterial pressure back to normal levels. They include the following:

1. *Baroreceptor reflexes*, which elicit powerful sympathetic stimulation of the circulation
2. *Central nervous system ischemic response*, which elicits even more powerful sympathetic stimulation throughout the body but is not activated significantly until the arterial pressure falls below 50 mm Hg
3. *Reverse stress-relaxation of the circulatory system*, which causes the blood vessels to contract around the diminished blood volume so that the blood volume that is available more adequately fills the circulation
4. *Increased secretion of renin by the kidneys and formation of angiotensin II*, which constricts peripheral arterioles and also causes decreased output of water and salt by the kidneys, both of which help prevent progression of shock
5. *Increased secretion by the posterior pituitary gland of vasopressin (antidiuretic hormone)*, which constricts peripheral arterioles and veins and greatly increases water retention by the kidneys
6. *Increased secretion by the adrenal medullae of epinephrine and norepinephrine*, which constricts peripheral arterioles and veins and increases heart rate
7. *Compensatory mechanisms that return the blood volume back toward normal*, including absorption of large quantities of fluid from the intestinal tract, absorption of fluid into the blood capillaries from the interstitial spaces of the body, conservation of water and salt by the kidneys, and increased thirst and increased appetite for salt, which make the person drink water and eat salty foods if they are able to do so

The sympathetic reflexes and increased secretion of catecholamines by the adrenal medullae provide rapid help toward bringing about recovery because they become maximally activated within 30 seconds to a few minutes after hemorrhage.

The angiotensin and vasopressin mechanisms, as well as the reverse stress-relaxation that causes contraction of the blood vessels and venous reservoirs, all require 10 to 60 minutes to respond completely, but they aid greatly in increasing the arterial pressure or increasing the

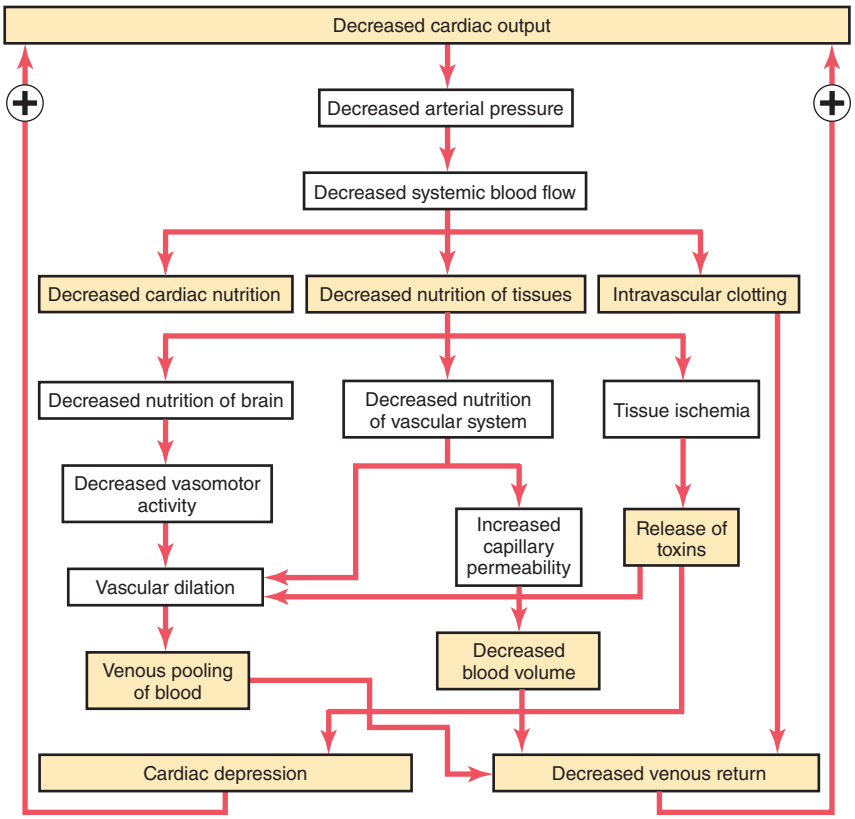

Figure 24.3 Different types of positive feedback that can lead to the progression of shock.

circulatory filling pressure, thereby increasing the return of blood to the heart.

Finally, readjustment of blood volume by absorption of fluid from the interstitial spaces and intestinal tract, as well as oral ingestion and absorption of additional quantities of water and salt, may require from 1 to 48 hours, but recovery eventually takes place, provided the shock does not become severe enough to enter the progressive stage.

Progressive Shock Is Caused By a Vicious Cycle of Cardiovascular Deterioration

Fig. 24.3 shows some of the positive feedbacks that further depress cardiac output in shock, thus causing the shock to become progressive. Some of the more important feedbacks are described in the following sections.

Cardiac Depression in Shock. When the arterial pressure falls low enough, *coronary blood flow decreases below that required for adequate nutrition of the myocardium*, weakening the heart muscle and further decreasing cardiac output. Thus, a positive feedback cycle has developed, whereby the shock becomes more and more severe.

Fig. 24.4 shows cardiac output curves extrapolated to the human heart from studies in experimental animals, demonstrating progressive deterioration of the heart at different times after the onset of shock. An anesthetized animal was bled until the arterial pressure fell to 30 mm Hg, and the pressure was held at this level by further bleeding or retransfusion of blood, as required. Note from the

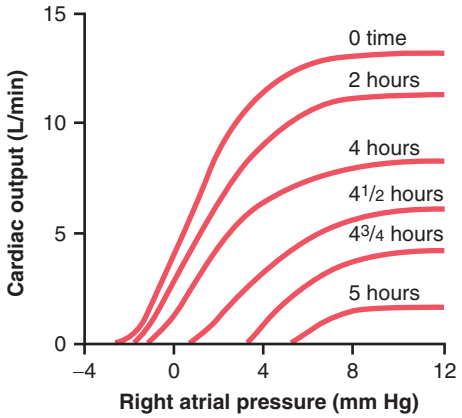

Figure 24.4 Cardiac output curves of the heart at different times after hemorrhagic shock begins. (These curves have been extrapolated to the human heart from data obtained in dog experiments by Dr. J.W. Crowell.)

second curve in the figure that there was little deterioration of the heart during the first 2 hours, but by 4 hours, the heart had deteriorated about 40%. Then, rapidly, during the last hour of the experiment (after 4 hours of low coronary blood pressure), the heart deteriorated completely.

Thus, one of the important features of progressive shock, whether it is hemorrhagic in origin or has another cause, is eventual progressive deterioration of the heart. In the early stages of shock, this deterioration plays very little

role in the condition of the person, partly because deterioration of the heart is not severe during the first hour or so of shock, but mainly because the heart has reserve capability that normally allows it to pump 300% to 400% more blood than is required by the body for adequate tissue nutrition. In the latest stages of shock, however, deterioration of the heart is often the most important factor in the final lethal progression of the shock.

Vasomotor Failure. In the early stages of shock, various circulatory reflexes cause intense activity of the sympathetic nervous system. This activity helps delay depression of cardiac output and especially helps prevent decreased arterial pressure. However, there comes a point when diminished blood flow to the brain's vasomotor center depresses the center so much that it, too, becomes progressively less active and, finally, totally inactive. For example, during the first 4 to 8 minutes, *complete circulatory arrest to the brain* causes the most intense of all sympathetic discharges, but by the end of 10 to 15 minutes, the vasomotor center becomes so depressed that no further evidence of sympathetic discharge can be demonstrated. Fortunately, the vasomotor center usually does not fail in the early stages of shock if the arterial pressure remains above 30 mm Hg.

Blockage of Very Small Vessels By Sludged Blood. In time, blockage occurs in many of the very small blood vessels in the circulatory system, and this blockage also causes the shock to progress. The initiating cause of this blockage is sluggish blood flow in the microvasculature. Because tissue metabolism continues despite the low flow, large amounts of acid, both carbonic acid and lactic acid, continue to empty into the local blood vessels and greatly increase local acidity of the blood. This acidic effect, plus other deterioration products from the ischemic tissues, causes local blood agglutination, resulting in minute blood clots and leading to very small plugs in small vessels. Even if the vessels do not become plugged, an increased tendency for the blood cells to stick to one another makes it more difficult for blood to flow through the microvasculature, giving rise to the term *sludged blood*.

Increased Capillary Permeability. After many hours of capillary hypoxia and lack of other nutrients, permeability of the capillaries gradually increases, and large quantities of fluid begin to transude into the tissues. This phenomenon decreases the blood volume even more, with a resultant further decrease in cardiac output, making the shock still more severe. Capillary hypoxia does not cause increased capillary permeability until the late stages of prolonged shock.

Release of Toxins By Ischemic Tissue. Tissue injury in shock causes damage to the vascular endothelium and can provoke an inflammatory response. Shock has been also suggested to cause tissues to release toxic substances, such as histamine, serotonin, and tissue enzymes, that cause further deterioration of the circulatory system. An excess of proinflammatory small protein mediators called *cytokines* produced by immune cells during shock can further exacerbate inflammation and damage to the tissues. Antiinflammatory drugs, such as corticosteroids, may be helpful in some forms of shock. Experimental studies have also proved the significance of at least one toxin, *endotoxin*, in some types of shock.

Cardiac Depression Caused By Endotoxin. *Endotoxin* is released from the bodies of dead gram-negative bacteria in the intestines. Diminished blood flow to the intestines often causes enhanced formation and absorption of this toxic substance. The circulating toxin then causes increased cellular metabolism, despite inadequate nutrition of the cells, which has a specific effect on the heart muscle, causing *cardiac depression*. Endotoxin can play a major role in some types of shock, especially septic shock, discussed later in this chapter.

Generalized Cellular Deterioration. As shock becomes severe, many signs of generalized cellular deterioration occur throughout the body. One organ especially affected is the *liver*, as illustrated in **Fig. 24.5**. The liver is especially affected mainly because of the lack of enough nutrients to support the normally high rate of metabolism in liver cells, but also partly because of the exposure of the liver cells to any vascular toxin or other abnormal metabolic factor occurring in shock.

Among the damaging cellular effects that are known to occur in most body tissues are the following:

1. Active transport of sodium and potassium through the cell membrane is greatly diminished. As a result, sodium and chloride accumulate in the cells, and potassium is lost from the cells. In addition, the cells begin to swell.
2. Mitochondrial activity in the liver cells, as well as in many other tissues of the body, becomes severely depressed.

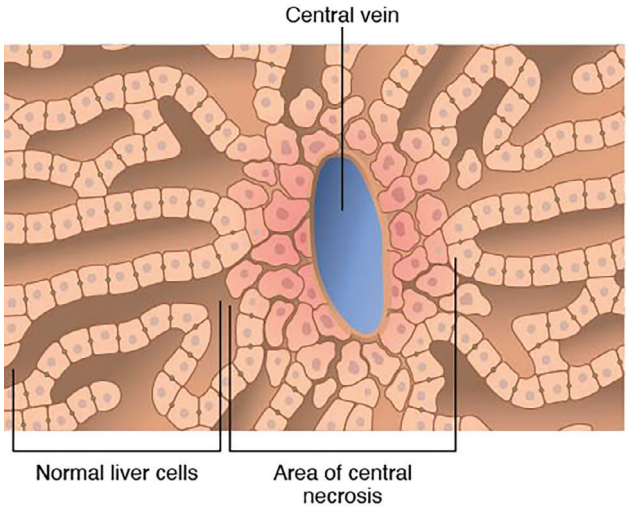

Figure 24.5 Necrosis of the central portion of a liver lobule during severe circulatory shock with areas of necrosis near the liver veins.

3. Lysosomes in the cells in widespread tissue areas begin to break open, with intracellular release of *hydrolases*, which cause further intracellular deterioration.
4. Cellular metabolism of nutrients, such as glucose, eventually becomes greatly depressed in the last stages of shock. The actions of some hormones are depressed as well, including almost 100% depression of the actions of insulin.

All these effects contribute to further deterioration of many organs of the body, including especially the following: (1) the *liver*, with depression of its many metabolic and detoxification functions; (2) the *lungs*, with eventual development of pulmonary edema and poor ability to oxygenate the blood; and (3) the *heart*, thereby further depressing its contractility.

Patchy Areas of Tissue Necrosis Caused By Patchy Blood Flows in Different Organs. Not all cells of the body are equally damaged by shock because some tissues have better blood supplies than others. For example, the cells adjacent to the arterial ends of capillaries receive better nutrition than cells adjacent to the venous ends of the same capillaries. Therefore, more nutritive deficiency occurs around the venous ends of capillaries than elsewhere. **Fig. 24.5** shows necrosis in the center of a liver lobule, the portion of the lobule that is the last to be exposed to the blood as it passes through the liver sinusoids.

Similar punctate lesions occur in heart muscle, although here a definite repetitive pattern, such as occurs in the liver, cannot be demonstrated. Nevertheless, the cardiac lesions play an important role in leading to the final irreversible stage of shock. Deteriorative lesions also occur in the kidneys, especially in the epithelium of the kidney tubules, leading to kidney failure and occasionally uremic death several days later. Deterioration of the lungs also often leads to respiratory distress and death several days later, called *acute respiratory distress syndrome (ARDS)*.

Acidosis in Shock. Metabolic derangements that occur in shocked tissue can lead to acidosis throughout the body. This results from poor delivery of oxygen to the tissues, which greatly diminishes oxidative metabolism of the foodstuffs. When this occurs, the cells obtain most of their energy by the anaerobic process of glycolysis, which leads to *excess lactic acid* in the blood. In addition, poor blood flow through tissues prevents normal removal of carbon dioxide. The carbon dioxide reacts locally in the cells with water to form high concentrations of intracellular carbonic acid, which, in turn, reacts with various tissue chemicals to form additional intracellular acidic substances. Thus, another deteriorative effect of shock is generalized and local tissue acidosis, leading to further progression of the shock.

Positive Feedback Deterioration of Tissues in Shock and Vicious Cycle of Progressive Shock. All the factors just discussed that can lead to further progression of shock are types of *positive feedback*—that is, each increase in the degree of shock causes a further increase in the shock. However, positive feedback does not necessarily lead to a vicious cycle. Development of a vicious cycle depends on the intensity of the positive feedback. In mild degrees of shock, the negative feedback mechanisms of the circulation, including sympathetic reflexes, reverse stress-relaxation mechanism of the blood reservoirs, and absorption of fluid into the blood from the interstitial spaces, can overcome the positive feedback influences and, therefore, initiate recovery. In severe shock, however, the deteriorative feedback mechanisms become more and more powerful, leading to such rapid deterioration of the circulation that all the normal negative feedback systems of circulatory control acting together cannot return the cardiac output to normal.

Considering once again the principles of positive feedback and vicious cycles discussed in Chapter 1, one can readily understand why there is a critical cardiac output level above which a person in shock recovers and below which a person enters a vicious cycle of circulatory deterioration that proceeds until death.

IRREVERSIBLE SHOCK

After shock has progressed to a certain stage, transfusion or any other type of therapy becomes incapable of saving the person's life. The person is then said to be in the *irreversible stage of shock*. Ironically, even in this irreversible stage, therapy can, on rare occasions, return the arterial pressure and even the cardiac output to normal or near normal for short periods, but the circulatory system nevertheless continues to deteriorate, and death ensues in another few minutes to few hours.

Fig. 24.6 shows that transfusion during the irreversible stage can sometimes cause cardiac output (as well as arterial pressure) to return to nearly normal. However, cardiac output soon begins to fall again, and subsequent transfusions have less and less effect. By this time, multiple deteriorative changes have occurred in heart muscle cells that may not necessarily affect the heart's *immediate* ability to pump blood but, over a long period, depress heart

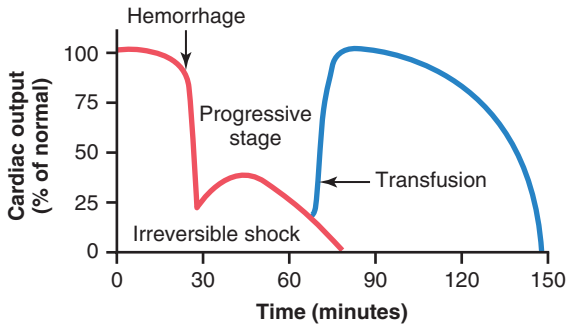

Figure 24.6 Failure of transfusion to prevent death in irreversible shock.

pumping enough to cause death. Beyond a certain point, so much tissue damage has occurred, so many destructive enzymes have been released into the body fluids, so much acidosis has developed, and so many other destructive factors are now in progress that even a normal cardiac output for a few minutes cannot reverse the continuing deterioration. Therefore, in severe shock, a stage is eventually reached at which the person will die, even though vigorous therapy might still return the cardiac output to normal for short periods.

Depletion of Cellular High-Energy Phosphate Reserves in Irreversible Shock. The high-energy phosphate reserves in the tissues of the body, especially in the liver and heart, are greatly diminished in severe shock. Essentially all the *creatine phosphate* has been degraded, and almost all the *adenosine triphosphate* has downgraded to *adenosine diphosphate, adenosine monophosphate*, and, eventually, *adenosine*. Much of this adenosine then diffuses out of the cells into the circulating blood and is converted into uric acid, a substance that cannot reenter the cells to reconstitute the adenosine phosphate system. New adenosine can be synthesized at a rate of only about 2% of the normal cellular amount an hour, meaning that once the high-energy phosphate stores of the cells are depleted, they are difficult to replenish.

Thus, one of the most devastating end results in shock, and the one that is perhaps most significant for development of the final state of irreversibility, is cellular depletion of these high-energy compounds.

HYPOVOLEMIC SHOCK CAUSED BY PLASMA LOSS

Hypovolemic shock can occur from hemorrhagic or nonhemorrhagic conditions. Loss of plasma from the circulatory system, even without loss of red blood cells, can sometimes be severe enough to reduce the total blood volume markedly, causing typical hypovolemic shock similar in most details to that caused by hemorrhage. Severe plasma loss occurs in the following conditions:

1. *Intestinal obstruction* may cause severely reduced plasma volume. Distention of the intestine in intestinal obstruction partly blocks venous blood flow in the intestinal walls, which increases intestinal capillary pressure, causing fluid to leak from the capillaries into the intestinal walls and intestinal lumen. Because the lost fluid has high protein content, the result is reduced total blood plasma protein, as well as reduced plasma volume.
2. *Severe burns or other denuding conditions of the skin* cause loss of plasma through the denuded skin areas so that the plasma volume becomes markedly reduced.

The hypovolemic shock that results from plasma loss has almost the same characteristics as the shock caused by hemorrhage, except for one additional complicating factor: the blood viscosity increases greatly as a result of increased red blood cell concentration in the remaining blood, and this increase in viscosity exacerbates the sluggishness of blood flow.

Loss of fluid from all fluid compartments of the body is called *dehydration*; this condition can also reduce the blood volume and cause hypovolemic shock similar to that resulting from hemorrhage. Some of the causes of this type of shock are the following: (1) excessive sweating; (2) fluid loss in severe diarrhea or vomiting; (3) excess loss of fluid by the kidneys; (4) inadequate intake of fluid and electrolytes; or (5) destruction of the adrenal cortices, with loss of aldosterone secretion and consequent failure of the kidneys to reabsorb adequate amounts of sodium, chloride, and water, which occurs in the absence of the adrenocortical hormone aldosterone.

HYPOVOLEMIC SHOCK CAUSED BY TRAUMA

One of the most common causes of circulatory shock is trauma to the body. Often, the shock results simply from hemorrhage caused by the trauma, but it can also occur even without hemorrhage because extensive contusion of the body can damage the capillaries sufficiently to allow excessive loss of plasma into the tissues. This phenomenon results in greatly reduced plasma volume, with resultant hypovolemic shock.

Various attempts have been made to implicate toxic factors released by the traumatized tissues as one of the causes of shock after trauma. However, cross-transfusion experiments with normal animals have failed to show significant toxic elements. Traumatic shock, therefore, seems to result mainly from hypovolemia, although there might also be a moderate degree of concomitant neurogenic shock caused by loss of vasomotor tone, as discussed next.

DISTRIBUTIVE SHOCK IS CHARACTERIZED BY SEVERE PERIPHERAL VASODILATION

Shock occasionally occurs without any loss of blood volume. Instead, the *vascular capacity* increases so much that even the normal amount of blood is incapable of filling the circulatory system adequately. One of the major causes of this condition is *sudden loss of vasomotor tone* throughout the body, resulting especially in massive dilation of the veins. The resulting condition is known as *distributive shock*.

The role of vascular capacity in helping regulate circulatory function was discussed in Chapter 15, where it was noted that an increase in vascular capacity or a decrease in blood volume *reduces the mean systemic filling pressure*, which reduces venous return to the heart. Diminished venous return caused by vascular dilation is called *venous pooling* of blood.

NEUROGENIC CAUSES OF DISTRIBUTIVE SHOCK

Some neurogenic factors that can cause loss of vasomotor tone include the following:

1. *Deep general anesthesia* often depresses the vasomotor center enough to cause vasomotor paralysis, with resulting neurogenic shock.
2. *Spinal anesthesia*, especially when this extends all the way up the spinal cord, blocks the sympathetic nervous outflow from the nervous system and can be a potent cause of neurogenic shock.
3. *Brain injury* is often a cause of vasomotor paralysis. Many patients who have had a brain concussion or contusion of the basal regions of the brain experience profound neurogenic shock. Also, even though brain ischemia for a few minutes almost always causes extreme vasomotor stimulation and increased blood pressure, prolonged ischemia (lasting >5–10 minutes) can cause the opposite effect—total inactivation of the vasomotor neurons in the brain stem, with a consequent decrease in arterial pressure and development of severe neurogenic shock.

ANAPHYLACTIC SHOCK AND HISTAMINE SHOCK

Anaphylaxis is another form of distributive shock; it is caused by an allergic condition in which cardiac output and arterial pressure often decrease drastically. This condition is discussed in Chapter 35. It results primarily from an antigen-antibody reaction that rapidly occurs after an antigen to which the person is sensitive enters the circulation. One of the principal effects is to cause the *basophils* in the blood and *mast* cells in the pericapillary tissues to release *histamine* or a *histamine-like substance*. The histamine causes the following: (1) an increase in vascular capacity because of venous dilation, thus causing a marked decrease in venous return; (2) dilation of the arterioles, resulting in greatly reduced arterial pressure; and (3) greatly increased capillary permeability, with rapid loss of fluid and protein into the tissue spaces. The net effect is a great reduction in venous return and, sometimes, such serious shock that the person may die within minutes.

Intravenous injection of large amounts of histamine causes histamine shock, which has characteristics almost identical to those of anaphylactic shock.

SEPTIC SHOCK IS THE MOST COMMON CAUSE OF DISTRIBUTIVE SHOCK

Septic shock refers to an infection widely disseminated to many areas of the body, with the infection being carried through the blood from one tissue to another and causing extensive damage. There are many varieties of septic shock because of the many types of infections that can cause it and because infection in different parts of the body produces different effects. Most cases of septic shock, however, are caused by gram-positive bacteria, followed by endotoxin-producing gram-negative bacteria. Severe viral or fungal infections can also lead to septic shock.

Septic shock is extremely important to the clinician because, other than cardiogenic shock, septic shock is currently the most frequent cause of shock-related death in the hospital.

Some of the typical causes of septic shock include the following:

1. Peritonitis caused by spread of infection from the uterus and fallopian tubes, sometimes resulting from an instrumental abortion performed under unsterile conditions
2. Peritonitis resulting from rupture of the gastrointestinal system, sometimes caused by intestinal disease or by wounds
3. Generalized bodily infection resulting from spread of a skin infection such as streptococcal or staphylococcal infection
4. Generalized gangrenous infection resulting specifically from gas gangrene bacilli, spreading first through peripheral tissues and finally via the blood to the internal organs, especially the liver
5. Infection spreading into the blood from the kidney or urinary tract, often caused by colon bacilli
6. Infection spreading into the blood from pneumonia, most commonly caused by streptococcal bacteria.

Special Features of Septic Shock. Because of the multiple types of septic shock, it is difficult to categorize this condition. The following features are often observed:

1. High fever (body temperature above 100.4°F [38°C]) or hypothermia in rare cases
2. Marked vasodilation throughout the body, especially in the infected tissues
3. High cardiac output in perhaps half of patients, caused by tachycardia and arteriolar dilation in the infected tissues and by high metabolic rate and vasodilation elsewhere in the body, resulting from bacterial toxin stimulation of cellular metabolism and from a high body temperature
4. Rapid breathing (*tachypnea*), often resulting in lower plasma carbon dioxide levels
5. Increase in blood leukocytes in response to the infectious source
6. Sludging of the blood, caused by red cell agglutination in response to degenerating tissues
7. Development of micro–blood clots in widespread areas of the body, a condition called *disseminated intravascular coagulation*; also, this causes the blood clotting factors to be used up, so hemorrhaging occurs in many tissues, especially in the gut wall of the intestinal tract

In early stages of septic shock, the patient usually does not have signs of circulatory collapse but only signs of the bacterial infection. As the infection becomes more severe, the circulatory system usually becomes involved because of direct extension of the infection or secondarily as a result of toxins from the bacteria, with resultant loss of plasma into the infected tissues through deteriorating blood capillary walls. There finally comes a point at which deterioration of the circulation becomes progressive in the same way that progression occurs in all other types of shock. The end stages of septic shock are not greatly different from the end stages of hemorrhagic shock, even though the initiating factors are markedly different in the two conditions.

OBSTRUCTIVE SHOCK IS USUALLY DUE TO NONCARDIAC CAUSES OF REDUCED CARDIAC OUTPUT

Obstructive shock is caused by conditions that impair blood flow from the right heart through the left heart, resulting in decreased cardiac output. Conditions such as a massive *pulmonary embolism* can obstruct blood flow from the pulmonary arteries to the lungs, resulting in reduced cardiac output.

Some conditions, such as *pericardial tamponade* (heart compression from a large pericardial effusion), can significantly reduce cardiac output even in the setting of normal blood volume and myocardial function.

PHYSIOLOGY OF TREATMENT IN SHOCK

REPLACEMENT THERAPY

Blood and Plasma Transfusion. If a person is in shock caused by hemorrhage, the best possible therapy is usually transfusion of whole blood. If the shock is caused by plasma loss, the best therapy is administration of plasma. When dehydration is the cause, administration of an appropriate electrolyte solution can correct the shock.

Whole blood is not always available, such as under battlefield conditions. Plasma can usually substitute adequately for whole blood because it increases the blood volume and restores normal hemodynamics. Plasma cannot restore a normal hematocrit, but the body can usually stand a decrease in hematocrit to about half of normal before serious consequences result if cardiac output is adequate. Therefore, in emergency conditions, it is reasonable to use plasma in place of whole blood for treatment of hemorrhagic or most other types of hypovolemic shock.

Sometimes, plasma is unavailable. In these cases, various *plasma substitutes* have been developed that perform almost exactly the same hemodynamic functions as plasma. One of these substitutes is dextran solution.

Dextran Solution as a Plasma Substitute. The principal requirement of a truly effective plasma substitute is that it remain in the circulatory system—that is, it does not filter through the capillary pores into the tissue spaces. In addition, the solution must be nontoxic and must contain appropriate electrolytes to prevent derangement of the body's extracellular fluid electrolytes on administration.

To remain in the circulation, the plasma substitute must contain some substance that has a large enough molecular size to exert colloid osmotic pressure. One substance developed for this purpose is *dextran*, a large polysaccharide polymer of glucose. Dextrans of appropriate molecular size do not pass through the capillary pores and, therefore, can replace plasma proteins as colloid osmotic agents.

Few toxic reactions have been observed when using purified dextran to provide colloid osmotic pressure; therefore, solutions containing this substance have been used as a substitute for plasma in fluid replacement therapy.

TREATMENT OF DISTRIBUTIVE SHOCK WITH SYMPATHOMIMETIC DRUGS

A *sympathomimetic drug* is a drug that mimics sympathetic stimulation. These drugs include *norepinephrine, epinephrine*, and a large number of long-acting drugs that have the same basic effects as epinephrine and norepinephrine.

In distributive (vasodilatory) shock, sympathomimetic drugs are especially beneficial. These drugs are especially effective in *neurogenic shock*, in which the sympathetic nervous system is severely depressed. Administering a sympathomimetic drug takes the place of the diminished sympathetic actions and can often restore full circulatory function.

Another type of shock in which sympathomimetic drugs are valuable is *anaphylactic shock*, in which excess histamine plays a prominent role. The sympathomimetic drugs have a vasoconstrictor effect that opposes the vasodilating effect of histamine. Therefore, epinephrine, norepinephrine, or other sympathomimetic drugs are often lifesaving.

Sympathomimetic drugs have not proved to be very valuable in hemorrhagic shock. The reason is that in this type of shock, the sympathetic nervous system is almost always maximally activated by the circulatory reflexes; so much norepinephrine and epinephrine are already circulating in the blood that sympathomimetic drugs have essentially no additional beneficial effect.

OTHER THERAPIES FOR SHOCK

Head-Down Position. When the pressure falls too low in most types of shock, especially in hemorrhagic and neurogenic shock, placing the patient with the head at

least 12 inches lower than the feet helps in promoting venous return, thereby also increasing cardiac output. This head-down position, often called the *Trendelenburg position*, is the first essential step in the treatment of many types of shock.

Oxygen Therapy. Because a major deleterious effect of most types of shock is too little delivery of oxygen to the tissues, giving the patient oxygen to breathe can be of benefit in some cases. However, this intervention frequently is far less beneficial than one might expect because the problem in most types of shock is not inadequate oxygenation of the blood by the lungs but inadequate transport of the blood after it is oxygenated.

Treatment With Corticosteroids. Glucocorticoids—adrenal cortex hormones that control glucose metabolism—are sometimes given to patients in severe shock for several reasons: (1) experiments have shown empirically that glucocorticoids frequently increase the strength of the heart in the late stages of shock; (2) glucocorticoids stabilize lysosomes in tissue cells and thereby prevent the release of lysosomal enzymes into the cytoplasm of the cells, thus preventing deterioration from this source; and (3) glucocorticoids might aid in the metabolism of glucose by the severely damaged cells.

Glucocorticoids are sometimes administered in patients with septic shock due to relative insufficiency of the adrenal glands and to attenuate excess inflammation. Sometimes these drugs are administered along with mineralocorticoids, adrenal cortex hormones, which promote increased sodium reabsorption in the kidneys.

CIRCULATORY ARREST

A condition closely allied to circulatory shock is circulatory arrest, in which all blood flow stops. This condition can occur, for example, as a result of *cardiac arrest* or *ventricular fibrillation*.

Ventricular fibrillation can usually be stopped by strong electroshock of the heart called *defibrillation*, the basic principles of which are described in Chapter 13.

In the case of complete cardiac arrest, a normal cardiac rhythm can sometimes be restored by immediately applying cardiopulmonary resuscitation (*CPR*) procedures while at the same time supplying the patient's lungs with adequate quantities of ventilatory oxygen.

Effect of Circulatory Arrest on the Brain

A special challenge in circulatory arrest is to prevent detrimental effects of the arrest on the brain. The brain is particularly susceptible to ischemia and injury during circulatory arrest due to its lack of innate energy stores. In general, more than 5 to 8 minutes of total circulatory arrest can cause at least some degree of permanent brain damage in more than half of patients. Circulatory arrest for as long as 10 to 15 minutes almost always permanently destroys significant amounts of mental capacity. Therefore, initiating early CPR, which can improve brain perfusion up to 25% during circulatory arrest, is critically important to preserve brain function. Strategies such as targeted hypothermia (cooling the body temperature below normal to reduce the brain's metabolic demands) or permissive hypercapnia (allowing the blood carbon dioxide concentration to increase because brain blood flow is partially regulated by carbon dioxide levels) have potential benefits to preserve brain function after circulatory arrest. However, clinical trial evidence demonstrating clear benefit is insufficient.

CHAPTER 25

Regulation of Body Fluid Compartments: Extracellular and Intracellular Fluids; Edema

The maintenance of a relatively constant volume and stable composition of the body fluids is essential for homeostasis. Some of the most common and important problems in clinical medicine arise because of abnormalities in the control systems that maintain this relative constancy of the body fluids. In this chapter and in the following chapters on the kidneys, we discuss overall regulation of body fluid volume, constituents of the extracellular fluid, acid–base balance, and control of fluid exchange between extracellular and intracellular compartments.

INTAKE AND OUTPUT OF FLUIDS AND SOLUTES ARE BALANCED DURING LONG-TERM STEADY-STATE CONDITIONS

The relative constancy of the body fluids is remarkable, because there is continuous exchange of fluid and solutes with the external environment, as well as within the different body compartments. For example, fluid and electrolytes added to the body are highly variable and must be carefully matched by equal output of fluid and electrolytes from the body to prevent body fluid volumes and electrolytes from increasing or decreasing.

DAILY INTAKE OF WATER

Water is added to the body by two major sources: (1) it is ingested in the form of liquids or water in food, which together normally add about 2100 mL/day to the body fluids; and (2) it is synthesized in the body by oxidation of carbohydrates, adding about 200 mL/day. These mechanisms provide a total water intake of about 2300 mL/day (**Table 25.1**). However, intake of water is highly variable among different people and even within the same person on different days, depending on climate, habits, and level of physical activity.

Daily Loss of Body Water

Insensible Water Loss. Some water losses cannot be precisely regulated. For example, humans experience continuous water loss by evaporation from the respiratory tract and diffusion through the skin, which together account for about 700 mL/day of water loss under normal conditions. This loss is termed *insensible water loss* because we are not consciously aware of it, even though it occurs continually in all living people.

Insensible water loss through the skin by diffusion averages about 300 to 400 mL/day, occurs independently of sweating, and is present even in people who are born without sweat glands. This loss is minimized by the cholesterol-filled, cornified layer of the skin, which provides a barrier against excessive loss by diffusion. When the cornified layer becomes denuded, as occurs with extensive burns, the rate of evaporation can increase as much as 10-fold, to 3 to 5 L/day. For this reason, persons with burns must be given large amounts of fluid, usually intravenously, to balance fluid loss.

Insensible water loss through the respiratory tract normally averages about 300 to 400 mL/day. As air enters the respiratory tract, it becomes saturated with moisture to a vapor pressure of about 47 mm Hg before it is expelled. Because the vapor pressure of the inspired air is usually less than 47 mm Hg, water is continuously lost through the lungs with respiration. In cold weather, the atmospheric vapor pressure decreases to nearly zero, causing an even greater loss of water from the lungs as the temperature decreases. This process explains the dry feeling in the respiratory passages in cold weather.

Fluid Loss in Sweat. The amount of water lost by sweating is highly variable, depending on physical activity and environmental temperature. The volume of sweat normally is about 100 mL/day, but in hot weather or during heavy exercise, fluid loss in sweat occasionally increases to 1 to 2 L/hr. This fluid loss would rapidly deplete the body fluids if intake were not also increased by activating the thirst mechanism, as discussed in Chapter 29.

Water Loss in Feces. Only a small amount of water (100 mL/day) normally is lost in the feces. This loss can increase to several liters a day in people with severe diarrhea. Therefore, severe diarrhea can be life-threatening if not corrected within a few days.

Water Loss By the Kidneys. The remaining water loss from the body occurs in the urine excreted by the kidneys. Multiple mechanisms control the rate of urine excretion.

Table 25.1 Daily Intake and Output of Water (mL/day)

Intake or Output	Normal	Prolonged Heavy Exercise
Intake		
Fluids ingested	2100	?
From metabolism	200	200
Total intake	2300	?
Output		
Insensible: skin	350	350
Insensible: lungs	350	650
Sweat	100	5000
Feces	100	100
Urine	1400	500
Total output	2300	6600

The most important means whereby the body maintains balance between water intake and output, as well as a balance between intake and output of most electrolytes in the body, is by controlling the rate at which the kidneys excrete these substances. For example, urine volume can be as low as 0.5 L/day in a dehydrated person or as high as 20 L/day in a person who has been drinking tremendous amounts of water.

This variability of intake is also true for most of the electrolytes of the body, such as sodium, chloride, and potassium. In some people, sodium intake may be as low as 20 mEq/day, whereas in others, sodium intake may be as high as 300 to 500 mEq/day. The kidneys have the task of adjusting the excretion rate of water and electrolytes to match the intake of these substances precisely, as well as compensating for excessive losses of fluids and electrolytes that occur in certain disease states. In Chapters 26 through 32, we discuss the mechanisms that allow the kidneys to perform these remarkable tasks.

BODY FLUID COMPARTMENTS

The total body fluid is distributed mainly between two compartments, the *extracellular fluid* and the *intracellular fluid* (**Fig. 25.1**). The extracellular fluid is divided into the *interstitial fluid* and the blood *plasma*.

There is another small compartment of fluid that is referred to as *transcellular fluid*. This compartment includes fluid in the synovial, peritoneal, pericardial, and intraocular spaces, as well as the cerebrospinal fluid; it is usually considered to be a specialized type of extracellular fluid, although in some cases its composition may differ markedly from that of the plasma or interstitial fluid. All the transcellular fluids together constitute about 1 to 2 liters.

In a 70-kg adult man, the total body water is about 60% of the body weight, or about 42 liters. This percentage depends on age, muscle mass, and percentage of body weight that is fat. As a person grows older, the percentage of total body weight that is fluid gradually decreases.

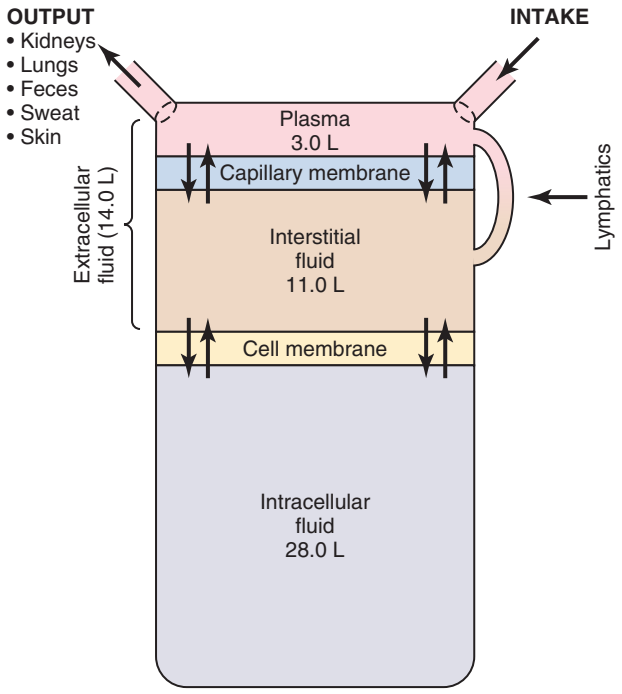

Figure 25.1 Summary of body fluid regulation, including the major body fluid compartments and the membranes that separate these compartments. The values shown are for an average 70-kg man.

This decrease is due in part to the fact that aging is usually associated with loss of muscle mass and an increased percentage of the body weight being fat, which decreases the percentage of water in the body.

Because women normally have a greater percentage of body fat compared with men, their total body water averages about 50% of the body weight. However, this percentage also varies considerably among women, depending on age, muscle mass, and body fat. In premature and newborn babies, the total body water ranges from 70% to 75% of body weight. Therefore, when discussing average body fluid compartments, we should realize that variations exist, depending on age, sex, muscle mass, and body fat.

In many other countries, the average body weight (and fat mass) has increased rapidly during the past 30 years. The average body weight for adult men older than 20 years in the United States is estimated to be approximately 90 kg (~198 lb), and for adult women it is 77.5 kg (~171 lb). Therefore, data discussed for an average 70-kg man in this and other chapters would need to be adjusted accordingly when considering body fluid compartments in many people.

INTRACELLULAR FLUID COMPARTMENT

About two-thirds (28 L of the total 42 L) of the fluid in the body is inside the trillions of cells and is collectively called the *intracellular fluid*. Thus, the intracellular fluid constitutes about 40% of the total body weight in an "average" person.

The fluid of each cell contains its individual mixture of different constituents, but the concentrations of these substances are similar from one cell to another. In fact, the composition of cell fluids is remarkably similar even in different animals, ranging from the most primitive microorganisms to humans. For this reason, the intracellular fluid of all the different cells together is considered to be one large fluid compartment.

EXTRACELLULAR FLUID COMPARTMENT

All the fluids outside the cells are collectively called the *extracellular fluid*. Together these fluids account for about 20% of the body weight, or about 14 liters in a 70-kg lean man. The two largest compartments of the extracellular fluid are the *interstitial fluid*, which makes up more than three-fourths (11 L) of the extracellular fluid, and the *plasma*, which makes up almost one-fourth of the extracellular fluid, or about 3 liters. The plasma is the noncellular part of the blood; it exchanges substances continuously with the interstitial fluid through the pores of the capillary membranes. These pores are highly permeable to almost all solutes in the extracellular fluid, except the proteins. Therefore, the extracellular fluids are constantly mixing, so the plasma and interstitial fluids have about the same composition, except for proteins, which have a higher concentration in the plasma.

BLOOD VOLUME

Blood contains extracellular fluid (plasma fluid) and intracellular fluid (fluid in red blood cells). However, blood is considered to be a separate fluid compartment because it is contained in a chamber of its own, the circulatory system. The blood volume is especially important in the control of cardiovascular dynamics.

The average blood volume of adults is about 7% of body weight, or about 5 liters. About 60% of the blood is plasma and 40% is red blood cells, but these percentages can vary considerably in different people, depending on sex, weight, and other factors.

Hematocrit (Packed Red Blood Cell Volume). The hematocrit is the fraction of the blood composed of red blood cells, as determined by centrifuging blood in a hematocrit tube until the cells are tightly packed in the bottom of the tube. Because the centrifuge does not completely pack the red blood cells together, about 3% to 4% of the plasma remains entrapped among the cells, and the true hematocrit is about 96% of the measured hematocrit.

In men, the measured hematocrit is normally about 0.42, and in women, it is about 0.38. In persons with severe *anemia*, the hematocrit may fall as low as 0.10, a value that is barely sufficient to sustain life. Conversely, in persons with *polycythemia*, excessive production of red blood cells may increase the hematocrit to as high as 0.65.

CONSTITUENTS OF EXTRACELLULAR AND INTRACELLULAR FLUIDS

Comparisons of the composition of the extracellular fluid, including the plasma and interstitial fluid, and the intracellular fluid are shown in **Figs. 25.2** and **25.3** and in **Table 25.2**.

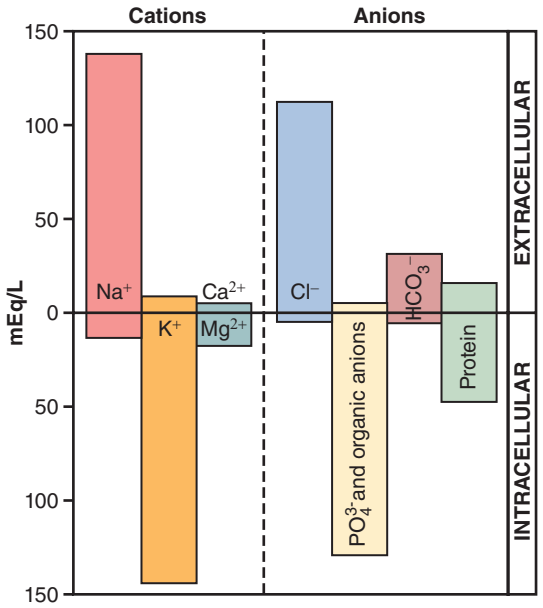

Figure 25.2 Major cations and anions of the intracellular and extracellular fluids. The concentrations of Ca^{2+} and Mg^{2+} represent the sum of these two ions. The concentrations shown represent the total of free ions and complexed ions.

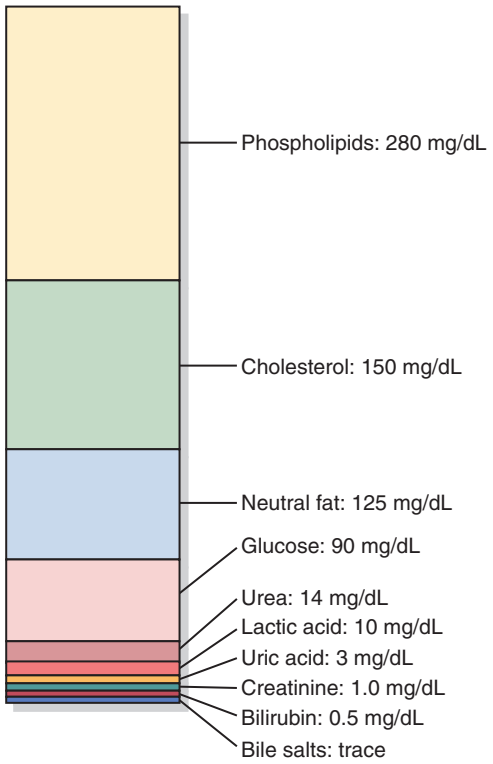

Figure 25.3 Nonelectrolytes of the plasma.

Table 25.2 Osmolar Substances in Extracellular and Intracellular Fluids

Substance	Plasma (mOsm/L H_2O)	Interstitial (mOsm/L H_2O)	Intracellular (mOsm/L H_2O)
Na^+	142	139	14
K^+	4.2	4.0	140
Ca^{2+}	1.3	1.2	0.0001
Mg^{2+}	0.8	0.7	20
Cl^-	106	108	4
HCO_3^-	24	28.3	10
HPO_4^{2-}, $H_2PO_4^-$	2	2	11
SO_4^{2-}	0.5	0.5	1
Phosphocreatine			45
Carnosine			14
Amino acids	2	2	8
Creatine	0.2	0.2	9
Lactate	1.2	1.2	1.5
Adenosine triphosphate			5
Hexose monophosphate			3.7
Glucose	5.6	5.6	
Protein	1.2	0.2	4
Urea	4	4	4
Others	4.8	3.9	10
Total mOsm/L	299.8	300.8	301.2
Corrected osmolar activity (mOsm/L)	282.0	281.0	281.0
Total osmotic pressure at 37°C (98.6°F) (mm Hg)	5441	5423	5423

Plasma and Interstitial Fluid Have Similar Ionic Composition

Because the plasma and interstitial fluid are separated only by highly permeable capillary membranes, their ionic composition is similar. The most important difference between these two compartments is the higher concentration of protein in the plasma; because the capillaries have a low permeability to the plasma proteins, only small amounts of proteins are leaked into the interstitial spaces in most tissues.

Because of the *Donnan effect*, the concentration of positively charged ions (cations) is slightly greater (~2%) in plasma than in interstitial fluid. Plasma proteins have a net negative charge and therefore tend to attract cations such as sodium and potassium ions, thus holding extra amounts of these cations in the plasma, along with the plasma proteins. Conversely, negatively charged ions (anions) tend to have a slightly higher concentration in interstitial fluid compared with plasma because the negative charges of the plasma proteins repel the negatively charged anions. For practical purposes, however, the concentrations of ions in interstitial fluid and plasma are considered to be about equal.

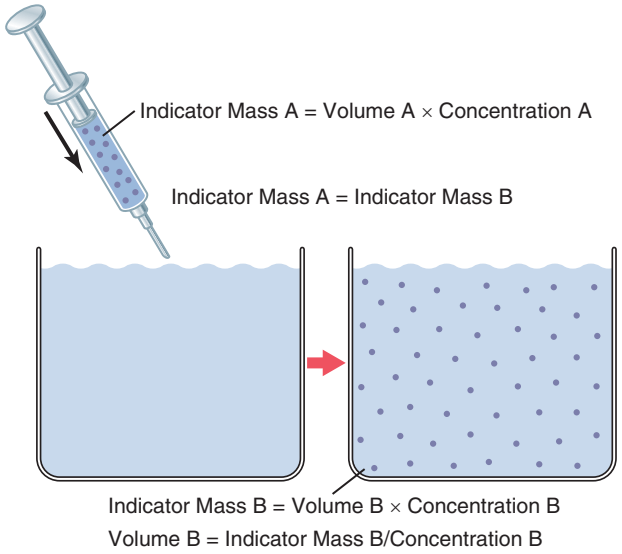

Figure 25.4 Indicator-dilution method for measuring fluid volumes.

Referring again to **Fig. 25.2**, one can see that the extracellular fluid, including the plasma and interstitial fluid, contains large amounts of sodium and chloride ions and reasonably large amounts of bicarbonate ions but only small quantities of potassium, calcium, magnesium, phosphate, and organic acid ions. The composition of extracellular fluid is carefully regulated by various mechanisms, especially by the kidneys, as discussed later. This regulation allows the cells to remain continually bathed in a fluid that contains the proper concentration of electrolytes and nutrients for optimal cell function.

Intracellular Fluid Constituents

The intracellular fluid is separated from the extracellular fluid by a cell membrane that is highly permeable to water but is not permeable to most electrolytes in the body. In contrast to the extracellular fluid, the intracellular fluid contains only small quantities of sodium and chloride ions and almost no calcium ions. Instead, it contains large amounts of potassium and phosphate ions plus moderate quantities of magnesium and sulfate ions, all of which have low concentrations in the extracellular fluid. Also, cells contain large amounts of protein—almost four times as much as in the plasma.

MEASUREMENT OF BODY FLUID COMPARTMENT VOLUMES—INDICATOR-DILUTION PRINCIPLE

The volume of a fluid compartment in the body can be measured by placing an indicator substance in the compartment, allowing it to disperse evenly throughout the compartment's fluid, and then analyzing the extent to which the substance becomes diluted. **Fig. 25.4** illustrates

this *indicator-dilution method* of measuring the volume of a fluid compartment. This method is based on the conservation of mass principle, which means that the total mass of a substance after dispersion in the fluid compartment will be the same as the total mass injected into the compartment.

In the example shown in **Fig. 25.4**, a small amount of dye or other substance contained in the syringe is injected into a chamber, and the substance is allowed to disperse throughout the chamber until it becomes mixed in equal concentrations in all areas. Then a sample of fluid containing the dispersed substance is removed, and the concentration is analyzed chemically, photoelectrically, or by other means. If none of the substance leaks out of the compartment, the total mass of substance in the compartment (Volume B × Concentration B) will equal the total mass of the substance injected (Volume A × Concentration A). By simple rearrangement of the equation, one can calculate the unknown volume of chamber B as follows:

$$\text{Volume B} = \frac{\text{Volume A} \times \text{Concentration A}}{\text{Concentration B}}$$

For this calculation, one needs to know the following: (1) the total amount of substance injected into the chamber (the numerator of the equation); and (2) the concentration of the fluid in the chamber after the substance has been dispersed (the denominator).

For example, if 1 milliliter of a solution containing 10 mg/mL of dye is dispersed into chamber B, and the final concentration in the chamber is 0.01 mg/mL of fluid, the unknown volume of the chamber can be calculated as follows:

$$\text{Volume B} = \frac{1\ \text{mL} \times 10\ \text{mg/mL}}{0.01\ \text{mg/mL}} = 1000\ \text{mL}$$

This method can be used to measure the volume of virtually any compartment in the body with the following assumptions (1) the indicator disperses *evenly* throughout the compartment; (2) the indicator disperses *only* in the compartment that is being measured; and (3) the indicator is *not metabolized or excreted*. If the indicator is metabolized or excreted, correction must be made for loss of the indicator from the body. Several substances can be used to measure the volume of each of the different body fluids.

DETERMINATION OF VOLUMES OF SPECIFIC BODY FLUID COMPARTMENTS

Measurement of Total Body Water. Radioactive water (tritium, ^3H_2O) or heavy water (deuterium, ^2H_2O) can be used to measure total body water. These forms of water mix with the total body water within a few hours after being injected into the blood, and the dilution principle can be used to calculate total body water (**Table 25.3**). Another substance that has been used to measure total body water is *antipyrine*, which is very lipid-soluble, rapidly penetrates cell membranes, and distributes uniformly throughout the intracellular and extracellular compartments.

Table 25.3 Measurement of Body Fluid Volumes

Volume	Indicators
Total body water	^3H_2O, ^2H_2O, antipyrine
Extracellular fluid	^{22}Na, ^{125}I-iothalamate, thiosulfate, inulin
Intracellular fluid	(Calculated as total body water—extracellular fluid volume)
Plasma volume	^{125}I-albumin, Evans blue dye (T-1824)
Blood volume	^{51}Cr-labeled red blood cells, or calculated as blood volume = plasma volume/(1 – hematocrit)
Interstitial fluid	Calculated as extracellular fluid volume – plasma volume

Measurement of Extracellular Fluid Volume. The volume of extracellular fluid can be estimated using any of several substances that disperse in the plasma and interstitial fluid but do not readily permeate the cell membrane. These include radioactive sodium, radioactive chloride, radioactive iothalamate, thiosulfate ion, and inulin. When any one of these substances is injected into the blood, it usually disperses almost completely throughout the extracellular fluid within 30 to 60 minutes. Some of these substances, however, such as radioactive sodium, may diffuse into the cells in small amounts. Therefore, one frequently speaks of the *sodium space* or *inulin space* instead of calling the measurement the true extracellular fluid volume.

Calculation of Intracellular Volume. The intracellular volume cannot be measured directly. However, it can be calculated as follows:

$$\text{Intracellular volume} = \text{Today body water} - \text{Extracellular volume}$$

Measurement of Plasma Volume. Plasma volume can be measured using substances that do not readily penetrate capillary membranes but remain in the vascular system after injection. One of the most commonly used substances for measuring plasma volume is serum albumin labeled with radioactive iodine (^{125}I-albumin) or with a dye that avidly binds to the plasma proteins, such as *Evans blue dye* (also called *T-1824*).

Calculation of Interstitial Fluid Volume. Interstitial fluid volume cannot be measured directly, but it can be calculated as follows:

$$\text{Interstitial fluid volume} = \text{Extracellular fluid volume} - \text{Plasma volume}$$

Measurement of Blood Volume. If one measures the *hematocrit* (the fraction of the total blood volume composed of cells) and plasma volume using the methods described earlier, blood volume can also be calculated using the following equation:

$$\text{Total blood volume} = \frac{\text{Plasma volume}}{1 - \text{Hematocrit}}$$

For example, if the plasma volume is 3 liters and hematocrit is 0.40, the total blood volume would be calculated as follows:

$$\frac{3 \text{ liters}}{1 - 0.4} = 5 \text{ liters}$$

Another method to measure blood volume (although rarely used in clinical settings) is to collect a small volume of red blood cells from the person, label the red blood cells with radioactive material, and then inject them back into the circulation. After these mix in the circulation, the radioactivity of a mixed blood sample can be measured, and the total blood volume can be calculated using the indicator-dilution principle. One substance that can be used to label the red blood cells is radioactive chromium (^{51}Cr), which binds tightly with the red blood cells.

FLUID EXCHANGE AND OSMOTIC EQUILIBRIUM BETWEEN INTRACELLULAR AND EXTRACELLULAR FLUID

A frequent problem in treating seriously ill patients is maintaining adequate fluids in one or both of the intracellular and extracellular compartments. As discussed in Chapter 16 and later in this chapter, the relative amounts of extracellular fluid distributed between the plasma and interstitial spaces are determined mainly by the balance of hydrostatic and colloid osmotic forces across the capillary membranes.

The distribution of fluid between intracellular and extracellular compartments, in contrast, is determined mainly by the osmotic effect of smaller solutes—especially sodium, chloride, and other electrolytes—acting across the cell membrane. The reason for this is that the cell membranes are highly permeable to water but relatively impermeable to even small ions such as sodium and chloride. Therefore, water moves across the cell membrane rapidly, and the intracellular fluid remains isotonic with the extracellular fluid.

In the next section, we discuss the interrelations between intracellular and extracellular fluid volumes and the osmotic factors that can cause shifts of fluid between these two compartments.

BASIC PRINCIPLES OF OSMOSIS AND OSMOTIC PRESSURE

The basic principles of osmosis and osmotic pressure were presented in Chapter 4. Therefore, we review here only the most important aspects of these principles as they apply to volume regulation.

Because cell membranes are relatively impermeable to most solutes but are highly permeable to water, whenever there is a higher concentration of impermeant solute on one side of the cell membrane, water diffuses across the membrane toward the region of higher solute concentration. Thus, if a solute such as sodium chloride is added to the extracellular fluid, water rapidly diffuses from the cells through the cell membranes into the extracellular fluid until the water concentration on both sides of the membrane becomes equal. Conversely, if a solute such as sodium chloride is removed from the extracellular fluid, water diffuses from the extracellular fluid through the cell membranes and into the cells.

Osmolality and Osmolarity. The osmolal concentration of a solution is called *osmolality* when the concentration is expressed as *osmoles per kilogram of water*; it is called *osmolarity* when it is expressed as *osmoles per liter of solution*. In dilute solutions such as the body fluids, these two terms can be used almost synonymously because the differences are small. Most of the calculations used clinically and the calculations expressed in the next several chapters are based on osmolarities rather than osmolalities.

Calculation of the Osmolarity and Osmotic Pressure of a Solution. Using the van 't Hoff law, one can calculate the potential osmotic pressure of a solution, assuming that the cell membrane is impermeable to the solute. For example, the osmotic pressure of a 0.9% sodium chloride solution is calculated as follows. A 0.9% solution means that there is 0.9 gram of sodium chloride per 100 milliliters of solution, or 9 g/L. Because the molecular weight of sodium chloride is 58.5 g/mol, the molarity of the solution is 9 g/L divided by 58.5 g/mol, or about 0.154 mol/L. Because each molecule of sodium chloride is approximately equal to 2 osmoles (assuming complete dissociation of the sodium and chloride ions in solution), the osmolarity of the solution is 0.154 × 2, or 0.308 Osm/L. Therefore, the osmolarity of this solution is 308 mOsm/L. The potential osmotic pressure of this solution would therefore be 308 mOsm/L × 19.3 mm Hg/mOsm/L, or 5944 mm Hg.

This calculation is an approximation, because sodium and chloride ions do not behave entirely independently in solution as a result of interionic attraction between them. One can correct for these deviations from the predictions of van 't Hoff's law by using a correction factor called the *osmotic coefficient*. For sodium chloride, the osmotic coefficient is about 0.93. Therefore, the actual osmolarity of a 0.9% sodium chloride solution is 308 × 0.93, or about 286 mOsm/L. For practical reasons, the osmotic coefficients of different solutes are sometimes neglected in determining the osmolarity and osmotic pressures of physiologic solutions.

Osmolarity of Body Fluids. Referring back to **Table 25.2**, note the approximate osmolarity of the various osmotically active substances in plasma, interstitial fluid, and intracellular fluid. About 80% of the total osmolarity of the interstitial fluid and plasma is due to sodium and chloride ions, whereas for intracellular fluid, almost half the osmolarity is due to potassium ions, and the remainder is divided among many other intracellular substances.

As shown in **Table 25.2**, the total osmolarity of each of the three compartments is about 300 mOsm/L, with the plasma being about 1 mOsm/L greater than that of the interstitial and intracellular fluids. The slight difference between plasma and interstitial fluid is caused by the osmotic effects of the plasma proteins, which maintain about 20 mm Hg greater pressure in the capillaries than in the surrounding interstitial spaces, as discussed in Chapter 16.

Corrected Osmolar Activity of Body Fluids. At the bottom of **Table 25.2** are shown *corrected osmolar activities* of plasma, interstitial fluid, and intracellular fluid. The reason for these corrections is that cations and anions exert interionic attraction, which can cause a slight decrease in the osmotic activity of the dissolved substances.

Osmotic Equilibrium Between Intracellular and Extracellular Fluids

High osmotic pressures can develop across the cell membrane with relatively small changes in the concentrations of solutes in the extracellular fluid. As discussed earlier, for each milliosmole concentration gradient of an *impermeant solute* (one that will not permeate the cell membrane), about 19.3 mm Hg of osmotic pressure is exerted across the cell membrane. If the cell membrane is exposed to pure water, and the osmolarity of intracellular fluid is 282 mOsm/L, the potential osmotic pressure that can develop across the cell membrane is more than 5400 mm Hg. This demonstrates the large force that can move water across the cell membrane when the intracellular and extracellular fluids are not in osmotic equilibrium. As a result of these forces, relatively small changes in the concentration of impermeant solutes in the extracellular fluid can cause large changes in cell volume.

Isotonic, Hypotonic, and Hypertonic Fluids. The effects of different concentrations of impermeant solutes in the extracellular fluid on cell volume are shown in **Fig. 25.5**. If a cell is placed in a solution of impermeant solutes having an osmolarity of 282 mOsm/L, the cells will not shrink or swell because the water concentration in the intracellular and extracellular fluids is equal, and the solutes cannot enter or leave the cell. Such a solution is said to be *isotonic* because it neither shrinks nor swells the cells. An example of an isotonic solution is a 0.9% solution of sodium chloride. This solution is important in clinical medicine because it can be infused into the blood without the danger of upsetting the osmotic equilibrium between the intracellular and extracellular fluids.

If a cell is placed into a *hypotonic* solution that has a lower concentration of impermeant solutes (<282 mOsm/L), water will diffuse into the cell, causing it to swell; water will continue to diffuse into the cell, diluting the intracellular fluid while also concentrating the extracellular fluid until both solutions have about the same osmolarity. Solutions of sodium chloride with a concentration of less than 0.9% are hypotonic and cause cells to swell.

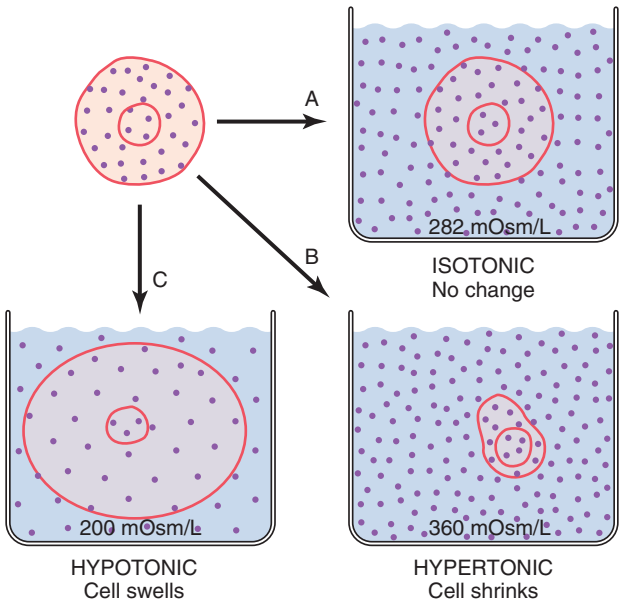

Figure 25.5 Effects of isotonic (A), hypertonic (B), and hypotonic (C) solutions on cell volume.

If a cell is placed in a *hypertonic* solution having a higher concentration of impermeant solutes, water will flow out of the cell into the extracellular fluid, concentrating the intracellular fluid and diluting the extracellular fluid. In this case, the cell will shrink until the two concentrations become equal. Solutions with sodium chloride greater than 0.9% are hypertonic.

Isosmotic, Hyperosmotic, and Hypo-Osmotic Fluids. The terms *isotonic, hypotonic*, and *hypertonic* refer to whether solutions will cause a change in cell volume. The tonicity of solutions depends on the concentration of impermeant solutes. Some solutes, however, can permeate the cell membrane. Solutions with an osmolarity the same as the cell are called *isosmotic*, regardless of whether the solute can penetrate the cell membrane. For example, a 5% glucose solution is nearly isosmotic and can be given intravenously without causing shrinkage or swelling of red blood cells although the glucose is ultimately transported into cells throughout the body and metabolized.

The terms *hyperosmotic* and *hypo-osmotic* refer to solutions that have a higher or lower osmolarity, respectively, compared with the normal extracellular fluid, without regard for whether the solute permeates the cell membrane. Highly permeating substances, such as urea, can cause transient shifts in fluid volume between the intracellular and extracellular fluids, but given enough time, the concentrations of these substances eventually become equal in the two compartments and have little effect on intracellular volume under steady-state conditions.

Osmotic Equilibrium Between Intracellular and Extracellular Fluids Is Rapidly Attained. Transfer of fluid across the cell membrane occurs so rapidly that any differences in osmolarities between these two compartments are usually corrected within seconds or, at the

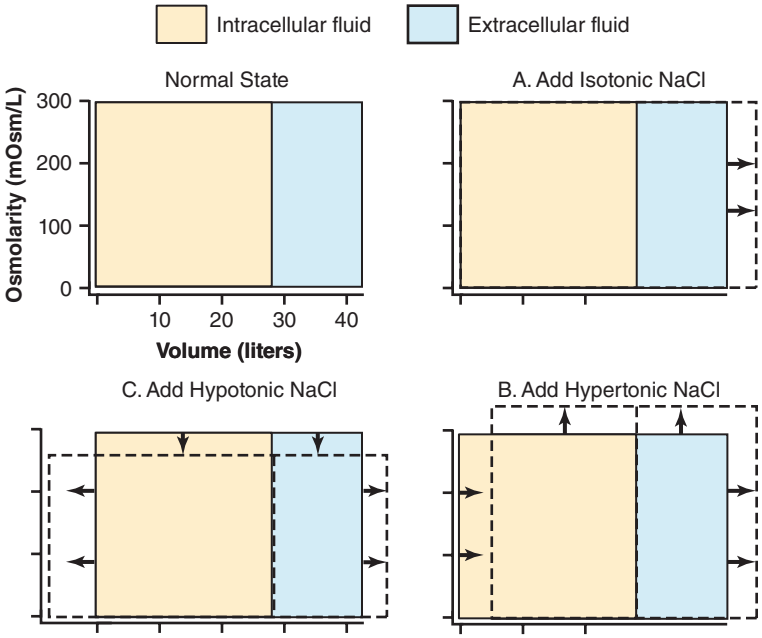

Figure 25.6 Effect of adding isotonic (A), hypertonic (B), and hypotonic solutions (C) to the extracellular fluid after osmotic equilibrium. The normal state is indicated by the *solid lines* and *shaded areas*, and the shifts from normal are shown by the *dashed lines*. The volumes of intracellular and extracellular fluid compartments are shown in the abscissa of each diagram, and the osmolarities of these compartments are shown on the ordinates.

most, minutes. This rapid movement of water across the cell membrane does not mean that complete equilibrium occurs between the intracellular and extracellular compartments throughout the whole body within the same short period. This is because fluid usually enters the body through the gut and must be transported by the blood to all tissues before complete osmotic equilibrium can occur. It usually takes about 30 minutes to achieve osmotic equilibrium everywhere in the body after drinking water.

VOLUME AND OSMOLALITY OF EXTRACELLULAR AND INTRACELLULAR FLUIDS IN ABNORMAL STATES

Some of the different factors that can cause extracellular and intracellular volumes to change markedly are excess ingestion or renal retention of water, dehydration, intravenous infusion of different types of solutions, loss of large amounts of fluid from the gastrointestinal tract, and loss of abnormal amounts of fluid by sweating or through the kidneys.

The changes in intracellular and extracellular fluid volumes and the types of therapy that should be instituted can be estimated if the following basic principles are kept in mind:

1. *Water moves rapidly across cell membranes;* therefore, the osmolarities of intracellular and extracellular fluids remain almost exactly equal to each other, except for a few minutes after a change in one of the compartments.
2. *Cell membranes are almost completely impermeable to many solutes*, such as sodium and chloride; therefore, the number of osmoles in the extracellular or intracellular fluid generally remains relatively constant unless solutes are added to or lost from the extracellular compartment.

With these basic principles in mind, we can analyze the effects of different abnormal fluid conditions on extracellular and intracellular fluid volumes and osmolarities.

Effect of Adding Saline Solution to the Extracellular Fluid

If *isotonic* saline is added to the extracellular fluid, the osmolarity of the extracellular fluid does not change. The main effect is an increase in extracellular fluid volume (**Fig. 25.6A**). The sodium and chloride largely remain in the extracellular fluid because the cell membrane behaves as though it were virtually impermeable to the sodium chloride.

If a *hypertonic* solution is added to the extracellular fluid, the extracellular osmolarity increases and causes osmosis of water out of the cells and into the extracellular compartment (see **Fig. 25.6B**). Again, almost all the added sodium chloride remains in the extracellular compartment, and fluid diffuses from the cells into the extracellular space to achieve osmotic equilibrium. The net effect is an increase in extracellular volume (greater than the volume of fluid added), a decrease in intracellular volume, and a rise in osmolarity in both compartments.

If a *hypotonic* solution is added to the extracellular fluid, the osmolarity of the extracellular fluid decreases, and some of the extracellular water diffuses into the cells until the intracellular and extracellular compartments have the same osmolarity (see **Fig. 25.6C**). Both the intracellular and extracellular volumes are increased by the addition of hypotonic fluid, although the intracellular volume increases to a greater extent.

Calculation of Fluid Shifts and Osmolarities After Infusion of Hypertonic Saline Solution. We can

calculate the sequential effects of infusing different solutions on extracellular and intracellular fluid volumes and osmolarities. For example, if 2 liters of a hypertonic 3.0% sodium chloride solution were infused into the extracellular fluid compartment of a 70-kg patient whose initial plasma osmolarity is 280 mOsm/L, what would be the approximate intracellular and extracellular fluid volumes and osmolarities after osmotic equilibrium?

The first step is to calculate the initial conditions, including the volume, concentration, and total milliosmoles in each compartment. Assuming that extracellular fluid volume is 20% of body weight, and intracellular fluid volume is 40% of body weight, the following volumes and concentrations can be calculated.

Step 1 Initial Conditions.

	Volume (liters)	Concentration (mOsm/L)	Total (mOsm)
Extracellular fluid	14	280	3920
Intracellular fluid	28	280	7840
Total body fluid	42	280	11,760

Next, we calculate the total milliosmoles added to the extracellular fluid in 2 liters of 3.0% sodium chloride. A 3.0% solution represents 3.0 g/100 mL, or 30 grams of sodium chloride per liter. Because the molecular weight of sodium chloride is about 58.5 g/mol, this means that there is about 0.5128 mole of sodium chloride per liter of solution. For 2 liters of solution, this would be 1.0256 mole of sodium chloride. Because 1 mole of sodium chloride is equal to approximately 2 osmoles (sodium chloride has two osmotically active particles per mole), the net effect of adding 2 liters of this solution is to add 2051 milliosmoles of sodium chloride to the extracellular fluid.

In step 2, we calculate the instantaneous effect of adding 2051 milliosmoles of sodium chloride to the extracellular fluid along with 2 liters of volume. There would be no change in the *intracellular fluid* concentration or volume, and there would be no osmotic equilibrium. In the *extracellular fluid*, however, there would be an additional 2051 milliosmoles of total solute, yielding a total of 5971 milliosmoles. Because the extracellular compartment now has 16 liters of volume, the concentration can be calculated by dividing 5971 milliosmoles by 16 liters to yield a concentration of about 373 mOsm/L. Thus, the following values would occur instantly after adding the solution.

Step 2. Instantaneous Effect of Adding 2 Liters of 3.0% Sodium Chloride.

	Volume (liters)	Concentration (mOsm/L)	Total (mOsm)
Extracellular fluid	16	373	5971
Intracellular fluid	28	280	7840
Total body fluid	44	No equilibrium	13,811

In the third step, we calculate the volumes and concentrations that would be found within a few minutes after osmotic equilibrium develops. In this case, the concentrations in the intracellular and extracellular fluid compartments would be equal and can be calculated by dividing the total milliosmoles in the body (13,811) by the total volume, which is now 44 liters. This calculation yields a concentration of 313.9 mOsm/L. Therefore, all the body fluid compartments will have this same concentration after osmotic equilibrium. Assuming that no solute or water has been lost from the body, and that there is no movement of sodium chloride into or out of the cells, we then calculate the volumes of the intracellular and extracellular compartments. The intracellular fluid volume is calculated by dividing the total milliosmoles in the intracellular fluid (7840) by the concentration (313.9 mOsm/L) to yield a volume of 24.98 liters. Extracellular fluid volume is calculated by dividing the total milliosmoles in extracellular fluid (5971) by the concentration (313.9 mOsm/L) to yield a volume of 19.02 liters. Again, these calculations are based on the assumption that the sodium chloride added to the extracellular fluid remains there and does not move into the cells.

Step 3. Effect of Adding 2 Liters of 3.0% Sodium Chloride After Osmotic Equilibrium.

	Volume (liters)	Concentration (mOsm/L)	Total (mOsm)
Extracellular fluid	19.02	313.9	5971
Intracellular fluid	24.98	313.9	7840
Total body fluid	44.0	313.9	13,811

Thus, one can see from this example that adding 2 liters of a hypertonic sodium chloride solution causes more than a 5-liter increase in extracellular fluid volume while *decreasing* intracellular fluid volume by almost 3 liters.

This method of calculating changes in intracellular and extracellular fluid volumes and osmolarities can be applied to virtually any clinical problem of fluid volume regulation. The reader should be familiar with such calculations because an understanding of the mathematical aspects of osmotic equilibrium between intracellular and extracellular fluid compartments is essential for understanding almost all fluid abnormalities of the body and their treatment.

GLUCOSE AND OTHER SOLUTIONS ADMINISTERED FOR NUTRITIVE PURPOSES

Several types of solutions are administered intravenously to provide nutrition to people who cannot otherwise ingest adequate amounts of nutrition. Glucose solutions are widely used; amino acid and homogenized fat solutions are used to a lesser extent. When these solutions are administered, their concentrations of osmotically active substances are usually adjusted to be nearly isosmotic, or they are given slowly enough that they do not upset the osmotic equilibrium of the red blood cells and body fluids.

After the glucose or other nutrients are metabolized, an excess of water often remains, especially if additional fluid is ingested. Ordinarily, the kidneys excrete this fluid in the form of dilute urine. The net result, therefore, is the addition of only nutrients to the body.

A 5% glucose solution, which is nearly isosmotic, is often used to treat dehydration. Because the solution is isosmotic, it can be infused intravenously without causing red blood cell swelling, as would occur with an infusion of pure water. Glucose in the solution is rapidly transported into the cells and metabolized. Therefore, infusion of a 5% glucose solution reduces extracellular fluid osmolarity and helps correct the increase in extracellular fluid osmolarity associated with dehydration.

CLINICAL ABNORMALITIES OF FLUID VOLUME REGULATION: HYPONATREMIA AND HYPERNATREMIA

A measurement that is readily available to the clinician for evaluating a patient's fluid status is the plasma sodium concentration. Plasma osmolarity is not routinely measured, but because sodium and its associated anions (mainly chloride) account for more than 90% of the solute in the extracellular fluid, plasma sodium concentration is a reasonable indicator of plasma osmolarity under many conditions. When plasma sodium concentration is reduced more than a few milliequivalents below normal (135 to 145 mmol/L), a person is said to have *hyponatremia*. When plasma sodium concentration is elevated above normal, a person is said to have *hypernatremia*.

Causes of Hyponatremia: Excess Water or Loss of Sodium

Decreased plasma sodium concentration can result from loss of sodium from the extracellular fluid or addition of excess water to the extracellular fluid (**Table 25.4**). A primary loss of sodium usually results in *hyponatremia and dehydration* and is associated with decreased extracellular fluid volume. Conditions that can cause hyponatremia as a result of the loss of sodium include *diarrhea* and *vomiting*. *Overuse of diuretics* that inhibit the ability of the kidneys to conserve sodium and certain types of sodium-wasting kidney diseases can also cause modest degrees of hyponatremia. *Addison disease*, which results from decreased secretion of the hormone *aldosterone*, impairs the ability of the kidneys to reabsorb sodium and can cause a modest degree of hyponatremia.

Hyponatremia can also be associated with excess water retention, which dilutes the sodium in the extracellular fluid, a condition referred to as *hyponatremia-overhydration*. For example, *excessive secretion of antidiuretic hormone* (ADH), also called *arginine vasopressin* (AVP), which increases water reabsorption by the kidney tubules, can lead to hyponatremia and overhydration.

Hyponatremia Causes Cell Edema. Rapid changes in cell volume as a result of hyponatremia can have profound effects on tissue and organ function, especially the brain. A rapid reduction in plasma sodium concentration, for example, can cause brain cell edema and neurological symptoms, including headache, nausea, lethargy, and disorientation. If plasma sodium concentration rapidly falls below 115 to 120 mmol/L, brain swelling may lead to seizures, coma, permanent brain damage, and death. Because the skull is rigid, the brain cannot increase its volume by more than about 10% without *herniation*, which means brain tissue being forced into a compartment that it normally does not occupy, such as through the *foramen magnum*, a hole at the base of the skull through which the spinal cord connects with the brain.

When hyponatremia evolves more slowly, over several days, the brain and other tissues respond by transporting sodium, chloride, potassium, and organic solutes, such as glutamate, from the cells into the extracellular compartment. This response attenuates osmotic flow of water into the cells and swelling of the tissues (**Fig. 25.7**).

Transport of solutes from the cells during slowly developing hyponatremia, however, can make the brain vulnerable to injury if the hyponatremia is corrected too rapidly. When hypertonic solutions are added too rapidly to correct chronic hyponatremia, this intervention can outpace the brain's ability to recapture the solutes lost from the cells and may lead to osmotic injury of the neurons that is associated with *demyelination*, a loss of the myelin sheath from nerves. This osmosis-mediated demyelination of

Table 25.4 Abnormalities of Body Fluid Volume Regulation: Hyponatremia and Hypernatremia

Abnormality	Cause	Plasma Na^+ Concentration	Extracellular Fluid Volume	Intracellular Fluid Volume
Hyponatremia—dehydration	Adrenal insufficiency; overuse of diuretics; diarrhea, vomiting; sodium-wasting kidney diseases	↓	↓	↑
Hyponatremia—overhydration	Excess ADH (SIADH); bronchogenic tumors; heart failure; cirrhosis; polydipsia	↓	↑	↑
Hypernatremia—dehydration	Central or nephrogenic diabetes insipidus; excessive sweating	↑	↓	↓
Hypernatremia—overhydration	Cushing disease; primary aldosteronism	↑	↑	↓

ADH, Antidiuretic hormone; *SIADH*, syndrome of inappropriate ADH.

neurons can be avoided by limiting the correction of chronic hyponatremia to less than 10 to 12 mmol/L in 24 hours and to less than 18 mmol/L in 48 hours. This slow rate of correction permits the brain to recover the osmoles that were lost from the cells as a result of adaptation to chronic hyponatremia.

Hyponatremia is the most common electrolyte disorder encountered in clinical practice and may occur in up to 15% to 25% of hospitalized patients.

Causes of Hypernatremia: Water Loss or Excess Sodium

An increased plasma sodium concentration, which also causes increased osmolarity, can be due to loss of water from the extracellular fluid, which concentrates the sodium ions, or excess sodium in the extracellular fluid. Primary loss of water from the extracellular fluid results in *hypernatremia and dehydration*. This condition can occur, for example, from an inability to secrete ADH, which is needed for the kidneys to conserve water. As a result of lack of ADH, the kidneys excrete large amounts of dilute urine (a disorder referred to as *central diabetes insipidus* or *AVP-deficiency*), causing dehydration and increased concentration of sodium chloride in the extracellular fluid. In certain types of renal diseases, the kidneys cannot respond to ADH, causing a type of *nephrogenic diabetes insipidus* (also called *AVP-resistance*). A more common cause of hypernatremia associated with decreased extracellular fluid volume is simple *dehydration* caused by water intake that is less than water loss, as can occur with sweating during prolonged heavy exercise.

Hypernatremia can also occur when excessive sodium chloride is added to the extracellular fluid. This often results in *hypernatremia-overhydration* because excess extracellular sodium chloride retention is also usually associated with at least some degree of water retention by the kidneys. For example, excessive secretion of the sodium-retaining hormone *aldosterone* can cause a mild degree of hypernatremia and overhydration. The reason that the hypernatremia is not more severe is that the sodium retention also stimulates secretion of ADH and causes the kidneys to reabsorb greater amounts of water. Also, the renal sodium-retaining effects of excess aldosterone are often counteracted by compensatory decreases in other antinatriuretic hormones, such as angiotensin II, and by increases in blood pressure, which cause pressure natriuresis, as explained in Chapters 30 and 78.

In analyzing abnormalities of plasma sodium concentration and deciding on proper therapy, one should first determine whether the abnormality is caused by a primary loss or gain of sodium or a primary loss or gain of water.

Hypernatremia Causes Cell Shrinkage

Hypernatremia is much less common than hyponatremia, and severe symptoms usually occur only with rapid and large increases in the plasma sodium concentration above 158 to 160 mmol/L. Hypernatremia usually promotes intense thirst and stimulates secretion of ADH, which both protect against large increases in plasma and extracellular fluid sodium, as discussed in Chapter 29. However, severe hypernatremia can occur in patients with hypothalamic lesions that impair their sense of thirst, in infants who may not have ready access to water, in older patients with altered mental status, or in persons with diabetes insipidus.

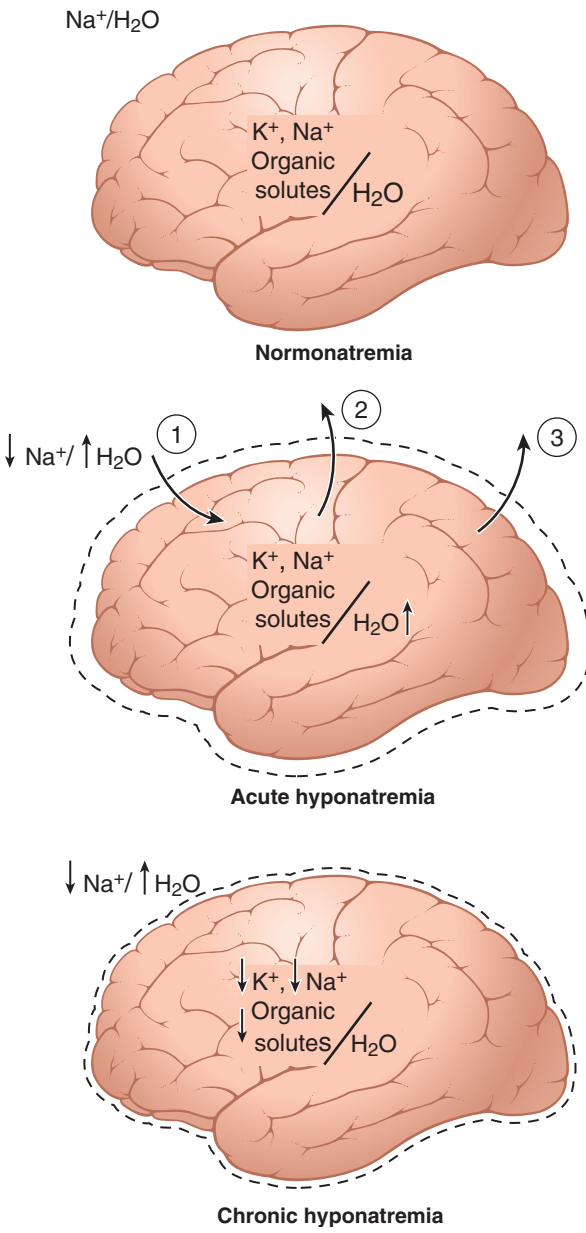

Figure 25.7 Brain cell volume regulation during hyponatremia. During acute hyponatremia, caused by loss of Na^+ or excess H_2O, there is diffusion of H_2O into the cells (1) and swelling of the brain tissue (indicated by the *dashed lines*). This process stimulates transport of Na^+, K^+, and organic solutes out of the cells (2), which then causes water diffusion out of the cells (3). With chronic hyponatremia, the brain swelling is attenuated by transport of solutes from the cells.

Correction of hypernatremia can be achieved by administering a hypo-osmotic sodium chloride or dextrose solution. However, it is prudent to correct the hypernatremia slowly in patients who have had chronic increases in their plasma sodium concentration because hypernatremia also activates defense mechanisms that protect the cell from changes in volume. These defenses are the opposite of those that occur for hyponatremia and consist of mechanisms that increase the intracellular concentration of sodium and other solutes.

EDEMA: EXCESS FLUID IN THE TISSUES

Edema refers to the presence of excess fluid in the body tissues. In many cases, edema occurs mainly in the extracellular fluid compartment, but it can also involve intracellular fluid accumulation.

INTRACELLULAR EDEMA

Three conditions are especially prone to cause intracellular swelling: (1) hyponatremia, as discussed earlier; (2) depression of the metabolic systems of the tissues; and (3) lack of adequate nutrition to the cells. For example, when blood flow to a tissue is decreased, the delivery of oxygen and nutrients is reduced. If blood flow becomes too low to maintain normal tissue metabolism, the cell membrane ionic pumps become depressed, and sodium ions that normally leak into the interior of the cell can no longer be pumped out of the cells. The excess intracellular sodium ions then cause osmosis of water into the cells. Sometimes this process can increase intracellular volume of a tissue area—even of an entire ischemic leg, for example—to two to three times normal. When such an increase in intracellular volume occurs, it is usually a prelude to death of the tissue.

Intracellular edema can also occur in inflamed tissues. Inflammation usually increases cell membrane permeability, allowing sodium and other ions to diffuse into the cell, with subsequent osmosis of water into the cells.

EXTRACELLULAR EDEMA

Extracellular edema occurs when excess fluid accumulates in the extracellular spaces. There are two general causes of extracellular edema: (1) abnormal leakage of fluid from the plasma to the interstitial spaces across the capillaries; and (2) failure of the lymphatics to return fluid from the interstitium back into the blood, often called *lymphedema*. The most common clinical cause of interstitial fluid accumulation is excessive capillary fluid filtration.

Factors That Can Increase Capillary Filtration

To understand the causes of excessive capillary filtration, it is useful to review the determinants of capillary filtration discussed in Chapter 16. Mathematically, capillary filtration rate can be expressed as follows:

$$\text{Filtration} = K_f \times (P_c - P_{if} - \pi_c + \pi_{if})$$

where K_f is the capillary filtration coefficient (the product of the permeability and surface area of the capillaries), P_c is the capillary hydrostatic pressure, P_{if} is the interstitial fluid hydrostatic pressure, π_c is the capillary plasma colloid osmotic pressure, and π_{if} is the interstitial fluid colloid osmotic pressure. From this equation, one can see that *any one of the following changes can increase the capillary filtration rate:*

- Increased capillary filtration coefficient
- Increased capillary hydrostatic pressure
- Decreased plasma colloid osmotic pressure

Lymphedema—Failure of Lymph Vessels to Return Fluid and Protein to the Blood

When lymphatic function is greatly impaired as a result of blockage or loss of the lymph vessels, edema can become especially severe because plasma proteins that leak into the interstitium cannot be removed. The rise in protein concentration raises the colloid osmotic pressure of interstitial fluid, which draws even more fluid out of the capillaries.

Blockage of lymph flow can be especially severe with infections of the lymph nodes, such as occurs with infection by *filarial nematodes (Wuchereria bancrofti)*, which are microscopic threadlike worms. The adult worms live in the human lymph system and are spread from person to person by mosquitoes. People with filarial infections can have severe lymphedema and *elephantiasis*, and men can have swelling of the scrotum, called *hydrocele*. Lymphatic filariasis currently affects more than 51 million people in at least 44 countries throughout the tropics and subtropics of Asia, Africa, the Western Pacific, and parts of the Caribbean and South America. In the past 20 years, there has been a major decline in lymphatic filariasis due to successful implementation of preventive chemotherapy.

Lymphedema can also occur in persons who have certain types of cancer or after surgery in which lymph vessels are removed or obstructed. For example, large numbers of lymph vessels are removed during a radical mastectomy, impairing the removal of protein and fluid from the breast and arm areas and causing edema and swelling of the tissue spaces. A few lymph vessels eventually regrow after this type of surgery; thus, the interstitial edema is usually temporary.

Summary of Causes of Extracellular Edema

A large number of conditions can cause edema in the interstitial spaces by abnormal leaking of fluid from the capillaries or by preventing the lymphatics from returning fluid from the interstitium back to the circulation. The following is a partial list of conditions that can cause extracellular edema by these two types of abnormalities:

I. Increased capillary hydrostatic pressure
  A. Excessive kidney retention of salt and water
    1. Acute or chronic kidney failure
    2. Mineralocorticoid excess
  B. High venous pressure and venous constriction
    1. Heart failure
    2. Venous obstruction
    3. Failure of venous pumps
      a) Paralysis of muscles
      b) Immobilization of parts of the body
      c) Failure of venous valves
  C. Decreased arteriolar resistance
    1. Excessive body heat
    2. Insufficiency of sympathetic nervous system
    3. Vasodilator drugs
II. Decreased plasma proteins
  A. Loss of proteins in urine (nephrotic syndrome)
  B. Loss of plasma proteins from denuded skin areas
    1. Burns
    2. Wounds
  C. Failure to produce plasma proteins
    1. Liver disease (e.g., cirrhosis)
    2. Serious protein or caloric malnutrition
III. Increased capillary permeability
  A. Immune reactions that cause release of histamine and other immune products
  B. Toxins
  C. Bacterial infections
  D. Vitamin deficiency, especially vitamin C
  E. Prolonged ischemia
  F. Burns
IV. Blockage of lymph return
  A. Cancer
  B. Infections (e.g., filarial nematodes)
  C. Surgery
  D. Congenital absence or abnormality of lymphatic vessels

Edema Caused By Heart Failure. One of the most serious and common causes of edema is heart failure, which was discussed in Chapter 22. In heart failure, the heart fails to pump blood normally from the veins into the arteries, which raises venous and capillary pressures, causing increased capillary filtration. In addition, the arterial pressure tends to fall, causing decreased excretion of salt and water by the kidneys, which causes still more edema. Also, blood flow to the kidneys is reduced in persons with heart failure, and this reduced blood flow stimulates secretion of renin, causing increased formation of angiotensin II and aldosterone, which both cause additional salt and water retention by the kidneys. In advanced heart failure, increased secretion of ADH stimulates water reabsorption by the renal tubules, leading to hyponatremia, as well as intracellular and extracellular edema. Thus, in persons with untreated heart failure, all these factors acting together can cause serious generalized edema.

In patients with left-sided heart failure but without significant failure of the right side of the heart, blood is pumped into the lungs normally by the right ventricle but cannot escape easily from the pulmonary veins to the left side of the heart because this part of the heart has been greatly weakened. Consequently, all the pulmonary vascular pressures, including pulmonary capillary pressure, rise far above normal, causing serious and life-threatening pulmonary edema. When untreated, fluid accumulation in the lungs can rapidly progress, causing death within a few hours.

Edema Caused By Decreased Kidney Excretion of Salt and Water. Most sodium chloride added to the blood remains in the extracellular compartment, and only a small amount enters the cells. Therefore, in kidney diseases that impair urinary excretion of salt and water, excessive sodium chloride and water are added to the extracellular fluid. Most of this salt and water leaks from the blood into the interstitial spaces, but some remains in the blood. The main effects of this are as follows: (1) widespread increases in interstitial fluid volume (extracellular edema); and (2) hypertension because of the increase in blood volume, as explained in Chapter 19. For example, in children who have acute glomerulonephritis, in which the renal glomeruli are injured by inflammation and therefore fail to filter adequate amounts of fluid, serious extracellular fluid edema and hypertension usually develop.

Edema Caused By Decreased Plasma Proteins. Failure to produce normal amounts of proteins or leakage of proteins from the plasma causes the plasma colloid osmotic pressure to fall. This leads to increased capillary filtration throughout the body and extracellular edema.

Loss of large amounts of protein in the urine occurs in certain kidney diseases, a condition referred to as *nephrotic syndrome*. Multiple types of renal diseases can damage the membranes of the renal glomeruli, causing the membranes to become leaky to the plasma proteins and often allowing large quantities of these proteins to pass into the urine, as discussed in Chapter 32. When this loss exceeds the ability of the body to synthesize proteins, a reduction in plasma protein concentration occurs. Serious generalized edema occurs when the plasma protein concentration falls below 2.5 g/100 mL.

Cirrhosis of the liver, also called *hepatic cirrhosis*, is associated with damage to large numbers of liver parenchymal cells, replacement of these cells with scar tissue (fibrosis), and reduced ability of the liver to produce sufficient plasma proteins. Decreased production of plasma proteins, especially albumin, reduces plasma colloid osmotic pressure and causes the generalized edema that accompanies cirrhosis.

Another way that cirrhosis causes edema is that the liver fibrosis sometimes compresses the abdominal portal venous drainage vessels as they pass through the liver before emptying back into the general circulation. Blockage of this portal venous outflow greatly increases portal

venous pressure (*portal hypertension*), which, in turn, raises capillary hydrostatic pressure throughout the gastrointestinal area and further increases fluid filtration out of the plasma into the intraabdominal areas. When this occurs, the combined effects of decreased plasma protein concentration and high portal capillary pressures cause transudation of large amounts of fluid and protein into the abdominal cavity, a condition referred to as *ascites*.

SAFETY FACTORS THAT NORMALLY PREVENT EDEMA

Even though many disturbances can cause edema, the abnormality must usually be severe before serious edema develops. Three major safety factors help to prevent excessive fluid accumulation in the interstitial spaces: (1) low compliance of the interstitium when interstitial fluid pressure is in the negative pressure range; (2) the ability of lymph flow to increase 10- to 50-fold; and (3) washdown of the interstitial fluid protein concentration, which reduces interstitial fluid colloid osmotic pressure as capillary filtration increases.

Safety Factor Caused By Low Compliance of the Interstitium in the Negative Pressure Range

In Chapter 16, we noted that interstitial fluid hydrostatic pressure in loose subcutaneous tissues of the body is slightly less than atmospheric pressure, averaging about −3 mm Hg. This slight suction in the tissues helps hold the tissues together. **Fig. 25.8** shows the approximate relationships between different levels of interstitial fluid pressure and interstitial fluid volume, as extrapolated to people from animal studies. Note in **Fig. 25.8** that as long as the interstitial fluid pressure is in the negative range, small changes in interstitial fluid volume are associated with relatively large changes in interstitial fluid hydrostatic pressure. Therefore, in the negative pressure range, the *compliance* of the tissues, defined as the change in volume per mm Hg pressure change, is low.

How does the low compliance of the tissues in the negative pressure range act as a safety factor against edema? When interstitial fluid hydrostatic pressure increases, this increased pressure tends to oppose further capillary filtration. Therefore, as long as the interstitial fluid hydrostatic pressure is in the negative pressure range, small increases in interstitial fluid volume cause relatively large increases in interstitial fluid hydrostatic pressure, opposing further filtration of fluid into the tissues.

Because the normal interstitial fluid hydrostatic pressure is −3 mm Hg, the interstitial fluid hydrostatic pressure must increase by about 3 mm Hg before large amounts of fluid will begin to accumulate in the tissues. Therefore, the safety factor against edema is a change of interstitial fluid pressure of about 3 mm Hg. In the positive tissue pressure range, this safety factor against edema is lost because of the large increase in compliance of the tissues.

Importance of Interstitial Gel in Preventing Fluid Accumulation in the Interstitium. Note in **Fig. 25.8** that in normal tissues with negative interstitial fluid pressure, virtually all the fluid in the interstitium is in gel form. That is, the fluid is bound in a proteoglycan meshwork (see Fig. 16.4) so that there are virtually no free fluid spaces larger than a few hundredths of a micrometer in diameter. The importance of the gel is that it prevents fluid from *flowing easily* through the tissues because of impediment from the brush pile of trillions of proteoglycan filaments. Also, when the interstitial fluid pressure falls to very negative values, the gel does not contract very much because the meshwork of proteoglycan filaments offers an elastic resistance to compression. In the negative fluid pressure range, the interstitial fluid volume does not change much, regardless of whether the degree of suction is only a few mm Hg negative pressure or 10 to 20 mm Hg negative pressure. In other words, the compliance of the tissues is very low in the negative pressure range.

By contrast, when interstitial fluid pressure rises to the positive pressure range, *free fluid* accumulates in the tissues. In this pressure range, the tissues are compliant, allowing large amounts of fluid to accumulate, with relatively small additional increases in interstitial fluid hydrostatic pressure. Most of the extra fluid that accumulates is free fluid because it pushes the brush pile of proteoglycan filaments apart. Therefore, the fluid can flow freely

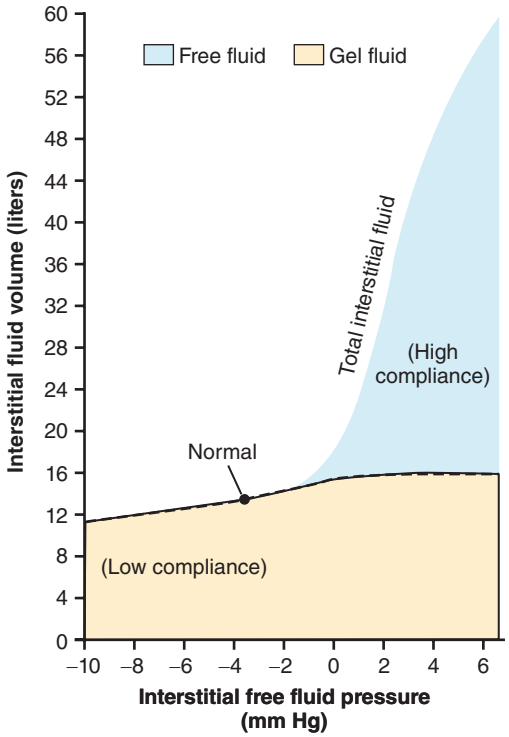

Figure 25.8 Relationship between interstitial fluid hydrostatic pressure and interstitial fluid volumes, including total volume, free fluid volume, and gel fluid volume, for loose tissues such as skin. Note that significant amounts of free fluid occur only when the interstitial fluid pressure becomes positive. *(Modified from Guyton AC, Granger HJ, Taylor AE. Interstitial fluid pressure.* Physiol Rev. *1971;51:527.)*

through the tissue spaces because it is not in gel form. When this free flow of fluid occurs, the edema is said to be *pitting edema* because one can press the thumb against the tissue area and push the fluid out of the area. When the thumb is removed, a pit is left in the skin for a few seconds until the fluid flows back from the surrounding tissues. This type of edema is distinguished from *nonpitting edema*, which occurs when the tissue cells swell instead of the interstitium or when the fluid in the interstitium becomes clotted with fibrinogen so that it cannot move freely within the tissue spaces.

Importance of Proteoglycan Filaments as a Spacer for Cells and in Preventing Rapid Flow of Fluid in Tissues. The proteoglycan filaments, along with much larger collagen fibrils in the interstitial spaces, act as a spacer between the cells. Nutrients and ions do not diffuse readily through cell membranes; therefore, without adequate spacing between the cells, these nutrients, electrolytes, and cell waste products cannot be rapidly exchanged between the blood capillaries and cells located at a distance from one another.

The proteoglycan filaments also prevent fluid from flowing too easily through the tissue spaces. If it were not for the proteoglycan filaments, the simple act of a person standing up would cause large amounts of interstitial fluid to flow from the upper body to the lower body. When too much fluid accumulates in the interstitium, as occurs in edema, this extra fluid creates large channels that allow the fluid to flow readily through the interstitium. Therefore, when severe edema occurs in the legs, the edema fluid often can be decreased by simply elevating the legs.

Even though fluid does not *flow* easily through the tissues in the presence of the compacted proteoglycan filaments, different substances within the fluid can *diffuse* through the tissues at least 95% as easily as they normally diffuse. Therefore, the usual diffusion of nutrients to the cells and the removal of waste products from the cells are not compromised by the proteoglycan filaments of the interstitium.

Increased Lymph Flow as a Safety Factor Against Edema

A major function of the lymphatic system is to return the fluid and proteins filtered from the capillaries into the interstitium to the circulation. Without this continuous return of the filtered proteins and fluid to the blood, the plasma volume would be rapidly depleted, and interstitial edema would occur.

The lymphatics act as a major safety factor against edema because lymph flow can increase 10- to 50-fold when fluid begins to accumulate in the tissues. This increased lymph flow allows the lymphatics to carry away large amounts of fluid and proteins in response to increased capillary filtration, preventing interstitial pressure from rising into the positive pressure range. The safety factor caused by increased lymph flow has been calculated to be about 7 mm Hg.

Washdown of Interstitial Fluid Protein as a Safety Factor Against Edema

As increased amounts of fluid are filtered into the interstitium, interstitial fluid pressure increases, causing increased lymph flow. In most tissues, the protein concentration of the interstitium decreases as lymph flow is increased because larger amounts of protein are carried away than are filtered out of the capillaries. Since the capillaries are relatively impermeable to proteins compared with the lymph vessels, the proteins are washed out of the interstitial fluid as lymph flow increases.

Because the interstitial fluid colloid osmotic pressure caused by the proteins tends to draw fluid out of the capillaries, decreasing the interstitial fluid proteins lowers the net filtration force across the capillaries and tends to prevent further accumulation of fluid. The safety factor from this effect has been calculated to be about 7 mm Hg.

SUMMARY OF SAFETY FACTORS THAT PREVENT EDEMA

Putting together all the safety factors against edema when capillary filtration tends to increase (**Fig. 25.9**), we find the following:

1. The safety factor caused by low tissue compliance and increased interstitial fluid hydrostatic pressure in the negative pressure range is about 3 mm Hg.
2. The safety factor caused by increased lymph flow is about 7 mm Hg.
3. The safety factor caused by washdown of proteins from the interstitial spaces and decreased interstitial fluid colloid osmotic pressure is about 7 mm Hg.

Therefore, the total safety factor against edema is about 17 mm Hg. This means that the capillary pressure in peripheral tissues could theoretically rise by 17 mm Hg, or approximately double the normal value, before marked edema would occur.

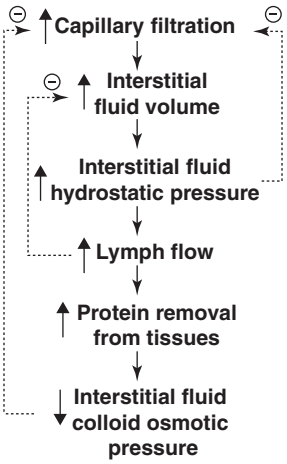

Figure 25.9 Summary of safety factors that tend to prevent edema when capillary filtration is increased.

FLUIDS IN POTENTIAL SPACES OF THE BODY

Some examples of potential spaces are the pleural, pericardial, peritoneal, and synovial cavities, including both the joint cavities and the bursae. Virtually all these potential spaces have surfaces that almost touch each other, with only a thin layer of fluid in between, and the surfaces slide over each other. To facilitate the sliding, a viscous proteinaceous fluid lubricates the surfaces.

Fluid Is Exchanged Between Capillaries and Potential Spaces. The surface membrane of a potential space usually does not offer significant resistance to the passage of fluids, electrolytes, or even proteins, which all move back and forth with relative ease between the space and interstitial fluid in the surrounding tissue. Consequently, fluid in the capillaries adjacent to the potential space diffuses not only into the interstitial fluid but also into the potential space.

Lymphatic Vessels Drain Protein From the Potential Spaces. Proteins collect in the potential spaces because of leakage out of the capillaries, similar to the collection of protein in the interstitial spaces throughout the body. The protein must be removed through lymphatics or other channels and returned to the circulation. Each potential space is directly or indirectly connected with lymph vessels. In some cases, such as the pleural cavity and peritoneal cavity, large lymph vessels arise directly from the cavity itself.

Edema Fluid in the Potential Spaces Is Called Effusion. When edema occurs in the subcutaneous tissues adjacent to the potential space, edema fluid usually collects in the potential space as well; this fluid is called *effusion*. Thus, lymph blockage or any of the multiple abnormalities that can cause excessive capillary filtration can cause effusion in the same way that interstitial edema is caused. The abdominal cavity is especially prone to collect effusion fluid and, in this case, the effusion is called *ascites*. In severe cases of cirrhosis, for example, 20 liters or more of ascitic fluid can accumulate.

The other potential spaces, such as the pleural cavity, pericardial cavity, and joint spaces, can become seriously swollen when generalized edema is present. Also, injury or local infection in any one of the cavities may block the lymph drainage, causing isolated swelling in the cavity.

The dynamics of fluid exchange in the pleural cavity are discussed in detail in Chapter 39. These dynamics are mainly representative of all the other potential spaces as well. The normal fluid pressure in most or all of the potential spaces in the nonedematous state is *negative* in the same way that this pressure is negative (subatmospheric) in loose subcutaneous tissue. For example, the interstitial fluid hydrostatic pressure is normally about −7 to −8 mm Hg in the pleural cavity, −3 to −5 mm Hg in the joint spaces, and −5 to −6 mm Hg in the pericardial cavity.

The Urinary System: Functional Anatomy and Urine Formation By the Kidneys

MULTIPLE FUNCTIONS OF THE KIDNEYS

Most people are familiar with one important function of the kidneys—to rid the body of waste materials that are ingested or produced by metabolism. A second function that is especially critical is to control the volume and electrolyte composition of the body fluids. For water and virtually all electrolytes in the body, the balance between intake (due to ingestion or metabolic production) and output (due to excretion or metabolic consumption) is maintained largely by the kidneys. This regulatory function of the kidneys is essential for maintaining the stable internal environment necessary for the cells to perform their various activities.

The kidneys perform many of their most critical functions by filtering the plasma and removing substances from the filtrate at variable rates, depending on the needs of the body. Ultimately, the kidneys clear unwanted substances from the filtrate (and therefore from the blood plasma) by excreting them in the urine while returning substances that are needed back to the blood.

Although this chapter and the next few chapters focus mainly on the control of renal excretion of water, electrolytes, and metabolic waste products, the kidneys serve many important homeostatic functions, including the following:

- Excretion of metabolic waste products and foreign chemicals
- Regulation of water and electrolyte balances
- Regulation of body fluid osmolality and electrolyte concentrations
- Regulation of arterial pressure
- Regulation of acid–base balance
- Regulation of erythrocyte production
- Secretion, metabolism, and excretion of hormones
- Gluconeogenesis

Excretion of Metabolic Waste Products, Foreign Chemicals, Drugs, and Hormone Metabolites. The kidneys are the primary means for eliminating most of the waste products of metabolism that are no longer needed by the body. These products include *urea* (from the metabolism of amino acids), *creatinine* (from muscle creatine), *uric acid* (from nucleic acids), *end products of hemoglobin breakdown* (e.g., bilirubin), and *metabolites of various hormones*. These waste products are usually eliminated from the body as rapidly as they are produced. The kidneys also eliminate most toxins and other foreign substances that are produced by the body or ingested, such as pesticides, drugs, and food additives.

Regulation of Water and Electrolyte Balances. For maintenance of homeostasis, excretion of water and electrolytes must, in the long term, match intake precisely. If intake exceeds excretion, the amount of that substance in the body will increase. If intake is less than excretion, the amount of that substance in the body will decrease. Although temporary (or cyclic) imbalances of water and electrolytes may occur in various physiological and pathophysiological conditions associated with altered intake or renal excretion, the maintenance of life depends on restoration of water and electrolyte balance.

Intake of water and many electrolytes is usually governed by a person's eating and drinking habits, requiring the kidneys to adjust their excretion rates to match the intakes of various substances. **Fig. 26.1** shows the response of the kidneys to a sudden 10-fold increase in sodium intake from a low level of 30 mEq/day to a high level of 300 mEq/day. Within 2 to 3 days after raising the sodium intake, renal excretion also increases to about 300 mEq/day so that the balance between intake and output is rapidly reestablished. However, during the 2 to 3 days of renal adaptation to the high sodium intake, there is usually a modest accumulation of sodium that raises extracellular fluid volume slightly and triggers hormonal changes and other compensatory responses that signal the kidneys to increase their sodium excretion.

The capability of the kidneys to alter sodium excretion in response to changes in sodium intake is tremendous. Experimental studies have shown that in many people, sodium intake can be increased to 1500 mEq/day (more than 10 times normal) or decreased to 10 mEq/day (<0.1 of normal), with relatively small changes in extracellular fluid volume or plasma sodium concentration. This phenomenon is also true for water and for most other electrolytes, such as chloride, potassium, calcium, hydrogen, magnesium, and phosphate ions. In the next few chapters, we discuss the specific mechanisms that permit the kidneys to perform these amazing feats of homeostasis.

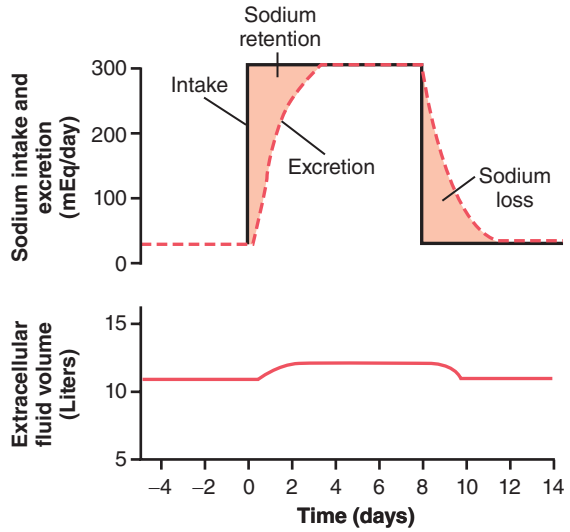

Figure 26.1 Effect of increasing sodium intake 10-fold (from 30 to 300 mEq/day) on urinary sodium excretion and extracellular fluid volume. The *shaded areas* represent the net sodium retention or net sodium loss, determined by the difference between sodium intake and sodium excretion.

Regulation of Arterial Pressure. As discussed in Chapters 19 and 30, the kidneys play a dominant role in long-term regulation of arterial pressure by excreting variable amounts of sodium and water. The kidneys also contribute to short-term arterial pressure regulation by secreting hormones and vasoactive factors or substances (e.g., *renin*) that lead to the formation of vasoactive products (e.g., angiotensin II).

Regulation of Acid–Base Balance. The kidneys contribute to acid–base regulation, along with the lungs and body fluid buffers, by excreting acids and by regulating the body fluid buffer stores, as discussed in Chapter 31. The kidneys are the only means of eliminating certain types of acids from the body, such as sulfuric acid and phosphoric acid, which are generated by the metabolism of proteins.

Regulation of Erythrocyte Production. The kidneys secrete *erythropoietin*, which stimulates production of red blood cells by *hematopoietic stem cells* in the bone marrow, as discussed in Chapter 33. One important stimulus for erythropoietin secretion by the kidneys is *hypoxia*. The kidneys normally account for almost all the erythropoietin secreted into the circulation. In people with severe kidney disease or who have had their kidneys removed and have been placed on hemodialysis, severe anemia develops as a result of decreased erythropoietin production.

Regulation of 1,25-Dihydroxyvitamin D_3 Production. The kidneys produce 1,25-dihydroxyvitamin D_3 (*calcitriol*), the active form of vitamin D, by hydroxylating this vitamin at the "number 1" position. Calcitriol is essential for normal calcium deposition in bone and calcium reabsorption by the gastrointestinal tract. As discussed in Chapter 80, calcitriol plays an important role in calcium and phosphate regulation.

Glucose Synthesis. The kidneys synthesize glucose from amino acids and other precursors during prolonged fasting, a process referred to as *gluconeogenesis*. The kidneys' capacity to add glucose to the blood during prolonged periods of fasting rivals that of the liver.

With chronic kidney disease or acute failure of the kidneys, these homeostatic functions are disrupted, and severe abnormalities of body fluid volumes and composition rapidly occur. With complete renal failure, enough potassium, acids, fluid, and other substances accumulate in the body to cause death within a few days unless clinical interventions such as hemodialysis are initiated to restore, at least partially, the body fluid and electrolyte balances.

PHYSIOLOGICAL ANATOMY OF THE KIDNEYS

GENERAL ORGANIZATION OF THE KIDNEYS AND URINARY TRACT

The two kidneys lie on the posterior wall of the abdomen, outside the peritoneal cavity (**Fig. 26.2**). Each kidney of the adult human weighs approximately 150 grams and is about the size of a clenched fist. Although kidney weight is generally greater in men than in women, this difference is partly related to greater body size in men. The medial side of each kidney contains an indented region called the *hilum*, through which pass the renal artery and vein, lymphatics, nerve supply, and ureter. The ureter carries the final urine from the kidney to the bladder, where it is stored until the bladder is emptied. The kidney is surrounded by a tough fibrous *capsule* that protects its delicate inner structures.

If the kidney is bisected from top to bottom, the two major regions that can be visualized are the outer *cortex* and the inner *medulla* regions. The medulla is divided into 8 to 10 cone-shaped masses of tissue called *renal pyramids*. The base of each pyramid originates at the border between the cortex and medulla and terminates in the *papilla*, which projects into the space of the *renal pelvis*, a funnel-shaped continuation of the upper end of the ureter. The outer border of the pelvis is divided into open-ended pouches called *major calyces* that extend downward and divide into *minor calyces*, which collect urine from the tubules of each papilla. The walls of the calyces, pelvis, and ureter contain contractile elements, including smooth muscle, that propel the urine toward the *bladder*, where urine is stored until it is emptied by *micturition*, discussed later in this chapter.

RENAL BLOOD SUPPLY

Blood flow to the two kidneys is normally about 22% of the cardiac output, or 1100 mL/min in the average adult, although considerable variation occurs, depending on various factors such as body size, age, and sex of the individual. The renal artery enters the kidney through

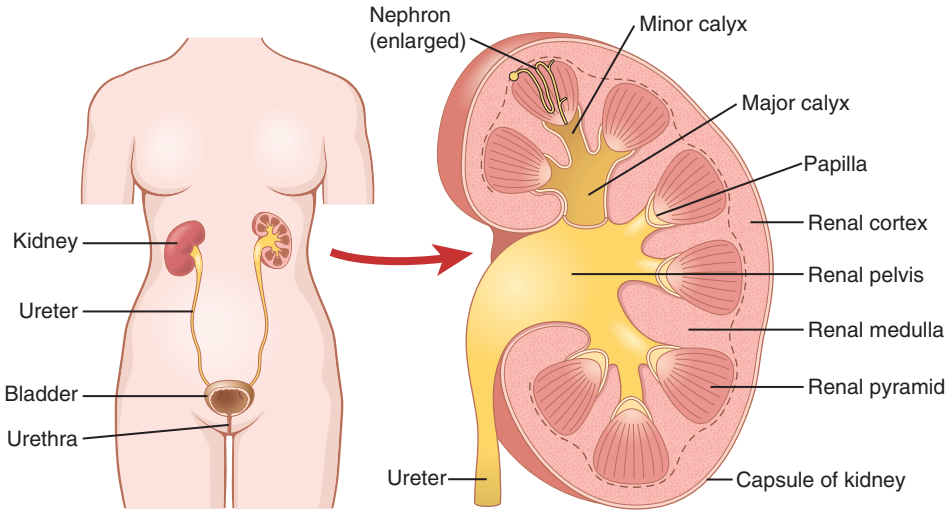

Figure 26.2 General organization of the kidneys and the urinary system.

the hilum and then branches progressively to form the *interlobar arteries, arcuate arteries, interlobular arteries* (also called *radial arteries*), and *afferent arterioles*, which lead to the *glomerular capillaries*, where large amounts of fluid and solutes (except the plasma proteins) are filtered to begin urine formation (**Fig. 26.3**). The distal ends of the capillaries of each glomerulus coalesce to form the *efferent arteriole*, which leads to a second capillary network, the *peritubular capillaries*, that surrounds the renal tubules.

The renal circulation is unique in having two capillary beds, the glomerular and peritubular capillaries, which are arranged in series and are separated by the efferent arterioles. These arterioles help regulate the hydrostatic pressure in both sets of capillaries. High hydrostatic pressure in the glomerular capillaries (~60 mm Hg) causes rapid fluid filtration, whereas a much lower hydrostatic pressure in the peritubular capillaries (~13 mm Hg) permits rapid fluid reabsorption. By adjusting the resistance of the afferent and efferent arterioles, the kidneys can regulate the hydrostatic pressure in the glomerular and the peritubular capillaries, thereby changing the rate of glomerular filtration, tubular reabsorption, or both in response to the body's homeostatic demands.

The peritubular capillaries empty into the vessels of the venous system, which run parallel to the arteriolar vessels. The blood vessels of the venous system progressively form the *interlobular vein, arcuate vein, interlobar vein*, and *renal vein*, which leaves the kidney beside the renal artery and ureter.

THE NEPHRON IS THE FUNCTIONAL UNIT OF THE KIDNEY

Each human kidney contains about 800,000 to 1,000,000 *nephrons*, each of which is capable of forming urine. The kidney cannot regenerate new nephrons. Therefore, with renal injury, disease, or normal aging, the number of nephrons gradually decreases. After age 40 years, the number of functioning nephrons usually decreases about 10% every 10 years; thus, at age 80 years, many people have 40% fewer functioning nephrons than they did at age 40 years. This loss is not life-threatening because adaptive changes in the remaining nephrons allow them to excrete the proper amounts of water, electrolytes, and waste products, as discussed in Chapter 32. However, common disorders such as obesity, hypertension, and diabetes mellitus may cause more rapid loss of nephrons with aging.

Each nephron contains (1) a tuft of glomerular capillaries called the *glomerulus*, through which large amounts of fluid are filtered from the blood, and (2) a long *tubule* in which the filtered fluid is converted into urine on its way to the pelvis of the kidney (see **Fig. 26.3**).

The glomerulus contains a network of branching and anastomosing glomerular capillaries that, compared with other capillaries, have high hydrostatic pressure (~60 mm Hg). The glomerular capillaries are covered by epithelial cells, and the total glomerulus is encased in *Bowman's capsule*.

Fluid filtered from the glomerular capillaries flows into Bowman's capsule and then into the *proximal tubule*, which lies in the cortex of the kidney (**Fig. 26.4**). From the proximal tubule, fluid flows into the *loop of Henle*, which dips into the renal medulla. Each loop consists of a *descending* and an *ascending limb*. The walls of the descending limb and lower end of the ascending limb are very thin and therefore are called the *thin segment of the loop of Henle*. After the ascending limb of the loop returns partway back to the cortex, its wall becomes much thicker; this segment is referred to as the *thick segment of the ascending limb*.

At the end of the thick ascending limb is a short segment that has in its wall a plaque of specialized epithelial cells, known as the *macula densa*. As discussed in Chapter 27, the macula densa plays an important role in controlling nephron function. Beyond the macula densa, fluid enters the *distal tubule*, which, like the proximal tubule, lies in the renal cortex. The distal tubule is followed by

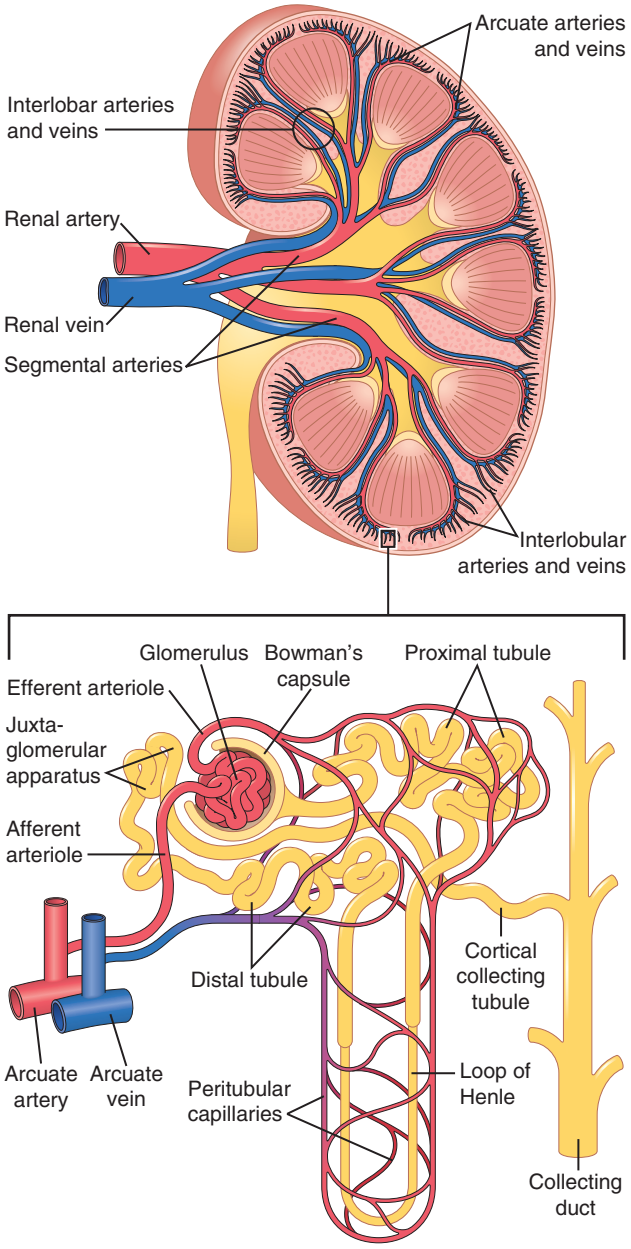

Figure 26.3 Section of the human kidney showing the major vessels that supply the blood flow to the kidney and a schematic of the microcirculation of each nephron.

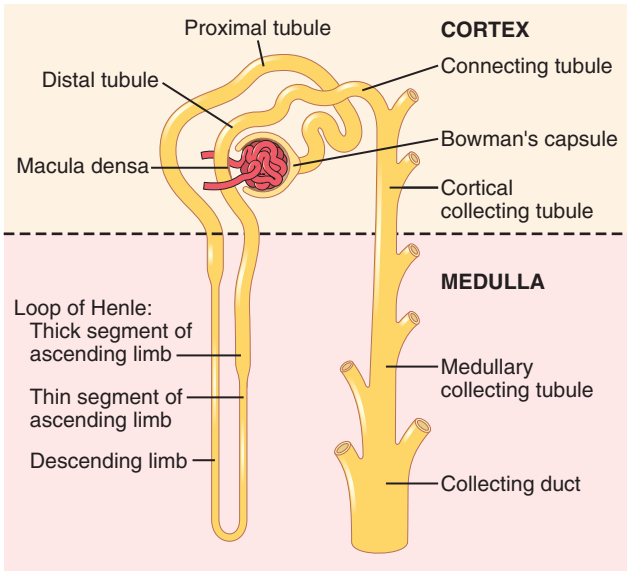

Figure 26.4 Basic tubular segments of the nephron. The relative lengths of the different tubular segments are not drawn to scale.

the *connecting tubule* and *cortical collecting tubule*, which lead to the *cortical collecting duct*. The initial parts of 8 to 10 cortical collecting ducts join to form a single, larger collecting duct that runs downward into the medulla and becomes the *medullary collecting duct*. The collecting ducts merge to form progressively larger ducts that eventually empty into the renal pelvis through the tips of the *renal papillae*. In each kidney, there are about 250 of these very large collecting ducts, each of which collects urine from about 4000 nephrons.

Regional Differences in Nephron Structure: Cortical and Juxtamedullary Nephrons. Although each nephron has all the components described earlier, there are some differences, depending on how deep the nephron lies within the kidney mass. The nephrons that have glomeruli located in the outer cortex are called *cortical nephrons*; they have short loops of Henle that penetrate only a short distance into the medulla (**Fig. 26.5**).

About 20% to 30% of the nephrons have glomeruli that lie deep in the renal cortex near the medulla and are called *juxtamedullary nephrons*. These nephrons have long loops of Henle that dip deeply into the medulla, in some cases all the way to the tips of the renal papillae.

The vascular structures supplying the juxtamedullary nephrons also differ from those supplying the cortical nephrons. For the cortical nephrons, the entire tubular system is surrounded by an extensive network of peritubular capillaries. For the juxtamedullary nephrons, long efferent arterioles extend from the glomeruli down into the outer medulla and then divide into specialized peritubular capillaries called *vasa recta*, which extend downward into the medulla, lying side by side with the loops of Henle. Like the loops of Henle, the vasa recta return toward the cortex and empty into the cortical veins. This specialized network of capillaries in the medulla plays an essential role in the formation of a concentrated urine, discussed in Chapter 29.

URINE FORMATION RESULTS FROM GLOMERULAR FILTRATION, TUBULAR REABSORPTION, AND TUBULAR SECRETION

The rates at which different substances are excreted in the urine represent the sum of three renal processes, shown in **Fig. 26.6**: (1) glomerular filtration of substances in the blood; (2) reabsorption of substances from the renal

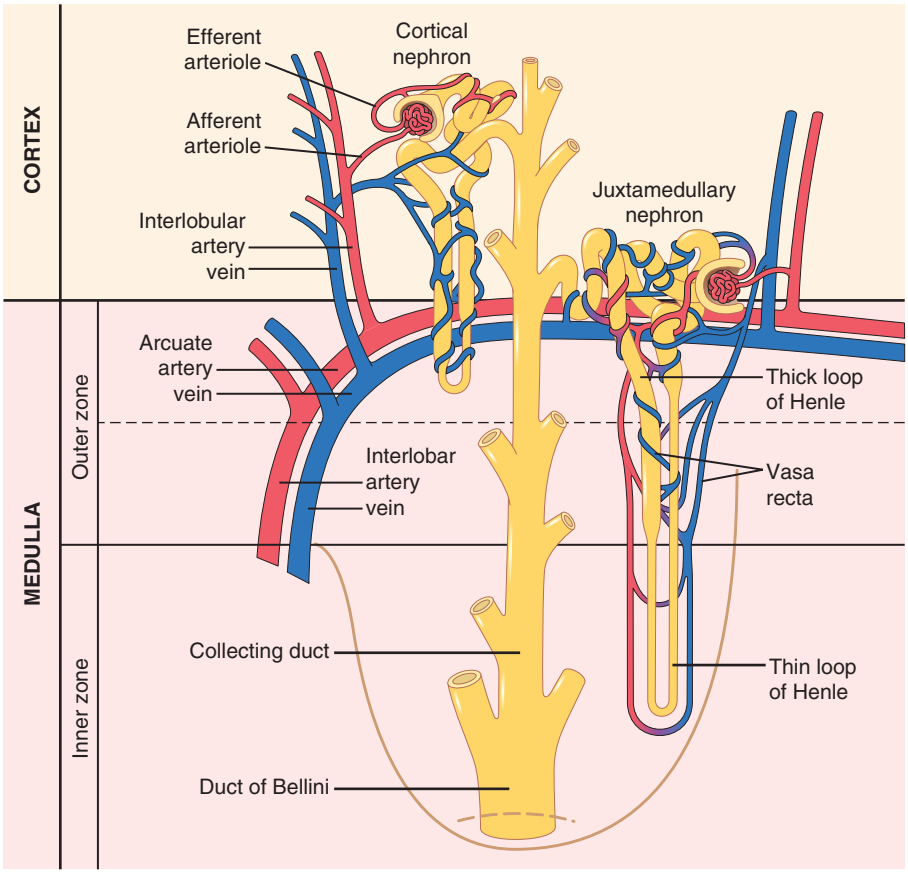

Figure 26.5 Schematic of relationships between blood vessels and tubular structures and differences between cortical and juxtamedullary nephrons.

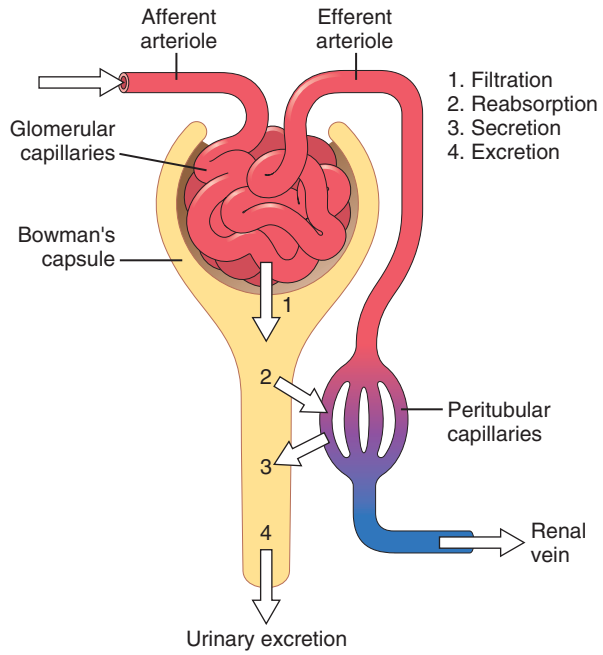

Figure 26.6 Basic kidney processes that determine the composition of the urine. The urinary excretion rate of a substance is equal to the rate at which the substance is filtered minus its reabsorption rate plus the rate at which it is secreted from the peritubular capillary blood into the tubules.

tubules into the blood; and (3) secretion of substances from the blood into the renal tubules as follows:

Urinary excretion rate
= Filtration rate − Reabsorption rate
+ Secretion rate

Urine formation begins when a large amount of fluid that is virtually free of protein is filtered from the glomerular capillaries into Bowman's capsule. Most substances in the plasma, except for proteins, are freely filtered, so their concentration in the glomerular filtrate in Bowman's capsule is almost the same as in the plasma. As filtered fluid leaves Bowman's capsule and passes through the tubules, it is modified by reabsorption of water and specific solutes back into the blood or by secretion of other substances from the peritubular capillaries into the tubules.

Fig. 26.7 shows the renal handling of four hypothetical substances. The substance shown in panel A is freely filtered by the glomerular capillaries but is neither reabsorbed nor secreted. Therefore, its excretion rate is equal to the rate at which it was filtered. Certain waste products in the body, such as creatinine, are handled by the kidneys in this manner, allowing excretion of essentially all that is filtered.

In panel B, the substance is freely filtered but is also partly reabsorbed from the tubules back into the blood.

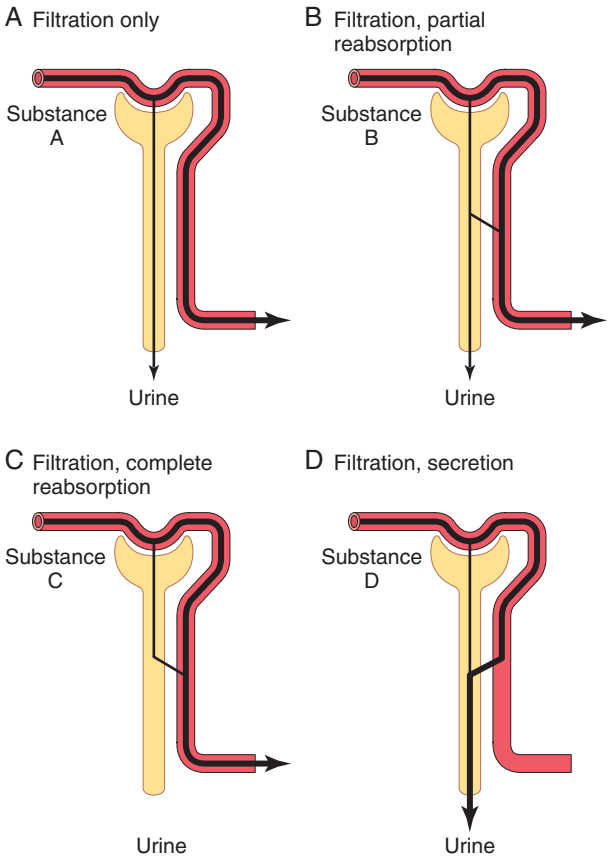

Figure 26.7 Renal handling of four hypothetical substances. (A) The substance is freely filtered but not reabsorbed. (B) The substance is freely filtered, but part of the filtered load is reabsorbed back in the blood. (C) The substance is freely filtered but is not excreted in the urine because all the filtered substance is reabsorbed from the tubules into the blood. (D) The substance is freely filtered and is not reabsorbed but is secreted from the peritubular capillary blood into the renal tubules.

Therefore, the rate of urinary excretion is less than the rate of filtration at the glomerular capillaries. In this case, the excretion rate is calculated as the filtration rate minus the reabsorption rate. This pattern is typical for many of the electrolytes of the body, such as sodium and chloride ions.

In panel C, the substance is freely filtered at the glomerular capillaries but is not excreted into the urine because all the filtered substance is reabsorbed from the tubules back into the blood. This pattern normally occurs for some of the nutritional substances in the blood, such as amino acids and glucose, allowing them to be conserved in the body fluids.

The substance in panel D is freely filtered at the glomerular capillaries and is not reabsorbed, but additional quantities of this substance are secreted from the peritubular capillary blood into the renal tubules. This pattern often occurs for organic acids and bases, permitting them to be cleared from the blood rapidly and excreted in large amounts in the urine. The excretion rate in this case is calculated as filtration rate plus tubular secretion rate.

For each substance in the plasma, a particular combination of filtration, reabsorption, and secretion occurs. The rate at which each substance is excreted in the urine depends on the relative rates of these three basic renal processes.

FILTRATION, REABSORPTION, AND SECRETION OF DIFFERENT SUBSTANCES

In general, tubular reabsorption is quantitatively more important than tubular secretion in the formation of urine, but secretion plays an important role in determining the amounts of potassium and hydrogen ions and a few other substances that are excreted in the urine. Most substances that must be cleared from the blood, especially the end products of metabolism, such as urea, creatinine, uric acid, and urates, are poorly reabsorbed and are therefore excreted in large amounts in the urine. Certain foreign substances and drugs are also poorly reabsorbed but, in addition, are secreted from the blood into the tubules, so their excretion rates are high. Conversely, electrolytes, such as sodium ions, chloride ions, and bicarbonate ions, are highly reabsorbed, so only small amounts appear in the urine. Certain nutritional substances, such as amino acids and glucose, are completely reabsorbed from the tubules and do not appear in the urine, even though large amounts are filtered by the glomerular capillaries.

Each of the processes—glomerular filtration, tubular reabsorption, and tubular secretion—is regulated according to the needs of the body. For example, when there is excess sodium in the body, the rate at which sodium is filtered usually increases slightly, and a smaller fraction of the filtered sodium is reabsorbed, causing increased urinary excretion of sodium. When there is excess potassium, increased urinary excretion of potassium is achieved mainly by increasing tubular secretion of potassium. As we discuss in the remaining chapters of this section, various combinations of changes in the rates of glomerular filtration, tubular reabsorption, and tubular secretion are used to regulate excretion of different substances.

For most substances, the rates of filtration and reabsorption are extremely large relative to the rates of excretion. Therefore, even slight changes of filtration or reabsorption can lead to relatively large changes in renal excretion. For example, an increase in the glomerular filtration rate (GFR) of only 10% (from 180 to 198 L/day) would raise the urine volume by 13-fold (from 1.5 to 19.5 L/day) if tubular reabsorption remained constant. In reality, changes in glomerular filtration, tubular reabsorption, and tubular secretion usually act in a coordinated manner to produce the necessary changes in renal excretion.

Why Are Large Amounts of Solutes Filtered and Then Reabsorbed By the Kidneys? One might question the wisdom of filtering such large amounts of water and solutes and then reabsorbing most of these substances. The high rate of tubular reabsorption required to recover most of the electrolytes, glucose, amino acids, and many other solutes filtered is metabolically expensive; approximately

10% of the total resting energy expenditure of the body is used to reabsorb the filtered solutes and convert the glomerular filtrate into urine.

One advantage of a high GFR is that it allows the kidneys to rapidly remove from the body waste products that depend mainly on glomerular filtration for their excretion. Most waste products are poorly reabsorbed by the tubules and, therefore, depend on a high GFR for rapid removal from the body. In vertebrate animals, GFR is proportional to metabolic rate and body size and is higher in warm-blooded mammals compared to cold-blooded fish, amphibians, and reptiles with lower metabolic rates. In humans, increasing body size and other factors that increase metabolic rate, such as fever or hyperthyroidism, are also associated with increased GFR, which permits increased excretion of the metabolic waste products.

A second equally important advantage of a high GFR is that it allows the body fluids to be filtered and processed by the kidneys many times each day. Because the entire plasma volume is only about 3 liters, whereas the GFR is approximately 180 L/day, the entire plasma can be filtered and processed about 60 times each day. This high GFR therefore allows the kidneys to control the volume and composition of the body fluids precisely and rapidly.

MICTURITION

Micturition is the process whereby the urinary bladder empties when it becomes filled. This process involves two main steps. First, the bladder fills progressively until the tension in its walls rises above a threshold level. This tension elicits the second step, which is a nervous reflex called the *micturition reflex* that empties the bladder or, if this fails, at least causes a conscious desire to urinate. Although the micturition reflex is an autonomic spinal cord reflex, it can also be inhibited or facilitated by centers in the cerebral cortex or brain stem.

PHYSIOLOGICAL ANATOMY OF THE BLADDER

The urinary bladder, shown in **Fig. 26.8**, is a smooth muscle chamber composed of two main parts: (1) the *body*, which is the major part of the bladder in which urine collects; and (2) the *neck*, which is a funnel-shaped extension of the body, passing inferiorly and anteriorly into the urogenital triangle and connecting with the *urethra*. The lower part of the bladder neck is also called the *posterior urethra* because of its relationship to the urethra.

The smooth muscle of the bladder is called the *detrusor muscle*. Its muscle fibers extend in all directions and, when contracted, can increase the pressure in the bladder to 40 to 60 mm Hg. Thus, *contraction of the detrusor muscle is a major step in emptying the bladder*. Smooth muscle cells of the detrusor muscle fuse with one another so that low-resistance electrical pathways exist from one muscle cell to the other. Therefore, an action potential can spread throughout the detrusor muscle, from one muscle cell to the next, to cause contraction of the entire bladder at once.

On the posterior wall of the bladder, lying immediately above the bladder neck, is a small triangular area called the *trigone*. At the lowermost apex of the trigone, the bladder neck opens into the *posterior urethra*, and the two *ureters* enter the bladder at the uppermost angles of the trigone. The trigone can be identified by the fact that its *mucosa*, the inner lining of the bladder, is smooth, in contrast to the remaining bladder mucosa, which is folded to form *rugae*.

Each ureter, as it enters the bladder, courses obliquely through the detrusor muscle and then passes another 1 to 2 centimeters beneath the bladder mucosa before emptying into the bladder.

The bladder neck (posterior urethra) is 2 to 3 centimeters long, and its wall is composed of detrusor muscle interlaced with a large amount of elastic tissue. The muscle in this area is called the *internal sphincter*. Its natural tone normally keeps the bladder neck and posterior urethra empty of urine and, therefore, prevents emptying of the bladder until the pressure in the main part of the bladder rises above a critical threshold.

Beyond the posterior urethra, the urethra passes through the *urogenital diaphragm*, which contains a layer of muscle called the *external sphincter* of the bladder. This muscle is a voluntary skeletal muscle, in contrast to the muscle of the bladder body and bladder neck, which is entirely smooth muscle. The external sphincter muscle is under voluntary control of the nervous system and can be used to consciously prevent urination, even when involuntary controls are attempting to empty the bladder.

Innervation of the Bladder. The principal nerve supply of the bladder is via the *pelvic nerves*, which connect with the spinal cord through the *sacral plexus*, mainly connecting with cord segments S2 and S3 (**Fig. 26.9**). Coursing through the pelvic nerves are both *sensory nerve fibers* and *motor nerve fibers*. The sensory fibers detect the degree of stretch in the bladder wall. Stretch signals from the posterior urethra are especially strong and are mainly responsible for initiating the reflexes that cause bladder emptying.

The motor nerves transmitted in the pelvic nerves are *parasympathetic fibers*. These fibers terminate on ganglion cells located in the wall of the bladder. Short postganglionic nerves then innervate the detrusor muscle.

In addition to the pelvic nerves, two other types of innervation are important in bladder function. Most important are the *skeletal motor fibers* transmitted through the *pudendal nerve* to the external bladder sphincter. These fibers are *somatic nerve fibers* that innervate and control the voluntary skeletal muscle of the sphincter. Also, the bladder receives *sympathetic innervation* from the sympathetic chain through the *hypogastric nerves*, connecting mainly with the L2 segment of the spinal cord. These sympathetic fibers stimulate mainly the blood vessels and have little to do with bladder contraction. Some

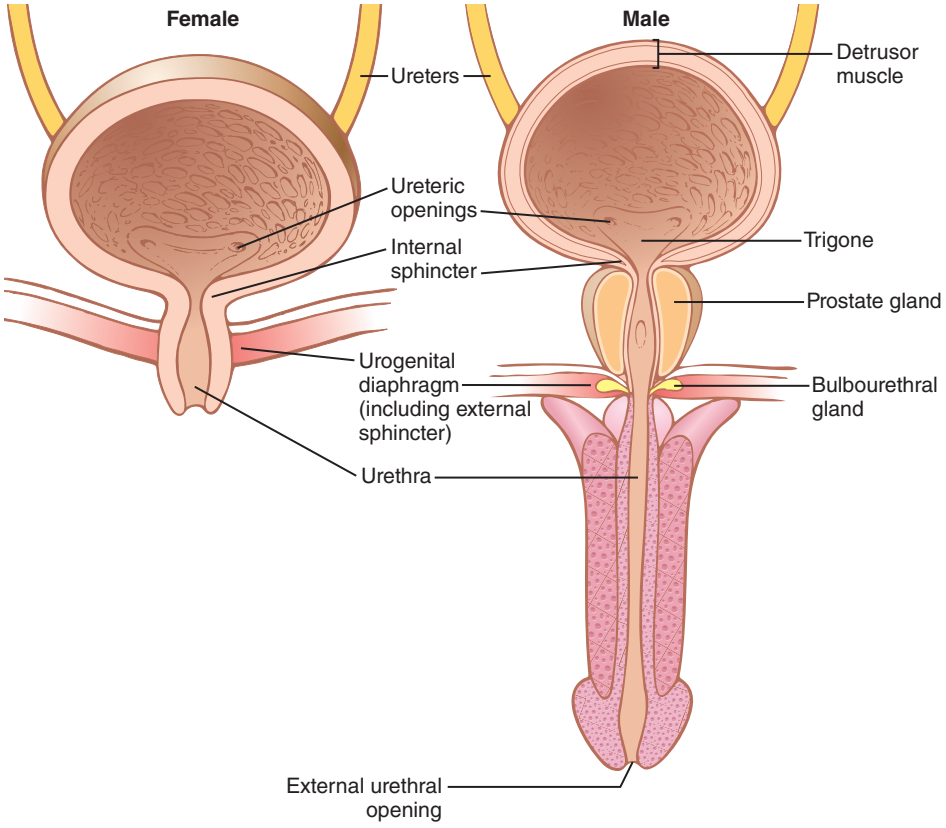

Figure 26.8 Anatomy of the urinary bladder and urethra in males and females.

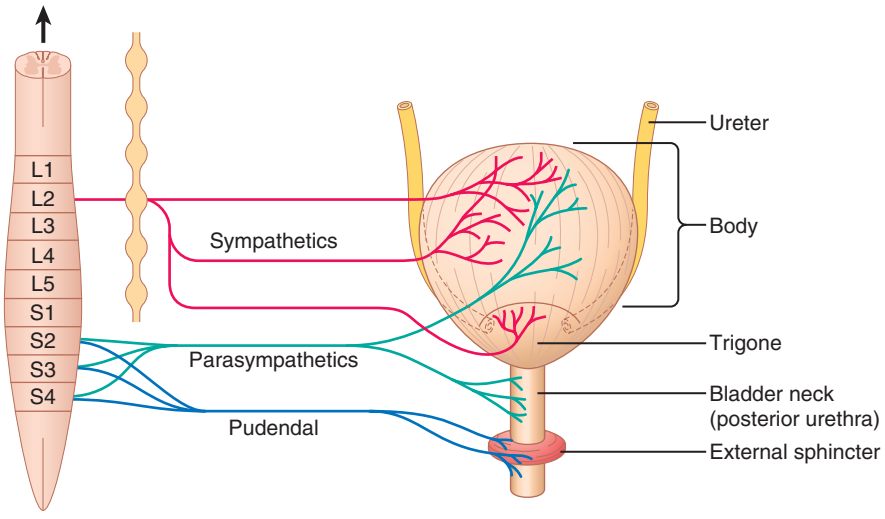

Figure 26.9 Innervation of the urinary bladder.

sensory nerve fibers also pass via the sympathetic nerves and may be important in the sensation of fullness and, in some cases, pain.

URINE TRANSPORT FROM THE KIDNEYS THROUGH THE URETERS AND INTO THE BLADDER

Urine that is expelled from the bladder has essentially the same composition as fluid flowing out of the collecting ducts. There are no significant changes in the composition of urine as it flows through the renal calyces and ureters to the bladder.

Urine flowing from the collecting ducts into the renal calyces stretches the calyces and increases their inherent *pacemaker activity*, which in turn initiates peristaltic contractions that spread to the renal pelvis and then downward along the length of the ureter, thereby forcing urine from the renal pelvis toward the bladder. In adults, the ureters are normally 25 to 35 centimeters (10–14 inches) long.

The walls of the ureters contain smooth muscle and are innervated by sympathetic and parasympathetic nerves, as well as by an intramural plexus of neurons and nerve fibers that extends along the entire length of the ureters. As with other visceral smooth muscle, *peristaltic contractions in the ureter are enhanced by parasympathetic stimulation and inhibited by sympathetic stimulation.*

The ureters enter the bladder through the *detrusor muscle* in the trigone region of the bladder, as shown in **Fig. 26.8**. Normally, the ureters course obliquely for several centimeters through the bladder wall. The normal tone of the detrusor muscle in the bladder wall tends to compress the ureter, thereby preventing backflow (reflux) of urine from the bladder when pressure builds up in the bladder during micturition or bladder compression. Each peristaltic wave along the ureter increases the pressure within the ureter so that the region passing through the bladder wall opens and allows urine to flow into the bladder.

Vesicoureteral Reflux. In some people, the distance that the ureter courses through the bladder wall is less than normal, and thus contraction of the bladder during micturition does not always lead to complete occlusion of the ureter. As a result, some of the urine in the bladder is propelled backward into the ureter, a condition called *vesicoureteral reflux*. Such reflux can lead to enlargement of the ureters and, if severe, can increase the pressure in the renal calyces and structures of the renal medulla, causing damage to these regions.

Pain Sensation in the Ureters and the Ureterorenal Reflex. The ureters are extensively supplied with pain nerve fibers. When a ureter becomes blocked (e.g., by a ureteral stone), intense reflex constriction occurs, which is associated with severe pain. Also, the pain impulses cause a sympathetic reflex back to the kidney to constrict the renal arterioles, thereby decreasing urine output from the kidney. This effect is called the *ureterorenal reflex* and is important for attenuating flow of fluid into the pelvis of a kidney with a blocked ureter.

Filling of the Bladder and Bladder Wall Tone—the Cystometrogram. **Fig. 26.10** shows the approximate changes in intravesicular pressure as the bladder fills with urine. When there is no urine in the bladder, the intravesicular pressure is about 0, but by the time 30 to 50 mL of urine have collected, the pressure rises to 5 to 10 cm of water. Additional urine—200 to 300 mL—can collect with only a small additional rise in pressure; this constant level of pressure is caused by intrinsic tone of the bladder wall. Beyond 300 to 400 mL, collection of more urine in the bladder causes the pressure to rise rapidly.

Superimposed on the tonic pressure changes during filling of the bladder are periodic acute increases in pressure that last from a few seconds to more than 1 minute. The pressure peaks may rise only a few cm of water or may rise to more than 100 cm of water. These pressure peaks are called *micturition waves* in the cystometrogram and are caused by the micturition reflex.

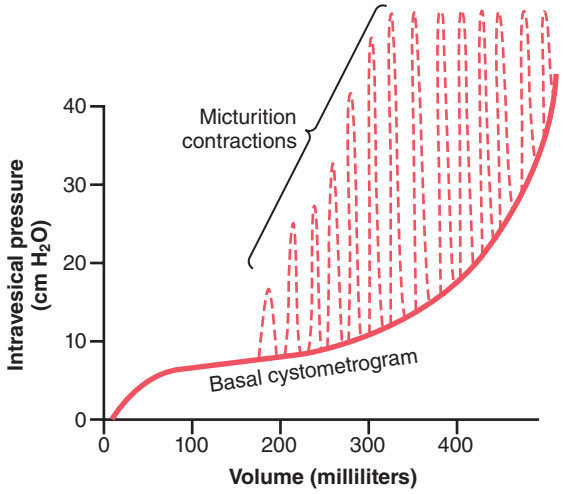

Figure 26.10 A normal cystometrogram, showing also acute pressure waves *(dashed spikes)* caused by micturition reflexes.

MICTURITION REFLEX

Referring again to **Fig. 26.10**, one can see that as the bladder fills, many superimposed *micturition contractions* begin to appear, as shown by the dashed spikes. These are the result of a stretch reflex initiated by *sensory stretch receptors* in the bladder wall, especially by the receptors in the posterior urethra when this area begins to fill with urine at the higher bladder pressures. Sensory signals from the bladder stretch receptors are conducted to the sacral segments of the cord through the *pelvic nerves* and then reflexively back again to the bladder through the *parasympathetic nerve fibers* by way of these same nerves.

When the bladder is only partially filled, these micturition contractions usually relax spontaneously after a fraction of a minute, the detrusor muscles stop contracting, and pressure falls back to the baseline. As the bladder continues to fill, the micturition reflexes become more frequent and cause greater contractions of the detrusor muscle.

Once a micturition reflex begins, it is self-regenerative. That is, initial contraction of the bladder activates the stretch receptors to cause a greater increase in sensory impulses from the bladder and posterior urethra, which causes a further increase in reflex contraction of the bladder; thus, the cycle is repeated again and again until the bladder has reached a strong degree of contraction. Then, after a few seconds to more than a minute, the self-regenerative reflex begins to fatigue, and the regenerative cycle of the micturition reflex ceases, permitting the bladder to relax.

Thus, the micturition reflex is a single complete cycle of the following: (1) progressive and rapid increase of pressure; (2) a period of sustained pressure; and (3) return of the pressure to the basal tone of the bladder. Once a micturition reflex has occurred but has not succeeded in emptying the bladder, the nervous elements of this reflex usually remain in an inhibited state for a few minutes to 1 hour or more before another micturition

reflex occurs. As the bladder becomes filled more and more, micturition reflexes occur more and more often and powerfully.

Once the micturition reflex becomes powerful enough, it causes another reflex, which passes through the *pudendal nerves* to the *external sphincter* to inhibit it. If this inhibition is more potent in the brain than the voluntary constrictor signals to the external sphincter, urination will occur. If not, urination will not occur until the bladder fills still further and the micturition reflex becomes more powerful.

Facilitation or Inhibition of Micturition By the Brain. The micturition reflex is an autonomic spinal cord reflex, but it can be inhibited or facilitated by centers in the brain. These centers include the following: (1) strong *facilitative* and *inhibitory centers in the brain stem, located mainly in the pons;* and (2) several *centers located in the cerebral cortex* that are mainly inhibitory but can become excitatory.

The micturition reflex is the basic cause of micturition, but the higher centers normally exert final control of micturition, as follows:

1. The higher centers keep the micturition reflex partially inhibited, except when micturition is desired.
2. The higher centers can prevent micturition, even if the micturition reflex occurs, by tonic contraction of the external bladder sphincter until a convenient time presents itself.
3. When it is time to urinate, the cortical centers can facilitate the sacral micturition centers to help initiate a micturition reflex and, at the same time, inhibit the external urinary sphincter so that urination can occur.

Voluntary urination is usually initiated in the following way. First, a person voluntarily contracts the abdominal muscles, which increases pressure in the bladder and allows extra urine to enter the bladder neck and posterior urethra under pressure, thus stretching their walls. This action stimulates the stretch receptors, which excites the micturition reflex and simultaneously inhibits the external urethral sphincter. Ordinarily, all the urine will be emptied, with rarely more than 5 to 10 milliliters left in the bladder.

Abnormalities of Micturition

Atonic Bladder and Incontinence Caused By Destruction of Sensory Nerve Fibers. Micturition reflex contraction cannot occur if the sensory nerve fibers from the bladder to the spinal cord are destroyed, thereby preventing transmission of stretch signals from the bladder. When this happens, a person loses bladder control, despite intact efferent fibers from the cord to the bladder and despite intact neurogenic connections within the brain. Instead of emptying periodically, the bladder fills to capacity and overflows a few drops at a time through the urethra. This occurrence is called *overflow incontinence*.

A common cause of atonic bladder is crush injury to the sacral region of the spinal cord. Certain diseases can also cause damage to the dorsal root nerve fibers that enter the spinal cord. For example, syphilis can cause constrictive fibrosis around the dorsal root nerve fibers, destroying them. This condition is called *tabes dorsalis*, and the resulting bladder condition is called *tabetic bladder*.

Automatic Bladder Caused By Spinal Cord Damage Above the Sacral Region. If the spinal cord is damaged above the sacral region but the sacral cord segments are still intact, typical micturition reflexes can still occur. However, they are no longer controlled by the brain. During the first few days to several weeks after the damage to the cord has occurred, the micturition reflexes are suppressed because of the state of spinal shock caused by the sudden loss of facilitative impulses from the brain stem and cerebrum. However, if the bladder is emptied periodically by catheterization to prevent bladder injury caused by overstretching of the bladder, the excitability of the micturition reflex gradually increases until typical micturition reflexes return; then, periodic (but unannounced) bladder emptying occurs.

Uninhibited Neurogenic Bladder Caused By Lack of Inhibitory Signals From the Brain. Another abnormality of micturition is the so-called *uninhibited neurogenic bladder*, which results in frequent and relatively uncontrolled micturition. This condition derives from partial damage in the spinal cord or the brain stem that interrupts most of the inhibitory signals. Therefore, facilitative impulses passing continually down the cord keep the sacral centers so excitable that even a small quantity of urine elicits an uncontrollable micturition reflex, thereby promoting frequent urination.

See the Bibliography for Chapters 27 to 32.

Glomerular Filtration, Renal Blood Flow, and Their Control

GLOMERULAR FILTRATION—THE FIRST STEP IN URINE FORMATION

The first step in urine formation is filtration of large amounts of fluid through the glomerular capillaries into the Bowman capsule—almost 180 L/day. Most of this filtrate is reabsorbed, leaving only about 1 liter of fluid to be excreted each day, although the urinary excretion rate is highly variable, depending on fluid intake. The high rate of glomerular filtration depends on a high rate of kidney blood flow (about 22% of the entire resting cardiac output), as well as the special properties of the glomerular capillary membranes. In this chapter, we discuss the physical forces that determine the glomerular filtration rate (GFR), as well as the physiological mechanisms that regulate GFR and renal blood flow.

COMPOSITION OF THE GLOMERULAR FILTRATE

Like most capillaries, the glomerular capillaries are relatively impermeable to proteins, so the filtered fluid (called the *glomerular filtrate*) normally has only tiny amounts of protein and is devoid of cellular elements, including red blood cells. The concentrations of other constituents of the glomerular filtrate, including most salts and organic molecules, are similar to the concentrations in the plasma. Exceptions to this generalization include a few low-molecular-weight substances such as calcium and fatty acids that are not freely filtered because they are partially bound to the plasma proteins. For example, almost half of the plasma calcium and most of the plasma fatty acids are bound to proteins, and these bound portions are not filtered through the glomerular capillaries.

GFR IS ABOUT 20% OF RENAL PLASMA FLOW

Similar to other capillaries, the glomerular capillaries filter fluid at a rate that is determined by the following: (1) the balance of hydrostatic and colloid osmotic forces acting across the capillary membrane; and (2) the capillary filtration coefficient (K_f), the product of the permeability and filtering surface area of the capillaries. The glomerular capillaries have a much higher rate of filtration than most other capillaries because of a high glomerular hydrostatic pressure and a large K_f. In the average adult human, the GFR is about 125 mL/min, or 180 L/day. However, GFR depends on body size, sex, and age of the individual. For example, the average GFR is about 10% lower in women than in men even after adjustment for body size, although this difference diminishes at older ages because of a slightly greater decline in GFR with aging in men.

Studies in healthy men and women indicate that substantial decreases in GFR occur with normal aging (**Fig. 27.1**), perhaps due to accumulated small injuries and gradual senescence of nephrons. From young adulthood (18 to 29 years) to age 70 to 75 years, healthy adults lose almost half of their nephrons. This loss is accelerated when there is underlying pathophysiology associated with diseases such as glomerulonephritis, diabetes, or hypertension, as discussed in Chapter 32.

The fraction of the renal plasma flow that is filtered (the *filtration fraction*) averages about 0.2, which means that about 20% of the plasma flowing through the kidney is filtered through the glomerular capillaries (**Fig. 27.2**). The filtration fraction is calculated as follows:

$$\text{Filtration fraction} = \text{GFR} / \text{Renal plasma flow}$$

GLOMERULAR CAPILLARY MEMBRANE

The glomerular capillary membrane is similar to that of other capillaries, except that it has three (instead of the usual two) major layers: (1) *endothelial cells* with a *glycocalyx* coat (composed of glycoproteins) on the luminal surface of the capillary; (2) a *basement membrane*; and (3) a layer of *epithelial cells (podocytes)* surrounding the outer surface of the capillary basement membrane (**Fig. 27.3**). Together, these layers make up the filtration barrier, which, despite the three layers, filters several hundred times as much water and solutes as the usual capillary membrane. Even with this high rate of filtration, the glomerular capillary membrane normally filters only a small amount of plasma proteins.

The high filtration rate across the glomerular capillary membrane is due partly to its special characteristics. The capillary *endothelium* is perforated by thousands of small

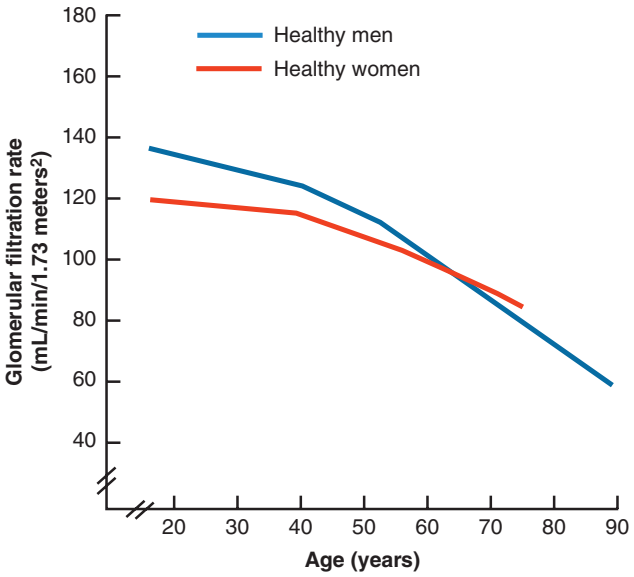

Figure 27.1 Age-related changes in glomerular filtration rate (GFR) in healthy men and women. The lines for men and women were drawn from average values of multiple cross-sectional studies summarized by Wesson (1969). Data for women older than 75 years were not available.

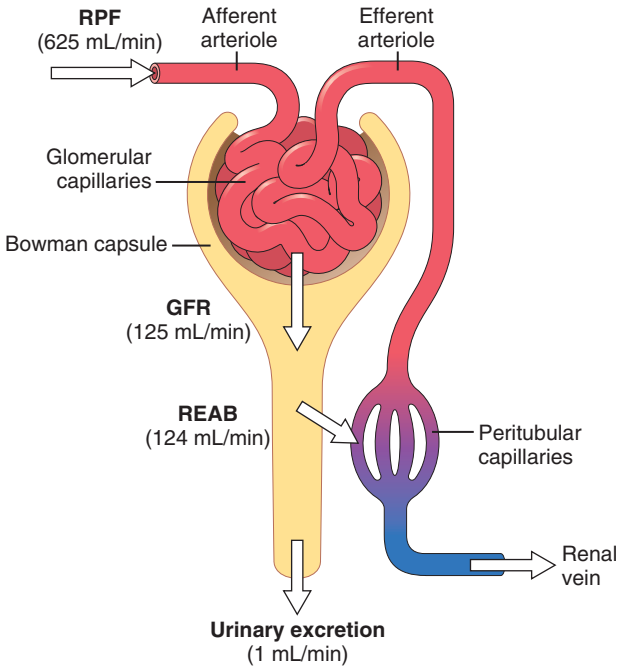

Figure 27.2 Average values for total renal plasma flow (RPF), glomerular filtration rate (GFR), tubular reabsorption (REAB), and urine flow rate. RPF is equal to renal blood flow × (1 − hematocrit). Note that the GFR averages about 20% of the RPF, whereas urine flow rate is less than 1% of the GFR. Therefore, more than 99% of the fluid filtered is normally reabsorbed. The filtration fraction is GFR/RPF.

holes called *fenestrae*, similar to the fenestrated capillaries found in the liver, although smaller than the fenestrae of the liver. Although the fenestrations are relatively large, endothelial cell proteins are richly endowed with fixed negative charges that hinder the passage of plasma proteins.

Surrounding the endothelium is the *basement membrane*, which consists of a meshwork of collagen and proteoglycan fibrillae that have large spaces through which large amounts of water and small solutes can filter. The basement membrane greatly hinders filtration of plasma proteins, partly because of strong negative electrical charges associated with the proteoglycans.

The final part of the glomerular membrane is a layer of epithelial cells (podocytes) that line the outer surface of the glomerulus. These podocytes are not continuous but have long footlike processes (*pedicels*) that encircle the outer surface of the capillaries (see **Fig. 27.3**). The foot processes are separated by gaps called *filtration slits* that are bridged by thin diaphragms that contain pores through which the glomerular filtrate moves. The *filtration slit diaphragm* is composed of several proteins, including *nephrin* and *podocin*, that, along with other epithelial cell proteins, play a critical role in restricting filtration of plasma proteins. For example, mutations in the nephrin gene alone can lead to abnormal or absent filtration slit diaphragms and large increases in filtration and excretion of plasma proteins (*proteinuria*). Thus, all layers of the glomerular capillary wall provide a barrier to the filtration of plasma proteins but still permit rapid filtration of water and most solutes in the plasma.

Another cell type that plays a key role in glomerular function is the mesangial cell. These cells lie around and between the glomerular capillaries and produce extracellular matrix and other factors that provide structural and functional support for the capillaries. Although the mesangial cells are not part of the glomerular filtration barrier, they contain actin and myosin-based microfilaments that contact the glomerular basement membrane and have contractile properties that may alter blood flow though the capillaries.

Filterability of Solutes Decreases as Their Size Increases. The glomerular capillary membrane is thicker than most other capillaries, but it is also much more porous and therefore filters fluid at a high rate. Despite the high filtration rate, the glomerular filtration barrier is selective in determining which molecules will be filtered, based on their size and electrical charge.

Table 27.1 illustrates the effect of molecular size on filterability of different molecules. A filterability of 1.0 means that the substance is filtered as freely as water, whereas a filterability of 0.75 means that the substance is filtered only 75% as rapidly as water. Note that electrolytes such as sodium and small organic molecules such as glucose are freely filtered. As the molecular weights of the molecules approach that of albumin, the filterability rapidly decreases, approaching zero.

Negatively Charged Large Molecules Are Filtered Less Easily Than Positively Charged Molecules of Equal Size. The molecular diameter of the plasma protein albumin is only about 6 nanometers, whereas the pores of

Table 27.1 Filterability of Substances By Glomerular Capillaries Based on Molecular Weight

Substance	Molecular Weight	Filterability
Water	18	1.0
Sodium	23	1.0
Glucose	180	1.0
Inulin	5500	1.0
Myoglobin	17,000	0.75
Albumin	69,000	0.005

the glomerular endothelial cell membrane are thought to be about 8 nanometers (80 angstroms [Å]). Albumin is restricted from filtration, however, because of its negative charge and the electrostatic repulsion exerted by negative charges of the glomerular capillary wall glycoproteins.

Fig. 27.4 shows how electrical charge affects the filtration of different molecular weight dextrans by the glomerulus. Dextrans are polysaccharides that can be manufactured as neutral molecules or with negative or positive charges. Note that for any given molecular radius, positively charged molecules are filtered much more readily than negatively charged molecules. Neutral dextrans are also filtered more readily than negatively charged dextrans of equal molecular weight. The reason for these differences in filterability is that the negative

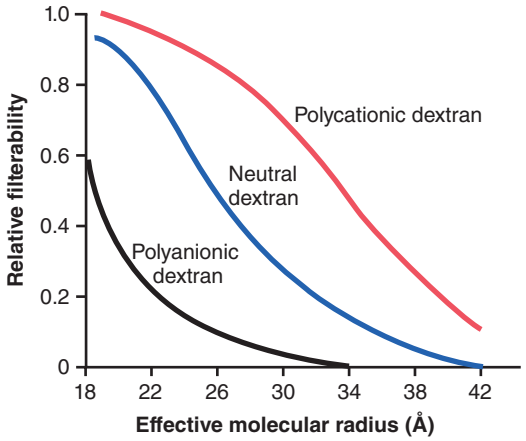

Figure 27.4 Effect of molecular radius and electrical charge of dextran on its filterability by the glomerular capillaries. A value of 1.0 indicates that the substance is filtered as freely as water, whereas a value of 0 indicates that it is not filtered. Dextrans are polysaccharides that can be manufactured as neutral molecules or with negative or positive charges and with varying molecular weights.

charges of the basement membrane and podocytes provide an important means for restricting large negatively charged molecules, including the plasma proteins.

Minimal-Change Nephropathy and Increased Glomerular Permeability to Plasma Proteins. In *minimal-change nephropathy*, the glomeruli become more permeable to plasma proteins, even though they may look normal when viewed with a standard light microscope. However, when viewed at high magnification with an electron microscope, the glomeruli usually display flattened podocytes with foot processes that may be detached from the glomerular basement membrane *(podocyte effacement)*.

The causes of minimal-change nephropathy are unclear but may be at least partly related to an immunological response and abnormal T-cell secretion of cytokines that injure the podocytes and increase their permeability to some of the lower molecular weight proteins, especially albumin. This increased permeability permits the proteins to be filtered by the glomerular capillaries and excreted in the urine, a condition known as *proteinuria* or *albuminuria*. Minimal-change nephropathy is most common in young children but can also occur in adults, especially in those who have autoimmune disorders.

DETERMINANTS OF GFR

The GFR equals the product of the *glomerular* K_f and the *net filtration pressure* across the glomerular capillaries:

$$GFR = K_f \times \text{Net filtration pressure}$$

The net filtration pressure represents the sum of the hydrostatic and colloid osmotic forces that favor or oppose filtration across the glomerular capillaries (**Fig. 27.5**).

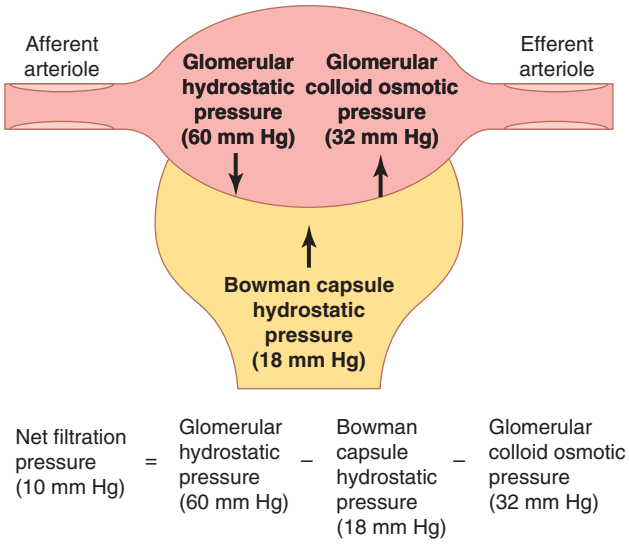

Figure 27.5 Summary of forces causing filtration by the glomerular capillaries. The values shown are estimates for healthy humans.

These forces include the following: (1) hydrostatic pressure inside the glomerular capillaries (glomerular hydrostatic pressure, P_G), which promotes filtration; (2) the hydrostatic pressure in the Bowman capsule (P_B) outside the capillaries, which opposes filtration; (3) the colloid osmotic pressure of the glomerular capillary plasma proteins (π_G), which opposes filtration; and (4) the colloid osmotic pressure of the proteins in the Bowman capsule (π_B), which promotes filtration. Under normal conditions, the concentration of protein in the glomerular filtrate is so low that the colloid osmotic pressure of the Bowman capsule fluid is considered to be zero.

The GFR can therefore be expressed as follows:

$$GFR = K_f \times (P_G - P_B - \pi_G + \pi_B)$$

Although the normal values for the determinants of GFR have not been measured directly in humans, they have been estimated in experimental animals such as dogs, rats, and mice. Based on the results in experimental animals, the approximate normal forces favoring and opposing glomerular filtration in humans are believed to be as follows (see **Fig. 27.5**):

Forces Favoring Filtration (mm Hg)	
Glomerular hydrostatic pressure	60
Bowman capsule colloid osmotic pressure	0
Forces Opposing Filtration (mm Hg)	
Bowman capsule hydrostatic pressure	18
Glomerular capillary colloid osmotic pressure	32

Thus, the net filtration pressure = 60 − 18 − 32 = +10 mm Hg.

Some of these values can change markedly under different physiological conditions, whereas others are altered mainly in disease states, as discussed later.

INCREASED GLOMERULAR CAPILLARY FILTRATION COEFFICIENT INCREASES GFR

The K_f is a measure of the product of the hydraulic conductivity and surface area of the glomerular capillaries. The K_f cannot be measured directly, but can be estimated experimentally by dividing the GFR by the net filtration pressure:

$$K_f = GFR / \text{Net filtration pressure}$$

Because the total GFR for both kidneys is about 125 mL/min, and the net filtration pressure is 10 mm Hg, the normal K_f is about 12.5 mL/min per mm Hg of filtration pressure. When K_f is expressed per 100 grams of kidney weight, it averages about 4.2 mL/min per mm Hg, a value about 400 times as high as the K_f of most other capillary systems of the body. This high K_f for the glomerular capillaries contributes to their rapid rate of fluid filtration.

Although increased K_f raises the GFR and decreased K_f reduces GFR, changes in K_f do not provide a primary mechanism for the normal daily regulation of GFR. Some diseases, however, lower K_f by reducing the number of functional glomerular capillaries (thereby reducing the surface area for filtration) or by increasing the thickness of the glomerular capillary membrane and reducing its hydraulic conductivity. For example, chronic uncontrolled hypertension may gradually reduce K_f by increasing the thickness of the glomerular capillary basement membrane and, eventually, by damaging the capillaries so severely that there is loss of capillary function.

INCREASED BOWMAN CAPSULE HYDROSTATIC PRESSURE DECREASES GFR

Direct measurements of hydrostatic pressure in the Bowman capsule and at different points in the proximal tubule in experimental animals using micropipettes suggest that a reasonable estimate for Bowman capsule pressure in humans is about 18 mm Hg under normal conditions. Increasing the hydrostatic pressure in the Bowman capsule reduces GFR, whereas decreasing this pressure raises GFR. However, changes in Bowman capsule pressure normally do not serve as a primary means for regulating GFR.

In certain pathophysiological states associated with obstruction of the urinary tract, Bowman capsule pressure can increase markedly, causing serious reduction of GFR. For example, precipitation of calcium or of uric acid may lead to formation of stones that lodge in the urinary tract, often in the ureter, thereby obstructing outflow of the urinary tract and raising Bowman capsule pressure. This situation reduces GFR and eventually can cause *hydronephrosis* (distention and dilation of the renal pelvis and calyces) and can damage or even destroy the kidney unless the obstruction is relieved.

INCREASED GLOMERULAR CAPILLARY COLLOID OSMOTIC PRESSURE DECREASES GFR

As blood passes from the afferent arteriole through the glomerular capillaries to the efferent arterioles, the plasma protein concentration increases about 20% (**Fig. 27.6**). The reason for this increase is that about one-fifth of the fluid in the glomerular capillaries filters into the Bowman capsule, thereby concentrating the glomerular plasma proteins that are not filtered. Assuming that the normal colloid osmotic pressure of plasma entering the glomerular capillaries is 28 mm Hg, this value usually rises to about 36 mm Hg by the time the blood reaches the efferent end of the capillaries. Therefore, the average colloid osmotic pressure of the glomerular capillary plasma proteins is midway between 28 and 36 mm Hg, or about 32 mm Hg.

Two factors that influence the glomerular capillary colloid osmotic pressure are the following: (1) the arterial plasma colloid osmotic pressure; and (2) the fraction of plasma filtered by the glomerular capillaries (filtration fraction). Increasing the arterial plasma colloid osmotic pressure raises the glomerular capillary colloid osmotic pressure, which in turn tends to decrease the GFR.

Increasing the filtration fraction also concentrates the plasma proteins and raises the glomerular colloid osmotic pressure (see **Fig. 27.6**). Because the filtration fraction is defined as the GFR divided by the renal plasma flow, the filtration fraction can be increased by raising GFR or by reducing renal plasma flow. For example, a reduction in renal plasma flow with no initial change in GFR would tend to increase the filtration fraction, which would raise the glomerular capillary colloid osmotic pressure and tend to reduce the GFR. For this reason, changes in renal blood flow can influence GFR independently of changes in glomerular hydrostatic pressure.

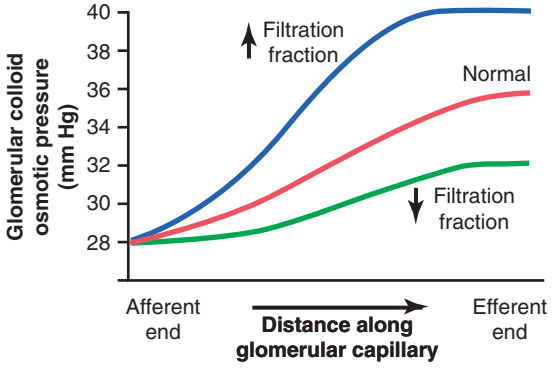

Figure 27.6 Increase in colloid osmotic pressure in plasma flowing through the glomerular capillary. Normally, about one-fifth of the fluid in the glomerular capillaries filters into the Bowman capsule, thereby concentrating the plasma proteins that are not filtered. Increases in the filtration fraction (glomerular filtration rate/renal plasma flow) increase the rate at which the plasma colloid osmotic pressure rises along the glomerular capillary; decreases in the filtration fraction have the opposite effect.

With increasing renal blood flow, a lower fraction of the plasma is initially filtered out of the glomerular capillaries, causing a slower rise in the glomerular capillary colloid osmotic pressure and less inhibitory effect on GFR. *Consequently, even with a constant glomerular hydrostatic pressure, a greater rate of blood flow into the glomerulus tends to increase GFR and a lower rate of blood flow into the glomerulus tends to decrease GFR.*

INCREASED GLOMERULAR CAPILLARY HYDROSTATIC PRESSURE INCREASES GFR

The glomerular capillary hydrostatic pressure has been estimated to be about 60 mm Hg under normal conditions. Changes in glomerular hydrostatic pressure serve as the primary means for physiological regulation of GFR. Increases in glomerular hydrostatic pressure raise the GFR, whereas decreases in glomerular hydrostatic pressure reduce the GFR.

Glomerular hydrostatic pressure is determined by three variables, each of which is under physiological control: (1) *arterial pressure*; (2) *afferent arteriolar resistance*; and (3) *efferent arteriolar resistance*.

Increased arterial pressure tends to raise glomerular hydrostatic pressure and, therefore, to increase the GFR. However, as discussed later, this effect is buffered by autoregulatory mechanisms that maintain a relatively constant glomerular pressure as arterial pressure fluctuates.

Increased resistance of afferent arterioles reduces glomerular hydrostatic pressure and decreases GFR (**Fig. 27.7**). Conversely, dilation of the afferent arterioles increases glomerular hydrostatic pressure and GFR.

Constriction of the efferent arterioles increases the resistance to outflow from the glomerular capillaries. This

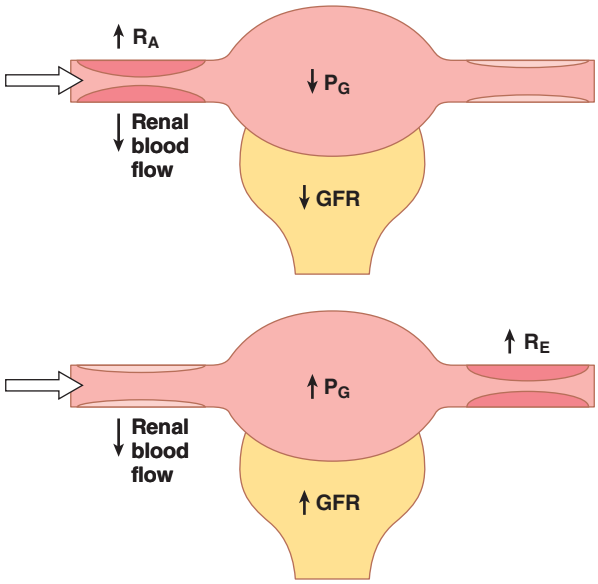

Figure 27.7 Effect of increases in afferent arteriolar resistance (R_A, *top panel*) or efferent arteriolar resistance (R_E, *bottom panel*) on renal blood flow, glomerular hydrostatic pressure (P_G), and glomerular filtration rate (GFR).

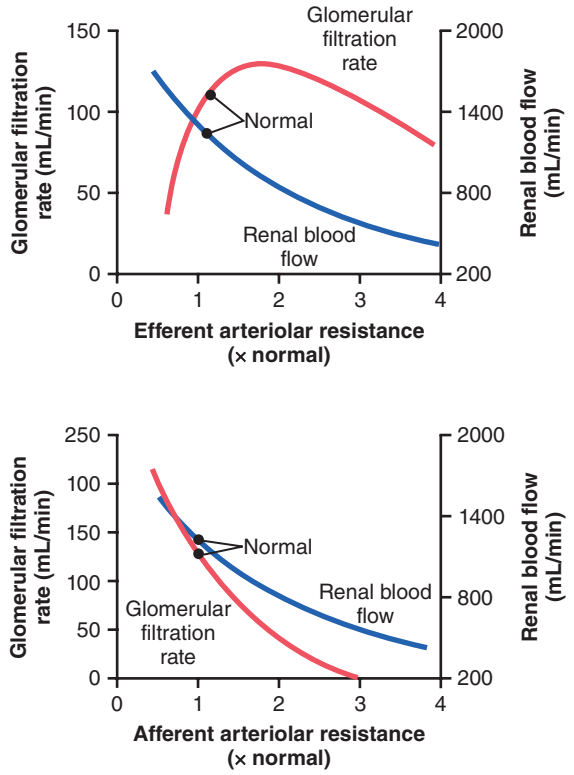

Figure 27.8 Effect of change in afferent arteriolar resistance or efferent arteriolar resistance on glomerular filtration rate and renal blood flow.

mechanism raises glomerular hydrostatic pressure and, as long as the increase in efferent resistance does not reduce renal blood flow too much, GFR increases slightly (see **Fig. 27.7**). However, because efferent arteriolar constriction also reduces renal blood flow, filtration fraction and glomerular colloid osmotic pressure increase as efferent arteriolar resistance increases. Therefore, if constriction of efferent arterioles is severe (more than about a 3-fold increase in efferent arteriolar resistance), the rise in colloid osmotic pressure exceeds the increase in glomerular capillary hydrostatic pressure caused by efferent arteriolar constriction. When this situation occurs, the *net filtration force* actually decreases, causing a reduction in GFR.

Thus, efferent arteriolar constriction has a biphasic effect on GFR (**Fig. 27.8**). At moderate levels of constriction, there is a slight increase in GFR but, with severe constriction, there is a decrease in GFR. The primary cause of the eventual decrease in GFR is as follows. As efferent constriction becomes severe, renal plasma flow progressively decreases, filtration fraction and glomerular plasma protein concentration progressively increase, and there is a rapid nonlinear increase in colloid osmotic pressure caused by the Donnan effect; the higher the protein concentration, the more rapidly the colloid osmotic pressure rises because of the interaction of ions bound to the plasma proteins, which also exert an osmotic effect, as discussed in Chapter 16.

To summarize, constriction of afferent arterioles reduces GFR. However, the effect of efferent arteriolar constriction depends on the severity of the constriction; modest efferent constriction raises GFR, but severe efferent constriction (more than a 3-fold increase in resistance) tends to reduce GFR.

Table 27.2 summarizes the factors that can decrease the GFR.

Table 27.2 Factors That Can Decrease the Glomerular Filtration Rate

Physical Determinants[a]	Physiological or Pathophysiological Causes
↓ K_f → ↓ GFR	Renal disease, diabetes mellitus, hypertension, aging
↑ P_B → ↓ GFR	Urinary tract obstruction (e.g., kidney stones)
↑ π_G → ↓ GFR	↓ Renal blood flow, increased plasma proteins
↓ P_G → ↓ GFR ↓ A_P → ↓ P_G	↓ Arterial pressure (has only a small effect because of autoregulation)
↓ R_E → ↓ P_G	↓ Angiotensin II (drugs that block angiotensin II formation)
↑ R_A → ↓ P_G	↑ Sympathetic activity, vasoconstrictor hormones (e.g., norepinephrine, endothelin)

[a]Opposite changes in the determinants usually increase the GFR. A_P, Systemic arterial pressure; GFR, glomerular filtration rate; K_f, glomerular filtration coefficient; P_B, Bowman capsule hydrostatic pressure; π_G, glomerular capillary colloid osmotic pressure; P_G, glomerular capillary hydrostatic pressure; R_A, afferent arteriolar resistance; R_E, efferent arteriolar resistance.

RENAL BLOOD FLOW

In a 70-kg healthy adult, the combined blood flow through both kidneys is about 1100 mL/min, or about 22% of the cardiac output, although there is considerable variation in renal blood flow depending on body size, age, and sex of the individual, similar to the variations in GFR. Considering that the two kidneys constitute only about 0.4% of the total body weight, one can readily see that they receive extremely high blood flow compared with other organs.

As with other tissues, blood flow supplies the kidneys with nutrients and removes waste products. However, the high blood flow to the kidneys greatly exceeds this need. The purpose of this additional flow is to supply enough plasma for the high rates of glomerular filtration that are necessary for precise regulation of body fluid volumes and solute concentrations. As might be expected, the mechanisms that regulate renal blood flow are closely linked to control of GFR and excretory functions of the kidneys.

Renal Blood Flow and Oxygen Consumption

On a per gram–weight basis, the kidneys normally consume oxygen at twice the rate of the brain but have almost

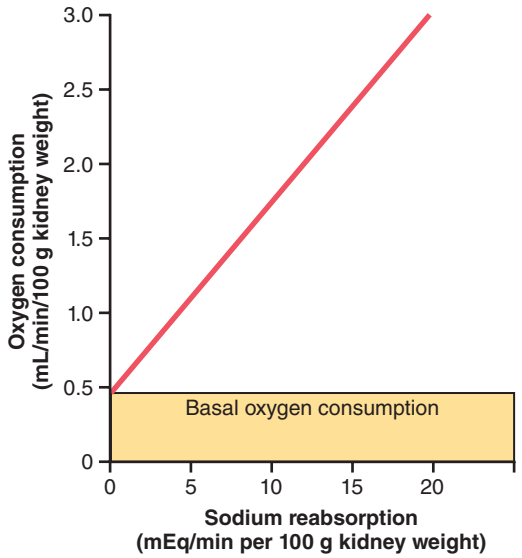

Figure 27.9 Relationship between oxygen consumption and sodium reabsorption in dog kidneys. *(From Kramer K, Deetjen P. Relation of renal oxygen consumption to blood supply and glomerular filtration during variations of blood pressure.* Pflugers Arch Physiol. *1960;271:782.)*

seven times the blood flow of the brain. Thus, the oxygen delivered to the kidneys far exceeds their metabolic needs, and the arterial-venous extraction of oxygen is relatively low compared with that of most other tissues.

A large fraction of the oxygen consumed by the kidneys is related to the high rate of active sodium reabsorption by the renal tubules. If renal blood flow and GFR are reduced, and less sodium is filtered, less sodium is reabsorbed and less oxygen is consumed. Therefore, renal oxygen consumption varies in proportion to renal tubular sodium reabsorption, which in turn is closely related to GFR and the rate of sodium filtered (**Fig. 27.9**). If glomerular filtration ceases completely, renal sodium reabsorption also ceases and oxygen consumption decreases to about one-fourth normal. This residual oxygen consumption reflects the basic metabolic needs of the renal cells.

Determinants of Renal Blood Flow

Renal blood flow (RBF) is determined by the pressure gradient across the renal vasculature (the difference between renal artery and renal vein hydrostatic pressures), divided by the total renal vascular resistance:

$$\text{RBF} = \frac{(\text{Renal artery pressure} - \text{Renal vein pressure})}{\text{Total renal vascular resistance}}$$

Renal artery pressure is about equal to systemic arterial pressure, and renal vein pressure averages about 3 to 4 mm Hg under most conditions. As in other vascular beds, the total vascular resistance through the kidneys is determined by the sum of the resistances in the individual vasculature segments, including the arteries, arterioles, capillaries, and veins (**Table 27.3**).

Table 27.3 Approximate Pressures and Vascular Resistances in Circulation of a Normal Kidney

Vessel	*Pressure in Vessel (mm Hg)*		Percentage of Total Renal Vascular Resistance
	Beginning	End	
Renal artery	100	100	~0
Interlobar, arcuate, and interlobular arteries	~100	85	~16
Afferent arteriole	85	60	~26
Glomerular capillaries	60	59	~1
Efferent arteriole	59	18	~43
Peritubular capillaries	18	8	~10
Interlobar, interlobular, and arcuate veins	8	4	~4
Renal vein	4	~4	~0

Most of the renal vascular resistance resides in three major segments—interlobular arteries, afferent arterioles, and efferent arterioles. Resistance of these vessels is controlled by the sympathetic nervous system, various hormones, and local internal renal control mechanisms, as discussed later. An increase in the resistance of any of the vascular segments of the kidneys tends to reduce the renal blood flow, whereas a decrease in vascular resistance increases renal blood flow if renal artery and renal vein pressures remain constant.

Although changes in arterial pressure have some influence on renal blood flow, the kidneys have effective mechanisms for maintaining renal blood flow and GFR relatively constant over an arterial pressure range between 80 and 170 mm Hg, a process called *autoregulation*. This capacity for autoregulation occurs through mechanisms that are intrinsic to the kidneys, as discussed later in this chapter.

Blood Flow in Vasa Recta of Renal Medulla Is Low Compared With Renal Cortex Flow

The outer part of the kidney, the renal cortex, receives most of the kidney's blood flow. The renal medulla receives only 1% to 2% of the total renal blood flow. Flow to the renal medulla is supplied by a specialized portion of the peritubular capillary system called the *vasa recta*. These vessels descend into the medulla in parallel with the loops of Henle and then return with the loops of Henle to the cortex before emptying into the venous system. As discussed in Chapter 29, the vasa recta play an important role in allowing the kidneys to form concentrated urine.

PHYSIOLOGICAL CONTROL OF GFR AND RENAL BLOOD FLOW

The determinant of GFR that is most variable and subject to physiological control is the glomerular hydrostatic

pressure. This variable, in turn, is influenced by the sympathetic nervous system, hormones, autacoids (vasoactive substances that are released in the kidneys and act locally), and other feedback controls that are intrinsic to the kidneys.

STRONG SYMPATHETIC NERVOUS SYSTEM ACTIVATION DECREASES GFR

Most of the kidney blood vessels, including the afferent and efferent arterioles, are richly innervated by sympathetic nerve fibers. Strong activation of the renal sympathetic nerves can constrict the renal arterioles and decrease renal blood flow and GFR. Moderate or mild sympathetic stimulation, however, has little influence on renal blood flow and GFR. For example, reflex activation of the sympathetic nervous system resulting from moderate decreases in pressure at the carotid sinus baroreceptors or cardiopulmonary receptors does not substantially alter renal blood flow or GFR. However, as discussed in Chapter 28, even mild increases in renal sympathetic activity can stimulate renin release and increase renal tubular reabsorption, causing decreased sodium and water excretion.

The renal sympathetic nerves seem to be the most important in reducing GFR during severe acute disturbances lasting for a few minutes to a few hours, such as those elicited by the defense reaction, brain ischemia, severe hemorrhage, or heavy exercise.

Hormonal and Autacoid Control of Renal Circulation

Several hormones and autacoids can influence GFR and renal blood flow, as summarized in **Table 27.4**.

Norepinephrine, Epinephrine, and Endothelin Constrict Renal Blood Vessels and Decrease GFR and Renal Blood Flow. Hormones that constrict afferent and efferent arterioles, causing reductions in GFR and renal blood flow, include *norepinephrine* and *epinephrine* released from the adrenal medulla. In general, blood levels of these hormones parallel activity of the sympathetic nervous system; thus, norepinephrine and epinephrine have little influence on renal hemodynamics except under conditions associated with strong activation of the sympathetic nervous system, such as severe hemorrhage.

Another vasoconstrictor, *endothelin*, is a peptide that is released by damaged vascular endothelial cells of the kidneys, as well as by other tissues. The physiological role of this autacoid is complex. Endothelin may contribute to hemostasis (minimizing blood loss) when a blood vessel is severed, which damages the endothelium and releases this powerful vasoconstrictor. Plasma endothelin levels are also increased in many disease states associated with endothelial injury, such as toxemia of pregnancy, acute renal failure, and chronic uremia, and may contribute to renal vasoconstriction and decreased GFR in some of these pathophysiological conditions.

Table 27.4 Hormones and Autacoids That Influence the Glomerular Filtration Rate (GFR) and Renal Blood Flow (RBF)

Hormone or Autacoid	Effect on GFR	Effect on RBF
Norepinephrine	↓	↓
Epinephrine	↓	↓
Endothelin	↓	↓
Angiotensin II	↔ (prevents ↓)	↓
Endothelial-derived nitric oxide	↑	↑
Prostaglandins	↑	↑

Angiotensin II Preferentially Constricts Efferent Arterioles in Most Physiological Conditions and Reduces Renal Blood Flow While Attenuating Decreases in GFR. A powerful renal vasoconstrictor, *angiotensin II*, can be considered to be a circulating hormone and a locally produced *autacoid* or *paracrine hormone* because it is formed in the kidneys and in the systemic circulation. Receptors for angiotensin II are present in virtually all blood vessels of the kidneys. However, the preglomerular blood vessels, especially the afferent arterioles, appear to be relatively protected from angiotensin II–mediated constriction in most physiological conditions associated with activation of the renin-angiotensin system, such as during a low-sodium diet or reduced renal perfusion pressure due to renal artery stenosis. This protection is due to release of vasodilators, especially *nitric oxide* and *prostaglandins*, which counteract the vasoconstrictor effects of angiotensin II in these blood vessels.

The efferent arterioles, however, are highly sensitive to angiotensin II. Because angiotensin II preferentially constricts efferent arterioles in most physiological conditions, increased angiotensin II levels tend to raise glomerular hydrostatic pressure while reducing renal blood flow. It should be kept in mind, however, that increased angiotensin II formation usually occurs in circumstances associated with decreased arterial pressure or volume depletion, which tend to decrease GFR. In these circumstances, the increased angiotensin II, by constricting efferent arterioles, helps *prevent* decreases in glomerular hydrostatic pressure and GFR. At the same time, the reduction in renal blood flow caused by efferent arteriolar constriction contributes to decreased flow through the peritubular capillaries, which, in turn, increases renal tubular reabsorption of sodium and water, as discussed in Chapter 28.

Thus, increased angiotensin II levels that occur with a low-sodium diet or volume depletion help maintain GFR and normal excretion of metabolic waste products, such as urea and creatinine, which depend on glomerular filtration for their excretion. At the same time, the angiotensin II–induced constriction of efferent arterioles increases tubular reabsorption of sodium and water, which helps restore blood volume and blood pressure. This effect of

angiotensin II in helping autoregulate GFR is discussed in more detail later in this chapter.

Endothelial-Derived Nitric Oxide Decreases Renal Vascular Resistance and Increases GFR and Renal Blood Flow. An autacoid that decreases renal vascular resistance and is released by the vascular endothelium throughout the body is *endothelial-derived nitric oxide*. A basal level of nitric oxide production appears to be important for maintaining vasodilation of the kidneys and normal excretion of sodium and water. Therefore, administration of drugs that inhibit formation of nitric oxide increases renal vascular resistance and decreases GFR and urinary sodium excretion, eventually causing high blood pressure. In some patients with hypertension or atherosclerosis, damage of the vascular endothelium and impaired nitric oxide production may contribute to increased renal vasoconstriction and elevated blood pressure.

Prostaglandins and Bradykinin Decrease Renal Vascular Resistance and Tend to Increase GFR and Renal Blood Flow. Prostaglandins (PGE2 and PGI2) and bradykinin serve as hormones and autacoids that cause vasodilation, increased renal blood flow, and increased GFR. These substances are discussed in Chapter 17. Although these vasodilators do not appear to be of major importance in regulating renal blood flow or the GFR in normal conditions, they may dampen the renal vasoconstrictor effects of the sympathetic nerves or angiotensin II, especially their effects to constrict the afferent arterioles.

By opposing vasoconstriction of afferent arterioles, the prostaglandins help prevent excessive reductions in GFR and renal blood flow. Under stressful conditions, such as volume depletion or after surgery, administration of nonsteroidal antiinflammatory drugs (NSAIDs), such as aspirin, that inhibit prostaglandin synthesis may cause significant reductions in GFR.

AUTOREGULATION OF GFR AND RENAL BLOOD FLOW

Feedback mechanisms intrinsic to the kidneys normally keep renal blood flow and GFR relatively constant, despite marked changes in arterial blood pressure. These mechanisms still function in blood-perfused kidneys that have been removed from the body, independent of systemic influences. This relative constancy of GFR and renal blood flow is referred to as *autoregulation* (**Fig. 27.10**).

The primary function of blood flow autoregulation in most tissues, other than the kidneys, is to maintain delivery of oxygen and nutrients at a normal level and remove the waste products of metabolism, despite changes in arterial pressure. In the kidneys, the normal blood flow is much higher than that required for these functions. The major function of autoregulation in the kidneys is to maintain a relatively constant GFR and allow precise control of renal excretion of water and solutes.

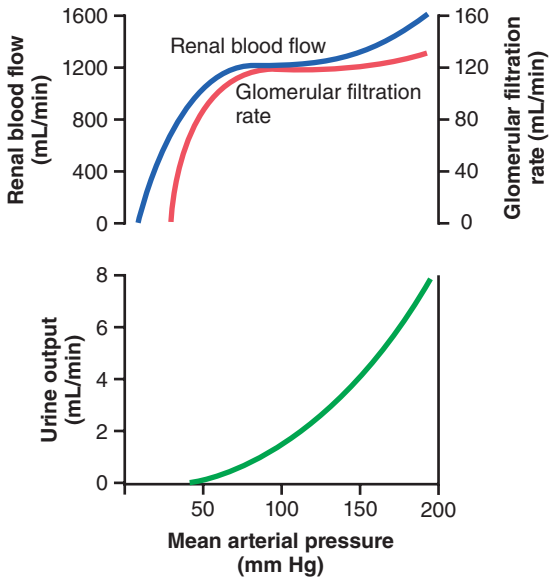

Figure 27.10 Autoregulation of renal blood flow and glomerular filtration rate but lack of autoregulation of urine flow during changes in renal arterial pressure.

The GFR normally remains relatively constant, despite considerable arterial pressure fluctuations that occur during a person's usual activities. For example, a decrease in arterial pressure to as low as 70 to 75 mm Hg or an increase to as high as 160 to 180 mm Hg usually changes the GFR less than 10%. In general, renal blood flow is autoregulated in parallel with GFR, but GFR is more efficiently autoregulated under certain conditions.

Importance of GFR Autoregulation in Preventing Extreme Changes in Renal Excretion

Although renal autoregulatory mechanisms are not perfect, they do prevent potentially large changes in GFR and renal excretion of water and solutes that would otherwise occur with changes in blood pressure. One can understand the quantitative importance of autoregulation by considering the relative magnitudes of glomerular filtration, tubular reabsorption, and renal excretion and the changes in renal excretion that would occur without autoregulatory mechanisms.

Normally, GFR is about 180 L/day, and tubular reabsorption is 178.5 L/day, leaving 1.5 L/day of fluid to be excreted in the urine. In the absence of autoregulation, a relatively small increase in blood pressure (from 100 to 125 mm Hg) would cause a similar 25% increase in GFR (from about 180 to 225 L/day). If tubular reabsorption remained constant at 178.5 L/day, the urine flow would increase to 46.5 L/day (the difference between GFR and tubular reabsorption)—a total increase in urine of more than 30-fold. Because the total plasma volume is only about 3 liters, such a change would quickly deplete the blood volume.

In reality, changes in arterial pressure usually exert much less effect on urine volume for two reasons: (1) renal autoregulation prevents large changes in GFR that would otherwise occur; and (2) there are additional adaptive mechanisms in the renal tubules that cause them to increase their reabsorption rate when GFR rises, a phenomenon called *glomerulotubular balance* (discussed in Chapter 28). Even with these special control mechanisms, changes in arterial pressure still have significant effects on renal excretion of water and sodium; this effect is referred to as *pressure diuresis* or *pressure natriuresis*, and it is crucial in the regulation of body fluid volumes and arterial pressure, as discussed in Chapters 19 and 30.

TUBULOGLOMERULAR FEEDBACK AND AUTOREGULATION OF GFR

The kidneys have a special *tubuloglomerular feedback* (TGF) mechanism that links changes in the sodium chloride concentration at the *macula densa* with the control of renal arteriolar resistance and autoregulation of GFR. This feedback helps ensure a relatively constant delivery of sodium chloride to the distal tubule and prevents spurious fluctuations in renal excretion that would otherwise occur. In many circumstances, this feedback autoregulates renal blood flow and GFR in parallel. However, because this mechanism is specifically directed toward stabilizing sodium chloride delivery to the distal tubule, instances occur when GFR is autoregulated at the expense of changes in renal blood flow, as discussed later. In other cases, this mechanism may actually cause changes in GFR in response to primary changes in renal tubular sodium chloride reabsorption.

The TGF mechanism has two components that act together to control GFR: (1) an afferent arteriolar feedback mechanism; and (2) an efferent arteriolar feedback mechanism. These feedback mechanisms depend on special anatomical arrangements of the *juxtaglomerular complex* (**Fig. 27.11**).

The juxtaglomerular complex consists of *macula densa cells* in the initial portion of the distal tubule and *juxtaglomerular cells* in the walls of the afferent and efferent arterioles. The macula densa is a specialized group of epithelial cells in the distal tubules that comes in close contact with the afferent and efferent arterioles. The macula densa cells contain the Golgi apparatus, which consists of intracellular secretory organelles directed toward the arterioles, suggesting that these cells may be secreting a substance toward the arterioles.

Increased Macula Densa Sodium Chloride Causes Vasoconstriction of Afferent Arterioles and Decreased Renin Release, Whereas Decreased Macula Densa Sodium Chloride Has the Opposite Effects. Macula densa cells sense changes in sodium chloride delivery to the distal tubule by way of signals that are not completely understood but likely involve *adenosine*, as

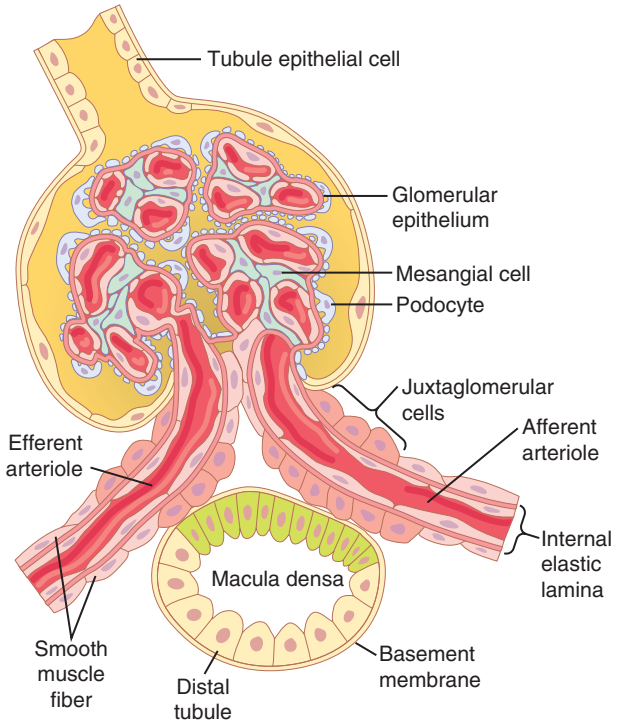

Figure 27.11 Structure of the juxtaglomerular apparatus, demonstrating its possible feedback role in the control of nephron function.

follows. Increased GFR tends to increase sodium chloride delivery to the macula densa cells, which activates the sodium-potassium-chloride co-transporter in these cells (discussed in Chapter 28), inducing depolarization and release of ATP. The ATP is ultimately converted to adenosine, which constricts the afferent arterioles, reducing glomerular hydrostatic pressure and helping to return GFR toward normal.

Several other factors may also be involved in transmitting signals from the macula densa cells to the afferent and efferent arterioles, or in altering TGF sensitivity. For example, angiotensin II enhances TGF sensitivity, whereas nitric oxide and some prostaglandins decrease TGF sensitivity. These modulators of TGF sensitivity appear to be important in regulating sodium chloride excretion. For example, increased sodium chloride intake and expansion of extracellular fluid volume lead to reductions in renin release and formation of angiotensin II, which has multiple effects to reduce sodium tubular sodium reabsorption and increase sodium excretion, as discussed in Chapter 28. Another important effect of decreased angiotensin II, however, is reduced TGF sensitivity, which permits increased sodium chloride delivery to the macula densa and distal tubules without causing a TGF-mediated constriction of afferent arterioles and decreased GFR.

Decreased GFR has the opposite effect, slowing delivery of sodium chloride to the macula densa cells and causing two effects (**Fig. 27.12**): (1) decreased resistance to blood flow in the afferent arterioles, which raises glomerular hydrostatic pressure and helps return GFR toward

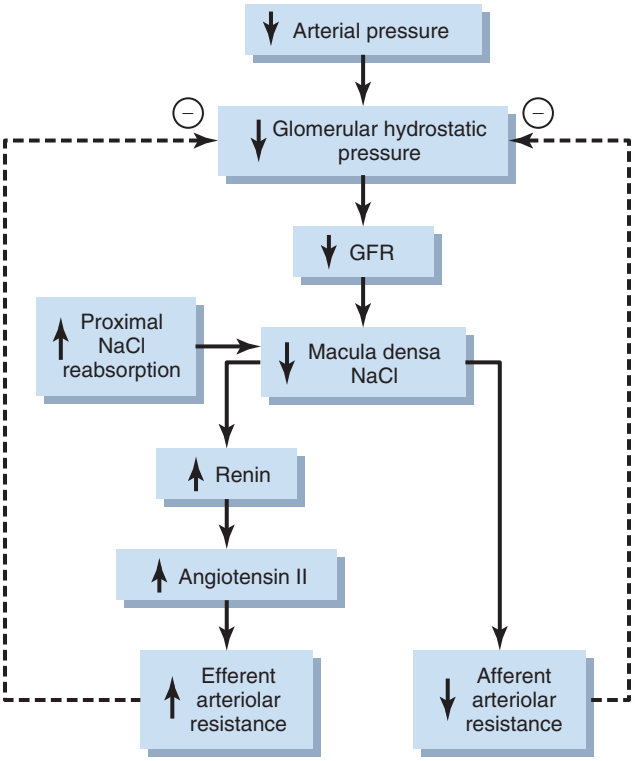

Figure 27.12 Macula densa feedback mechanism for autoregulation of glomerular hydrostatic pressure and glomerular filtration rate (GFR) during decreased renal arterial pressure.

normal; and (2) increased renin release from the juxtaglomerular cells of the afferent and efferent arterioles, which are the major storage sites for renin. Renin released from these cells then functions as an enzyme to increase formation of angiotensin I, which is converted to angiotensin II. Finally, angiotensin II constricts the efferent arterioles, thereby increasing glomerular hydrostatic pressure and helping return GFR toward normal.

These two components of the tubuloglomerular feedback mechanism, operating together by way of the special anatomical structure of the juxtaglomerular apparatus, provide feedback signals to the afferent and efferent arterioles for efficient autoregulation of GFR during changes in arterial pressure. When both of these mechanisms are functioning together, GFR changes by only a few percentage points, even with large fluctuations in arterial pressure between the limits of 75 and 160 mm Hg.

Blockade of Angiotensin II Formation During Renal Hypoperfusion Further Reduces GFR. As discussed earlier, a preferential constrictor action of angiotensin II on efferent arterioles helps prevent serious reductions in glomerular hydrostatic pressure and GFR when renal perfusion pressure falls below normal. Administration of drugs that block formation of angiotensin II (e.g., angiotensin-converting enzyme inhibitors) or that block the action of angiotensin II (e.g., angiotensin II receptor antagonists) may cause greater reductions in GFR than usual when renal arterial pressure falls below normal. Therefore, an important complication of using these drugs to treat patients who have hypertension because of renal artery stenosis (partial blockage of the renal artery) is a severe decrease in GFR that can, in some cases, cause acute renal failure. Nevertheless, angiotensin II–blocking drugs are important therapeutic agents in many patients with hypertension, congestive heart failure, and other conditions, as long as the patients are monitored to ensure that severe decreases in GFR do not occur.

MYOGENIC AUTOREGULATION OF RENAL BLOOD FLOW AND GLOMERULAR FILTRATION RATE

Another mechanism that contributes to the maintenance of a relatively constant renal blood flow and GFR is the ability of individual blood vessels to resist stretching during increased arterial pressure, referred to as the *myogenic mechanism*. Studies of individual blood vessels (especially small arterioles) throughout the body have shown that they respond to increased wall tension or wall stretch by contraction of the vascular smooth muscle. Stretch of the vascular wall allows increased movement of calcium ions from the extracellular fluid into the cells, causing them to contract through the mechanisms discussed in Chapter 8. This contraction prevents excessive stretch of the vessel and, by raising vascular resistance, helps prevent excessive increases in renal blood flow and the GFR when arterial pressure increases.

Although the myogenic mechanism operates in most arterioles throughout the body, its importance in renal blood flow and GFR autoregulation has been questioned by some physiologists because this pressure-sensitive mechanism has no means of directly detecting changes in renal blood flow or GFR per se. On the other hand, this mechanism may be more important in protecting the kidney from hypertension-induced injury. In response to sudden increases in blood pressure, the myogenic constrictor response in afferent arterioles occurs within seconds and therefore attenuates transmission of increased arterial pressure to the glomerular capillaries.

High Protein Intake and Hyperglycemia Increase Renal Blood Flow and GFR. Although renal blood flow and GFR are relatively stable under most conditions, there are circumstances in which these variables change significantly. For example, *a high protein intake is known to increase renal blood flow and GFR*. With a long-term, high-protein diet, such as one that contains large amounts of meat, increases in GFR and renal blood flow are due partly to growth of the kidneys. However, the GFR and renal blood flow also increase 20% to 30% within 1 or 2 hours after a person eats a high-protein meal.

One likely explanation for the increased GFR is the following. Digestion of a high-protein meal releases into the

blood amino acids, which are reabsorbed in the proximal tubules. Because amino acids and sodium are reabsorbed together by co-transport in the proximal tubules, increased amino acid reabsorption also stimulates sodium reabsorption. This increased reabsorption of sodium decreases sodium delivery to the macula densa (**Fig. 27.13**), which elicits a tubuloglomerular feedback–mediated decrease in resistance of the afferent arterioles, as discussed earlier. The decreased afferent arteriolar resistance then raises renal blood flow and GFR, allowing sodium excretion to be maintained at a nearly normal level while increasing excretion of the waste products of protein metabolism, such as urea.

A similar mechanism may also explain the marked increases in renal blood flow and the GFR that occur with large increases in blood glucose levels in persons with uncontrolled diabetes mellitus. Because glucose, like some of the amino acids, is also reabsorbed along with sodium in the proximal tubule, increased glucose delivery to the tubules causes them to reabsorb excess sodium along with glucose. This increased reabsorption of sodium, in turn, decreases the sodium chloride concentration at the macula densa, activating a tubuloglomerular feedback–mediated dilation of the afferent arterioles and subsequent increases in renal blood flow and GFR.

These examples demonstrate that renal blood flow and GFR per se are not the primary variables controlled by the tubuloglomerular feedback mechanism. The main purpose of this feedback is to ensure a constant delivery of sodium chloride to the distal tubule, where final processing of the urine takes place. Thus, disturbances that tend to increase the reabsorption of sodium chloride at tubular sites before the macula densa often elicit increased renal blood flow and GFR, which helps return distal sodium chloride delivery toward normal so that normal rates of sodium and water excretion can be maintained (see **Fig. 27.13**).

An opposite sequence of events occurs when proximal tubular reabsorption is reduced. For example, when the proximal tubules are damaged (which can occur as a result of poisoning by heavy metals, such as mercury, or large doses of drugs, such as tetracyclines), their ability to reabsorb sodium chloride is decreased. As a consequence, large amounts of sodium chloride are delivered to the distal tubule and, without appropriate compensation, would quickly cause excessive volume depletion. One of the important compensatory responses appears to be a tubuloglomerular feedback–mediated renal vasoconstriction. These examples again demonstrate the importance of this feedback mechanism for ensuring that the distal tubules receive the proper rate of delivery of sodium chloride, other tubular fluid solutes, and tubular fluid volume so that appropriate amounts of these substances are excreted in the urine.

Other Factors That Influence Renal Blood Flow and GFR. Renal blood flow and GFR are low at birth, approach normal adult levels after about 2 years of life, and in the absence of kidney disease, are maintained relatively constant until the fourth decade. Thereafter, GFR declines by about 5% to 10% per decade, although there is considerable variability among individuals. This decline in GFR coincides with nitric oxide deficiency, increased oxidative stress, and loss of functional nephrons, which may be related partly to increasing blood pressure, metabolic disorders, and other insults that cause cumulative glomerular injury with aging.

Men have higher renal blood flow and GFR than women, even when corrected for body mass. However, men also have a more rapid decline in GFR with aging than premenopausal women. Although the mechanisms responsible for these sex differences are not fully understood, beneficial effects of estrogens and damaging effects of androgens on the kidneys have been suggested as partial explanations. **Table 27.5** summarizes some additional factors that influence renal blood flow and GFR regulation, and that should be considered when assessing kidney function.

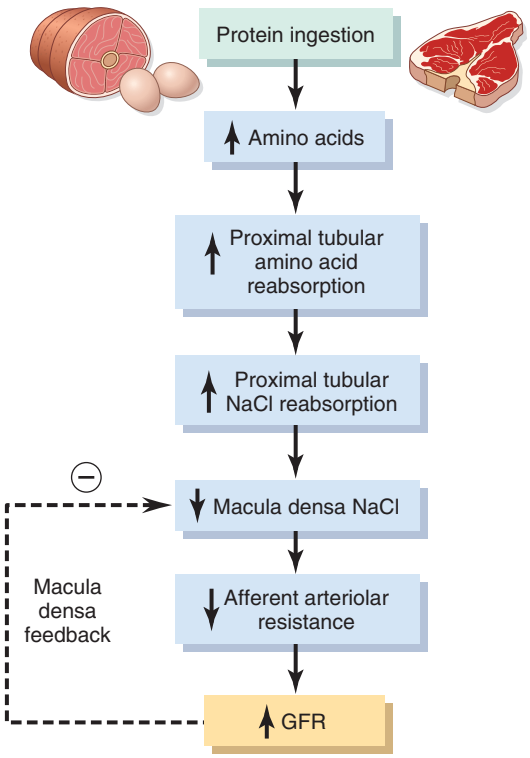

Figure 27.13 Possible role of macula densa feedback in mediating increased glomerular filtration rate (GFR) after a high-protein meal.

Table 27.5 Some Conditions That Influence Renal Blood Flow (RBF) and the Glomerular Filtration Rate (GFR)

Condition	RBF	GFR
Aging	↓	↓
High dietary protein	↑	↑
Hyperglycemia[a]	↑	↑
Obesity[a]	↑	↑
High NaCl intake[a]	↑	↑
Glucocorticoids	↑	↑
Fever, pyrogens	↑	↑

[a]Refers to early effects, prior to development of glomerular injury that may occur with chronic hyperglycemia, obesity, and high salt intake.

CHAPTER 28

Renal Tubular Reabsorption and Secretion

As the glomerular filtrate enters the renal tubules, it flows sequentially through the successive parts of the tubules—the *proximal tubules, loops of Henle, distal tubules, collecting tubules,* and *collecting ducts*—before it is excreted as urine. Along this course, some substances are selectively reabsorbed from the tubules back into the blood, whereas others are secreted from the blood into the tubular lumen. Eventually, the urine that is formed and all the substances in the urine represent the sum of three basic renal processes—glomerular filtration, tubular reabsorption, and tubular secretion:

$$\text{Urinary excretion} = \text{Glomerular filtration} - \text{Tubular reabsorption} + \text{Tubular secretion}$$

For many substances, tubular reabsorption plays a much more important role than secretion in determining the final urinary excretion rate. However, tubular secretion accounts for significant amounts of potassium ions, hydrogen ions, and a few other substances that appear in the urine.

TUBULAR REABSORPTION IS QUANTITATIVELY LARGE AND HIGHLY SELECTIVE

Table 28.1 shows the renal handling of several substances that are all freely filtered by the kidney glomeruli and reabsorbed at variable rates. The rate at which each of these substances is filtered is calculated as follows:

$$\text{Filtration} = \text{Glomerular filtration rate} \times \text{Plasma concentration}$$

This calculation assumes that the substance is freely filtered and not bound to plasma proteins. For example, if plasma glucose concentration is 1 g/L, the amount of glucose filtered each day is about 180 L/day × 1 g/L, or 180 g/day. Because virtually none of the filtered glucose is normally excreted, the rate of glucose reabsorption is also 180 g/day.

From **Table 28.1**, two things are immediately apparent. First, the processes of glomerular filtration and tubular reabsorption are quantitatively large relative to urinary excretion for many substances. Thus, a small change in glomerular filtration or tubular reabsorption can potentially cause a relatively large change in urinary excretion. For example, a 10% decrease in tubular reabsorption, from 178.5 to 160.7 L/day, would increase urine volume from 1.5 to 19.3 L/day (almost a 13-fold increase) if glomerular filtration rate (GFR) remained constant. In reality, changes in tubular reabsorption and glomerular filtration are closely coordinated to prevent large fluctuations in urinary excretion.

Second, unlike glomerular filtration, which is relatively nonselective (essentially all solutes in the plasma are filtered except the plasma proteins or substances bound to them), *tubular reabsorption is highly selective*. Some substances, such as glucose and amino acids, are almost completely reabsorbed from the tubules, so the urinary excretion rate is essentially zero. Many ions in the plasma, such as sodium, chloride, and bicarbonate, are also highly reabsorbed, but their rates of reabsorption and urinary excretion are variable, depending on the needs of the body. In contrast, waste products such as urea and creatinine are poorly reabsorbed from the tubules and are excreted in relatively large amounts.

Therefore, by controlling their tubular reabsorption or secretion of different substances, the kidneys can regulate excretion of solutes independently of one another, a capability that is essential for precise control of the body fluid composition. In this chapter, we discuss the mechanisms that allow the kidneys to selectively reabsorb or secrete different substances at variable rates.

TUBULAR REABSORPTION INCLUDES PASSIVE AND ACTIVE MECHANISMS

For a substance to be reabsorbed, it must first be transported (1) across the tubular epithelial membranes into the renal interstitial fluid and then (2) through the peritubular capillary membrane back into the blood (**Fig. 28.1**). Thus, reabsorption of water and solutes includes a series of transport steps. Reabsorption across the tubular epithelium into the interstitial fluid includes active or passive transport by the same basic mechanisms discussed in Chapter 4 for transport across other cell membranes of the body. For example, water and solutes can be transported through the cell membranes *(transcellular route)*

Table 28.1 Filtration, Reabsorption, and Excretion Rates of Different Substances by the Kidneys

Substance	Amount Filtered	Amount Reabsorbed	Amount Excreted	% of Filtered Load Reabsorbed
Glucose (g/day)	180	180	0	100
Bicarbonate (mEq/day)	4320	4318	2	>99.9
Sodium (mEq/day)	25,560	25,410	150	99.4
Chloride (mEq/day)	19,440	19,260	180	99.1
Potassium (mEq/day)	756	664	92	87.8
Urea (g/day)	46.8	23.4	23.4	50
Creatinine (g/day)	1.8	0	1.8	0

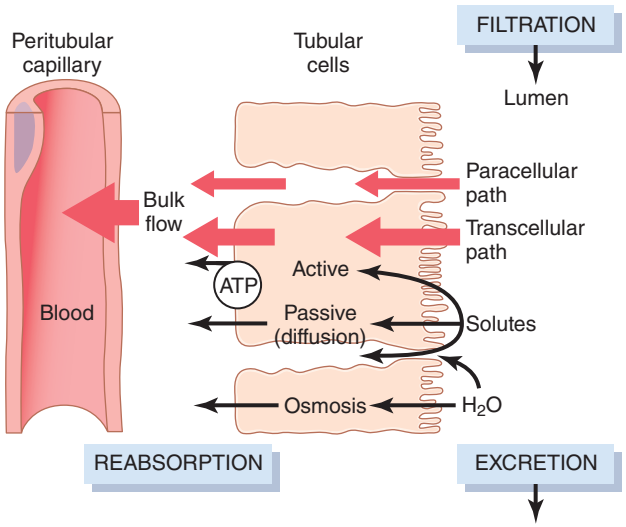

Figure 28.1 Reabsorption of filtered water and solutes from the tubular lumen across the tubular epithelial cells, through the renal interstitium, and back into the blood. Solutes are transported through the cells (*transcellular path*) by passive diffusion or active transport, or between the cells (*paracellular path*) by diffusion. Water is transported through the cells and between the tubular cells by osmosis. Transport of water and solutes from the interstitial fluid into the peritubular capillaries occurs by ultrafiltration (*bulk flow*).

or through the spaces between the cell junctions *(paracellular route)*. Then, after absorption across the tubular epithelial cells into the interstitial fluid, water and solutes are transported through the peritubular capillary walls into the blood by *ultrafiltration (bulk flow)* that is mediated by hydrostatic and colloid osmotic forces. The peritubular capillaries behave like the venous ends of most other capillaries because there is a net reabsorptive force that moves the fluid and solutes from the interstitium into the blood.

ACTIVE TRANSPORT

Active transport can move a solute against an electrochemical gradient; this requires energy derived from metabolism. Transport that is coupled directly to an energy source, such as the hydrolysis of adenosine triphosphate (ATP), is termed *primary active transport*. An example of this mechanism is the sodium-potassium adenosine triphosphatase (ATPase) pump (Na^+-K^+ ATPase pump) that functions throughout most parts of the renal tubule, as well as in other cells of the body. Transport that is coupled *indirectly* to an energy source, such as that due to an ion gradient, is referred to as *secondary active transport*. Reabsorption of glucose by the renal tubule is an example of secondary active transport. Although solutes can be reabsorbed by active and/or passive mechanisms by the tubule, water is always reabsorbed passively across the tubular epithelial membrane by *osmosis*.

Solutes Can Be Transported Through Epithelial Cells or Between Cells. Renal tubular cells, like other epithelial cells, are held together by *tight junctions*. Lateral intercellular spaces lie behind the tight junctions and separate the epithelial cells of the tubule. Solutes can be reabsorbed or secreted across the cells through the *transcellular pathway* or between the cells by moving across the tight junctions and intercellular spaces via the *paracellular pathway*.

The tight junctions contain an array of proteins, including *occludin*, *claudins*, and *junctional adhesion molecules*, that fuse the epithelial cells together and regulate paracellular movement of water and solutes. In mammalian kidneys, variations in tight junction proteins contribute to more than a 100-fold decrease in paracellular permeability from the proximal tubule to the collecting duct. The tight junction proteins also determine selectivity for paracellular movement of different substances, forming pores as well as barriers. For example, proximal tubule claudins play a role in the paracellular reabsorption of salt and water. In the thick ascending loop of Henle, claudins are important for paracellular calcium and magnesium reabsorption and are regulated by the calcium-sensing receptor. In the distal nephron, claudins form tight barriers to paracellular movement of cations.

Some substances, such as sodium, are transported through paracellular and transcellular pathways. In some nephron segments, especially the proximal tubule, water is also reabsorbed across the paracellular pathway, and substances dissolved in the water, especially sodium, potassium, magnesium, and chloride ions, are carried with the reabsorbed fluid between the cells.

Primary Active Transport Through the Tubular Membrane Is Linked to Hydrolysis of Adenosine Triphosphatase. *The special importance of primary active transport is that it can move solutes against an electrochemical gradient.* The energy for this active transport comes from hydrolysis of ATP by way of membrane-bound ATPase, which is also a component of the carrier mechanism that binds and moves solutes across the cell membranes. The primary active transporters in the kidneys that are known include *Na^+-K^+ ATPase, hydrogen ATPase, hydrogen-potassium ATPase*, and *calcium ATPase*.

A good example of primary active transport is the reabsorption of sodium ions across the proximal tubular membrane, as shown in **Fig. 28.2**. On the basolateral sides of the tubular epithelial cell, the cell membrane has extensive Na^+-K^+ ATPase that hydrolyzes ATP and uses the released energy to transport sodium ions out of the cell into the interstitium. At the same time, potassium is transported from the interstitial fluid to the inside of the cell. The operation of this ion pump maintains low intracellular sodium and high intracellular potassium concentrations and creates a net negative charge of about −70 millivolts within the cell. This active pumping of sodium out of the cell across the *basolateral* membrane favors passive diffusion of sodium across the *luminal* membrane of the cell, from the tubular lumen into the cell, for two reasons: (1) there is a concentration gradient favoring sodium diffusion into the cell because the intracellular sodium concentration is low (12 mEq/L) and tubular fluid sodium concentration is high (140 mEq/L); and (2) the negative, −70-millivolt, intracellular potential attracts the positive sodium ions from the tubular lumen into the cell.

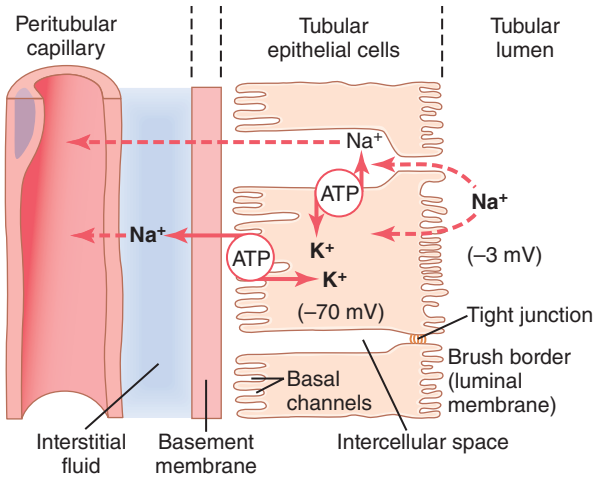

Figure 28.2 Basic mechanism for active transport of sodium through the tubular epithelial cell. The sodium-potassium pump transports sodium from the interior of the cell across the basolateral membrane, creating a low intracellular sodium concentration and a negative intracellular electrical potential. The low intracellular sodium concentration and negative electrical potential cause sodium ions to diffuse from the tubular lumen into the cell through the brush border.

Active reabsorption of sodium by Na^+-K^+ ATPase occurs in most parts of the tubule. In certain parts of the nephron, there are also additional provisions for moving large amounts of sodium into the cell. In the proximal tubule, there is an extensive brush border on the luminal side of the membrane (the side that faces the tubular lumen) that multiplies the surface area by about 20-fold. There are also carrier proteins that bind sodium ions on the luminal surface of the membrane and release them inside the cell, providing *facilitated diffusion* of sodium through the membrane into the cell. These sodium carrier proteins are also important for secondary active transport of other substances, such as glucose and amino acids, as discussed later.

Thus, the net *transcellular* reabsorption of sodium ions from the tubular lumen back into the blood involves at least three steps:

1. Sodium diffuses across the luminal membrane (also called the *apical membrane*) into the cell down an electrochemical gradient established by the Na^+-K^+ ATPase pump on the basolateral side of the membrane.
2. Sodium is transported across the basolateral membrane against an electrochemical gradient by the Na^+-K^+ ATPase pump.
3. Sodium, water, and other substances are reabsorbed from the interstitial fluid into the peritubular capillaries by ultrafiltration, a passive process driven by the hydrostatic and colloid osmotic pressure gradients.

Secondary Active Reabsorption Through the Tubular Membrane. In secondary active transport, two or more substances interact with a specific membrane protein (a carrier molecule) and are transported together across the membrane. As one of the substances (e.g., sodium) diffuses down its electrochemical gradient, the energy released is used to drive another substance (e.g., glucose) against its electrochemical gradient. Thus, secondary active transport does not require energy directly from ATP or from other high-energy phosphate sources. Rather, the direct source of the energy is that liberated by the simultaneous facilitated diffusion of another transported substance down its own electrochemical gradient.

Fig. 28.3 shows secondary active reabsorption of glucose and amino acids in the proximal tubule. In both cases, specific carrier proteins in the brush border combine with a sodium ion and an amino acid or a glucose molecule at the same time. These transport mechanisms are so efficient that they remove virtually all the glucose and amino acids from the tubular lumen. After entry into the cell, glucose and amino acids exit across the basolateral membranes by diffusion, driven by the high glucose and amino acid concentrations in the cell facilitated by specific transport proteins.

Sodium glucose co-transporters (SGLT2 and *SGLT1)* are located on the brush border of proximal tubular cells and

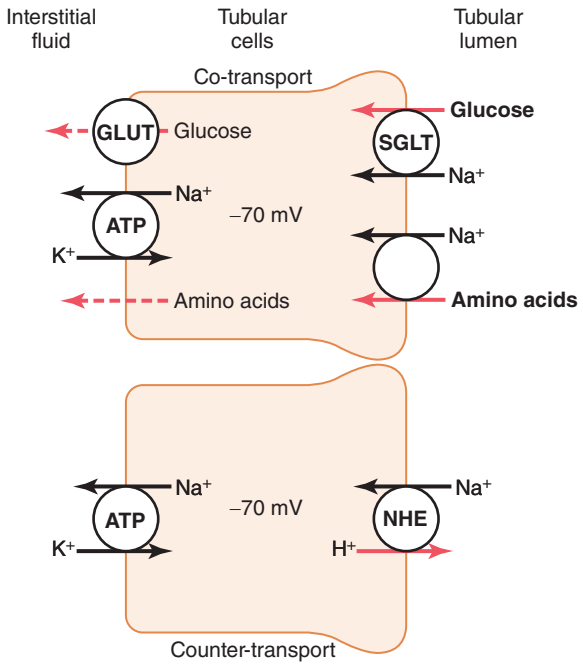

Figure 28.3 Mechanisms of secondary active transport. The upper cell shows the *co-transport* of glucose and amino acids along with sodium ions through the apical side of the tubular epithelial cells, followed by facilitated diffusion through the basolateral membranes. The lower cell shows the *counter-transport* of hydrogen ions from the interior of the cell across the apical membrane and into the tubular lumen; movement of sodium ions into the cell, down an electrochemical gradient established by the sodium-potassium pump on the basolateral membrane, provides the energy for transport of the hydrogen ions from inside the cell into the tubular lumen. *ATP*, Adenosine triphosphate; *GLUT*, glucose transporter; *NHE*, sodium-hydrogen exchanger; *SGLT*, sodium-glucose co-transporter.

carry glucose into the cell cytoplasm against a concentration gradient, as described previously. Approximately 90% of the filtered glucose is reabsorbed by SGLT2 in the early part of the proximal tubule (S1 segment), and the residual 10% is transported by SGLT1 in the latter segments of the proximal tubule. On the basolateral side of the membrane, glucose diffuses out of the cell into the interstitial spaces with the help of *glucose transporters—GLUT2* in the S1 segment and *GLUT1* in the latter part (S3 segment) of the proximal tubule.

Although transport of glucose against a chemical gradient does not directly use ATP, the reabsorption of glucose depends on energy expended by the primary active Na^+-K^+ ATPase pump in the basolateral membrane. Because of the activity of this pump, an electrochemical gradient for facilitated diffusion of sodium across the luminal membrane is maintained, and it is this downhill diffusion of sodium to the interior of the cell that provides the energy for the simultaneous uphill transport of glucose across the luminal membrane. Thus, this reabsorption of glucose is referred to as *secondary active transport* because glucose itself is reabsorbed uphill against a chemical gradient, but it is secondary to primary active transport of sodium.

Another important point is that a substance is said to undergo active transport when at least one of the steps in the reabsorption involves primary or secondary active transport, even though other steps in the reabsorption process may be passive. For glucose reabsorption, secondary active transport occurs at the luminal membrane, but passive facilitated diffusion occurs at the basolateral membrane, and passive uptake by bulk flow occurs at the peritubular capillaries.

Secondary Active Secretion Into the Tubules. Some substances are secreted into the tubules by secondary active transport, which often involves *counter-transport* of the substance with sodium ions. In counter-transport, the energy liberated from the downhill movement of one of the substances (e.g., sodium ions) enables the uphill movement of a second substance in the opposite direction.

One example of counter-transport, shown in **Fig. 28.3**, is active secretion of hydrogen ions coupled to sodium reabsorption in the luminal membrane of the proximal tubule. In this case, sodium entry into the cell is coupled with hydrogen extrusion from the cell by sodium-hydrogen counter-transport. This transport is mediated by a *sodium-hydrogen exchanger* protein in the brush border of the luminal membrane. As sodium is carried to the interior of the cell, hydrogen ions are forced outward in the opposite direction into the tubular lumen. The basic principles of primary and secondary active transport are discussed in Chapter 4.

Pinocytosis Is an Active Transport Mechanism for Reabsorption of Proteins. Some parts of the tubule, especially the proximal tubule, reabsorb large molecules such as proteins via *pinocytosis*, a type of *endocytosis*. In this process, the protein attaches to the brush border of the luminal membrane, and this portion of the membrane then invaginates to the interior of the cell until it is completely pinched off and a vesicle is formed containing the protein. Once inside the cell, the protein is digested into its constituent amino acids, which are reabsorbed through the basolateral membrane into the interstitial fluid. Because pinocytosis requires energy, it is considered a form of active transport.

Transport Maximum for Substances That Are Actively Reabsorbed. For most substances that are actively reabsorbed or secreted, there is a limit to the rate at which the solute can be transported, which is often referred to as the *transport maximum*. This limit is due to saturation of the specific transport systems involved when the amount of solute delivered to the tubule (referred to as the *tubular load*) exceeds the capacity of the carrier proteins and specific enzymes involved in the transport process.

The glucose transport system in the proximal tubule is a good example. Normally, measurable glucose does not appear in the urine because essentially all the filtered glucose is reabsorbed in the proximal tubule. However, when the filtered load exceeds the capability of the tubules to reabsorb glucose, urinary excretion of glucose does occur.

In the adult human, the transport maximum for glucose averages about 375 mg/min, whereas the filtered load of glucose is only about 125 mg/min (GFR × plasma glucose = 125 mL/min × 1 mg/mL). With large increases in GFR and/or plasma glucose concentration that increase the filtered load of glucose above 375 mg/min, the excess glucose filtered is not reabsorbed and passes into the urine.

Fig. 28.4 shows the relationship between plasma concentration of glucose, filtered load of glucose (assuming a GFR of 125 mL/min), tubular transport maximum for glucose, and rate of glucose loss in the urine. Note that when the plasma glucose concentration is 100 mg/100 mL and the filtered load is at its normal level (125 mg/min), there is no loss of glucose in the urine. However, when the plasma concentration of glucose rises above about 200 mg/100 mL, increasing the filtered load to above 250 mg/min, a small amount of glucose begins to appear in the urine. This point is termed the *threshold* for glucose. *Note that this appearance of glucose in the urine (at the threshold) occurs before the transport maximum is reached*. One reason for the difference between the threshold and transport maximum is that not all nephrons have the same transport maximum for glucose, and some nephrons begin to excrete glucose before others have reached their transport maximum. *The overall transport maximum for the kidneys, which is normally about 375 mg/min, is reached when all nephrons have reached their maximal capacity to reabsorb glucose.*

The plasma glucose of a healthy person almost never becomes high enough to cause glucose excretion in the urine, even after eating a meal. However, in uncontrolled *diabetes mellitus*, plasma glucose concentration may rise to high levels, causing the filtered load of glucose to exceed the transport maximum and resulting in urinary glucose excretion. Some of the average transport maximums for substances *actively reabsorbed* by the tubules are as follows:

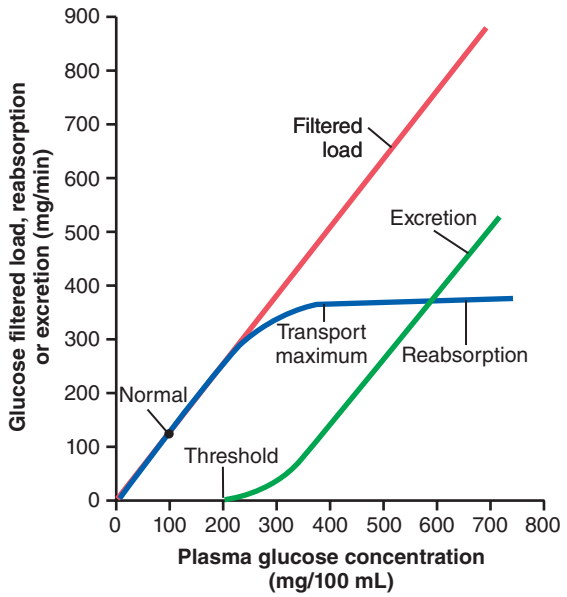

Figure 28.4 Relationships among the filtered load of glucose, rate of glucose reabsorption by the renal tubules, and rate of glucose excretion in the urine. The *transport maximum* is the maximum rate at which glucose can be reabsorbed from the tubules. The *threshold* for glucose refers to the filtered load of glucose at which glucose first begins to be excreted in the urine.

Substance	Transport Maximum
Glucose	375 mg/min
Phosphate	0.10 mmol/min
Sulfate	0.06 mmol/min
Amino acids	1.5 mmol/min
Urate	15 mg/min
Lactate	75 mg/min
Plasma protein	30 mg/min

Transport Maximums for Actively Secreted Substances. Substances that are *actively secreted* also exhibit transport maximums, as follows:

Substance	Transport Maximum
Creatinine	16 mg/min
Para-aminohippuric acid	80 mg/min

Substances That Are Actively Transported But Do Not Exhibit a Typical Transport Maximum. Actively transported solutes often exhibit a transport maximum because the transport carrier system becomes saturated as the tubular load increases. *Some substances that are actively reabsorbed do not demonstrate a typical transport maximum* because their rate of transport is determined by other factors, such as the following: (1) the electrochemical gradient for diffusion of the substance across the membrane; (2) the permeability of the membrane for the substance; and (3) the time that the fluid containing the substance remains within the tubule. Transport of this type is referred to as *gradient-time transport* because the rate of transport depends on the electrochemical gradient and the time that the substance is in the tubule, which in turn depends on the tubular flow rate.

An example of gradient-time transport is sodium reabsorption in the proximal tubule, where the maximum transport capacity of the basolateral Na^+-K^+ ATPase pump is usually far greater than the actual rate of net sodium reabsorption because a significant amount of sodium transported out of the cell leaks back into the tubular lumen down an electrochemical gradient through junctions of the epithelial cells. The rate at which this backleak occurs depends on (1) the permeability of the tight junctions; and (2) the interstitial physical forces, which determine the rate of bulk flow reabsorption from the interstitial fluid into the peritubular capillaries. Therefore, sodium transport in the proximal tubules obeys mainly gradient-time transport principles rather than typical tubular maximum transport characteristics. This observation means that the higher the concentration of sodium in the proximal tubules, the higher is its reabsorption rate.

Also, the slower the flow rate of tubular fluid, the greater the percentage of sodium that can be reabsorbed from the proximal tubules.

In the more distal parts of the nephron, the epithelial cells have much tighter junctions and transport much smaller amounts of sodium. In these segments, sodium reabsorption exhibits a transport maximum similar to that for other actively transported substances. Furthermore, this transport maximum can be increased by certain hormones, such as *aldosterone*.

PASSIVE WATER REABSORPTION BY OSMOSIS IS COUPLED MAINLY TO SODIUM REABSORPTION

When solutes are transported out of the tubule by primary or secondary active transport, their concentrations tend to decrease inside the tubule while increasing in the renal interstitium. This phenomenon creates a concentration difference that causes osmosis of water in the same direction that the solutes are transported, from the tubular lumen to the renal interstitium. Some parts of the renal tubule, especially the proximal tubule, are highly permeable to water, and water reabsorption occurs so rapidly that there is only a small concentration gradient for solutes across the tubular membrane.

A large part of the osmotic flow of water in the proximal tubules occurs through *aquaporin-1 (AQP-1)* water channels in the cell membranes, as well as through the *tight junctions* between the epithelial cells. As noted previously, the junctions between the cells are not as tight as their name would imply and permit significant diffusion of water and small ions. This condition is especially true in the proximal tubules, which have a relatively high permeability for water and a smaller but significant permeability to most ions, such as sodium, chloride, potassium, calcium, and magnesium.

Water moving across the tight junctions by osmosis also carries with it some of the solutes, a process referred to as *solvent drag*. In addition, because the reabsorption of water, organic solutes, and ions is coupled to sodium reabsorption, changes in sodium reabsorption significantly influence the reabsorption of water and many other solutes.

In the more distal parts of the nephron, beginning in the loop of Henle and extending through the collecting tubule, the tight junctions are far less permeable to water and solutes, and the epithelial cells also have a greatly decreased membrane surface area. Therefore, water cannot move easily across the tight junctions of the tubular membrane by osmosis. However, antidiuretic hormone (ADH) greatly increases the water permeability by increasing membrane *aquaporin-2 (AQP-2)* in the epithelial cell membranes of the distal and collecting tubules, as discussed later in this chapter.

Thus, water movement across the tubular epithelium can occur only if the membrane is permeable to water, no matter how large the osmotic gradient. In the proximal tubule and descending loop of Henle, water permeability is always high, and water is rapidly reabsorbed to reach osmotic equilibrium with the surrounding interstitial fluid. This high permeability is due to abundant expression of AQP-1 in the luminal and basolateral membranes. In the ascending loop of Henle, water permeability is always low, so almost no water is reabsorbed, despite a large osmotic gradient. Water permeability in the last parts of the tubules—the distal tubules, collecting tubules, and collecting ducts—occurs through aquaporins and can be high or low, depending on the presence or absence of ADH.

REABSORPTION OF CHLORIDE, UREA, AND OTHER SOLUTES BY PASSIVE DIFFUSION

When sodium is reabsorbed through the tubular epithelial cell, negative ions such as chloride are transported along with sodium because of electrical potentials. That is, transport of positively charged sodium ions out of the lumen leaves the inside of the lumen negatively charged, compared with the interstitial fluid causing chloride ions to diffuse *passively* through the *paracellular pathway*. Additional reabsorption of chloride ions occurs because of a chloride concentration gradient that develops when water is reabsorbed from the tubule by osmosis, thereby concentrating the chloride ions in the tubular lumen (**Fig. 28.5**). Thus, active reabsorption of sodium is closely coupled to passive reabsorption of chloride by way of an electrical potential and a chloride concentration gradient.

Chloride ions can also be reabsorbed by secondary active transport. The most important of the secondary active transport processes for chloride reabsorption involves the co-transport of chloride with sodium and potassium across the luminal membrane of the thick ascending loops of Henle and co-transport with sodium across the luminal membrane of the distal tubules.

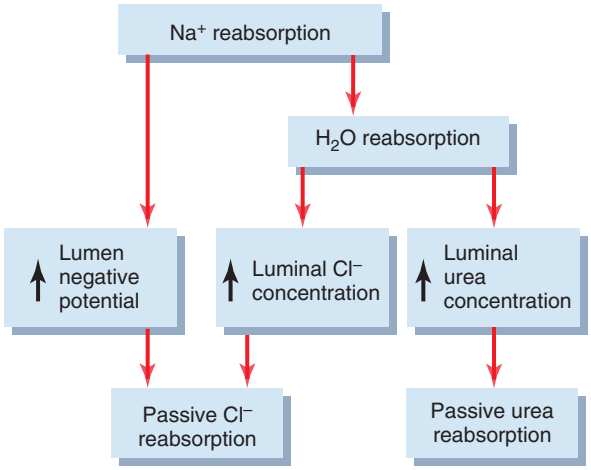

Figure 28.5 Mechanisms whereby water, chloride, and urea reabsorption are coupled with sodium reabsorption.

Urea is also passively reabsorbed from the tubule, but to a much lesser extent than chloride ions. As water is reabsorbed from the tubules (by osmosis coupled to sodium reabsorption), urea concentration in the tubular lumen increases (**Fig. 28.5**). This increase creates a concentration gradient favoring reabsorption of urea. However, urea does not permeate the tubule as readily as water. In some parts of the nephron, especially the inner medullary collecting duct, passive urea reabsorption is facilitated by specific *urea transporters*. Yet, only about half of the urea that is filtered by the glomerular capillaries is reabsorbed from the tubules. The remaining urea passes into the urine, allowing the kidneys to excrete large amounts of this waste product of metabolism. In mammals, more than 90% of waste nitrogen, mainly generated in the liver as a product of protein metabolism, is normally excreted by the kidneys as urea.

Another waste product of metabolism, creatinine, is an even larger molecule than urea and is essentially impermeant to the tubular membrane. Therefore, almost none of the creatinine that is filtered is reabsorbed, so virtually all the creatinine filtered by the glomerulus is excreted in the urine.

REABSORPTION AND SECRETION ALONG DIFFERENT PARTS OF THE NEPHRON

In previous sections, we discussed the basic principles whereby water and solutes are transported across the tubular membrane. With these generalizations in mind, we can now discuss some of the different characteristics of the individual tubular segments that enable them to perform their specific functions. Only the tubular transport functions that are quantitatively most important will be discussed, especially as they relate to the reabsorption of sodium, chloride, and water. In subsequent chapters, we discuss the reabsorption and secretion of other substances in different parts of the tubular system.

PROXIMAL TUBULAR REABSORPTION

Normally, about 65% of the filtered load of sodium and water and a slightly lower percentage of filtered chloride are reabsorbed by the proximal tubules before the filtrate reaches the loops of Henle. These percentages can be increased or decreased in different physiological conditions, as discussed later.

Proximal Tubules Have High Capacity for Active and Passive Reabsorption. The high capacity of the proximal tubule for reabsorption results from its special cellular characteristics, as shown in **Fig. 28.6**. The proximal tubule epithelial cells are highly metabolic and have large numbers of mitochondria to support powerful active transport processes. In addition, the proximal tubular cells have an extensive brush border on the luminal (apical) side of the membrane, as well as an extensive

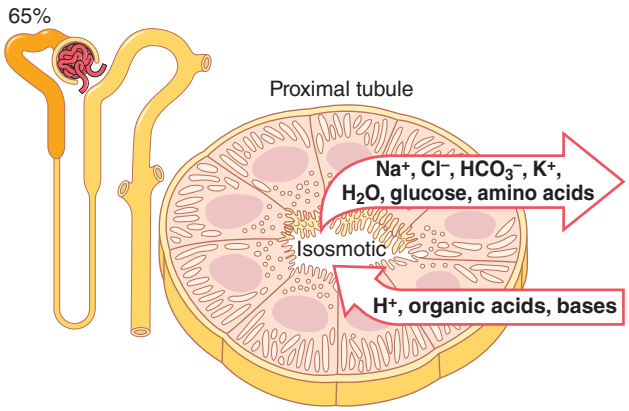

Figure 28.6 Cellular ultrastructure and primary transport characteristics of the proximal tubule. The proximal tubules reabsorb about 65% of the filtered sodium, chloride, bicarbonate, and potassium and essentially all the filtered glucose and amino acids. The proximal tubules also secrete organic acids, bases, and hydrogen ions into the tubular lumen.

labyrinth of intercellular and basal channels, all of which together provide an extensive membrane surface area on the luminal and basolateral sides of the epithelium for rapid transport of sodium ions and other substances.

The extensive membrane surface of the epithelial brush border is also loaded with protein carrier molecules that transport a large fraction of the sodium ions across the luminal membrane linked via the *co-transport* mechanism with multiple organic nutrients such as amino acids and glucose. Additional sodium is transported from the tubular lumen into the cell by *counter-transport* mechanisms that reabsorb sodium while secreting other substances into the tubular lumen, especially hydrogen ions. As discussed in Chapter 31, secretion of hydrogen ions into the tubular lumen is an important step in the removal of bicarbonate ions from the tubule (by combining H^+ with the HCO_3^- to form H_2CO_3, which then dissociates into H_2O and CO_2).

Although the Na^+-K^+ ATPase pump provides the major force for the reabsorption of sodium, chloride, and water throughout proximal tubule, there are some differences in the mechanisms whereby sodium and chloride are transported through the luminal side of the early and late portions of the proximal tubular membrane.

In the first half of the proximal tubule, sodium is reabsorbed by co-transport along with glucose, amino acids, and other solutes. However, in the second half of the proximal tubule, little glucose and few amino acids remain to be reabsorbed. Instead, sodium is now reabsorbed, mainly with chloride ions. The second half of the proximal tubule has a relatively high concentration of chloride (~140 mEq/L) compared with the early proximal tubule (~105 mEq/L) because when sodium is reabsorbed, it preferentially carries with it glucose, bicarbonate, and organic ions in the early proximal tubule, leaving behind a solution that has a higher concentration of chloride.

In the second half of the proximal tubule, the higher chloride concentration favors diffusion of this ion from

the tubule lumen through the intercellular junctions into the renal interstitial fluid. In addition, passive reabsorption of chloride is coupled to fluid reabsorption by solvent drag. Smaller amounts of chloride may also be reabsorbed through specific chloride channels in the proximal tubular cell membrane.

Concentrations of Solutes Along Proximal Tubules. Fig. 28.7 summarizes the changes in concentration of various solutes along the proximal tubule. Although the *amount* of sodium in the tubular fluid decreases markedly along the proximal tubule, sodium *concentration* (and total osmolarity) remains relatively constant because water permeability of the proximal tubules is so great that water reabsorption keeps pace with sodium reabsorption.

Certain organic solutes, such as glucose, amino acids, and bicarbonate, are much more avidly reabsorbed than water, and their concentrations decrease markedly along the length of the proximal tubule. Other organic solutes that are less permeant and not actively reabsorbed, such as creatinine, increase their concentration along the proximal tubule. The total solute concentration, as reflected by osmolarity, remains essentially the same all along the proximal tubule because of the high permeability of this part of the nephron to water.

Secretion of Organic Acids and Bases By Proximal Tubules. The proximal tubule is also an important site for secretion of organic acids and bases such as *bile salts*, *oxalate*, *urate*, and *catecholamines*. Many of these substances are the end products of metabolism and must be rapidly removed from the body. The *secretion* of these substances into the proximal tubule plus *filtration* into the proximal tubule by the glomerular capillaries and almost total lack of tubular reabsorption, all combined, contribute to rapid excretion in the urine.

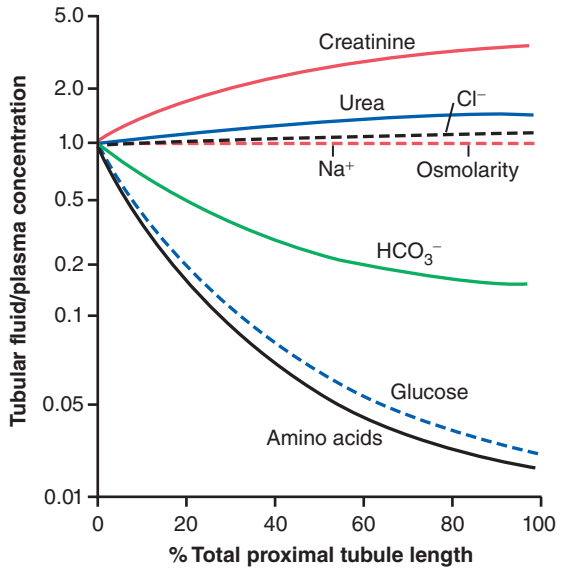

Figure 28.7 Changes in concentrations of different substances in tubular fluid along the proximal convoluted tubule relative to the concentrations of these substances in the plasma and glomerular filtrate. A value of 1.0 indicates that the concentration of the substance in the tubular fluid is the same as the concentration in the plasma. Values below 1.0 indicate that the substance is reabsorbed more avidly than water, whereas values above 1.0 indicate that the substance is reabsorbed to a lesser extent than water or is secreted into the tubules.

In addition to the waste products of metabolism, the kidneys secrete many potentially harmful drugs or toxins into the tubules and rapidly clear these substances from the blood. In the case of certain drugs, such as penicillin and salicylates, the rapid clearance by the kidneys creates a challenge in maintaining a therapeutically effective drug concentration.

Another compound that is rapidly secreted by the proximal tubule is para-aminohippuric acid (PAH). PAH is secreted so rapidly that the average person can clear about 90% of the PAH from the plasma flowing through the kidneys and excrete it in the urine. For this reason, the rate of PAH clearance can be used to estimate the renal plasma flow (RPF), as discussed later.

SOLUTE AND WATER TRANSPORT IN LOOPS OF HENLE

The loop of Henle consists of three functionally distinct segments—the *thin descending segment, thin ascending segment*, and *thick ascending segment*. The thin descending and thin ascending segments, as their names imply, have thin epithelial membranes with no brush borders, few mitochondria, and minimal levels of metabolic activity (**Fig. 28.8**).

About 20% of the filtered water is reabsorbed in the loop of Henle, and almost all of this occurs in the thin descending limb. The descending part of the thin segment is highly permeable to water with reabsorption occurring passively through AQP-1 water channels. The ascending limb, including both the thin and thick portions, is virtually impermeable to water, a characteristic that is important for concentrating the urine, as discussed in Chapter 29.

The thick segment of the loop of Henle, which begins about halfway up the ascending limb, has thick epithelial cells that have high metabolic activity and are capable of active reabsorption of sodium, chloride, and potassium (**Fig. 28.8**). About 25% of the filtered loads of sodium, chloride, and potassium are reabsorbed in the loop of Henle, mostly in the thick ascending limb. Considerable amounts of other ions, such as calcium, bicarbonate, and magnesium, are also reabsorbed in the thick ascending loop of Henle. The thin segment of the ascending limb has a much lower reabsorptive capacity than the thick segment, and the thin descending limb does not reabsorb significant amounts of any of these solutes.

An important component of solute reabsorption in the thick ascending limb is the Na^+-K^+ ATPase pump in the epithelial cell basolateral membranes. As in the proximal tubule, the reabsorption of other solutes in the thick segment of the ascending loop of Henle is closely linked to the reabsorptive capability of the Na^+-K^+ ATPase pump,

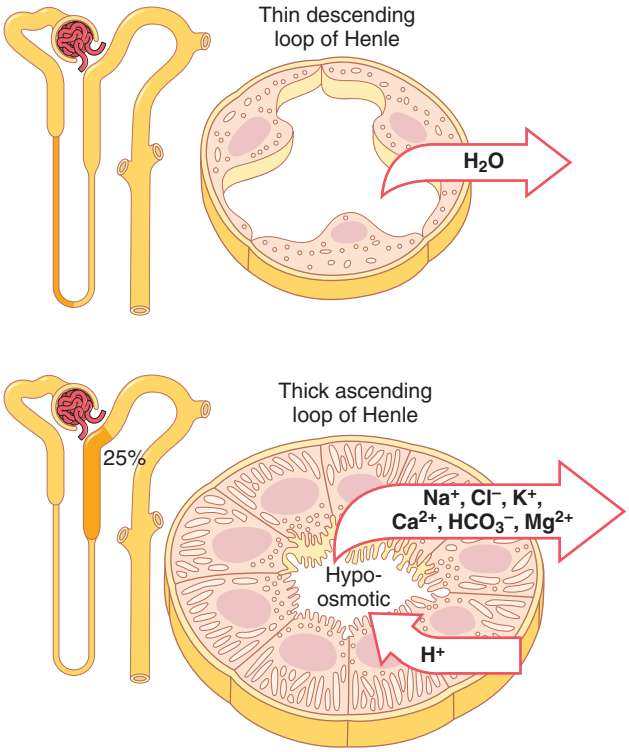

Figure 28.8 Cellular ultrastructure and transport characteristics of the thin descending loop of Henle (*top*) and thick ascending segment of the loop of Henle (*bottom*). The descending part of the thin segment of the loop of Henle is highly permeable to water but has few mitochondria and little or no active reabsorption. The thick ascending limb of the loop of Henle reabsorbs about 25% of the filtered loads of sodium, chloride, and potassium, as well as large amounts of calcium, bicarbonate, and magnesium. This segment also secretes hydrogen ions into the tubular lumen.

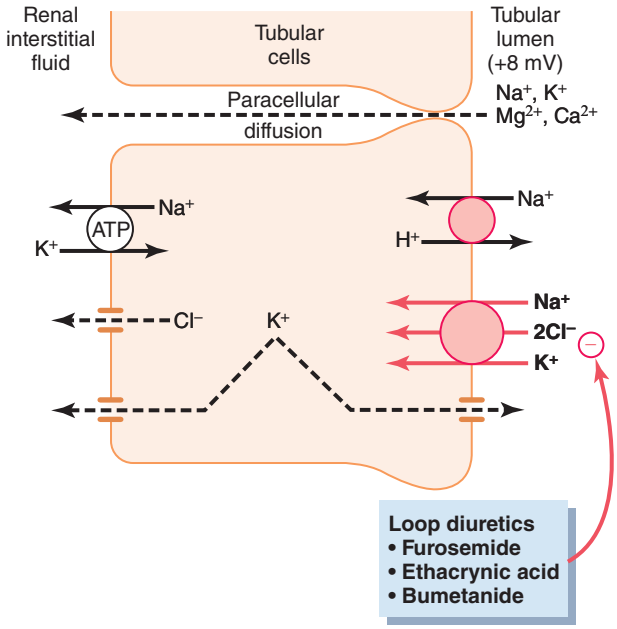

Figure 28.9 Mechanisms of sodium, chloride, and potassium transport in the thick ascending loop of Henle. The Na^+-K^+ ATPase pump in the basolateral cell membrane maintains a low intracellular sodium concentration and a negative electrical potential in the cell. The 1-sodium, 2-chloride, 1-potassium co-transporter in the luminal membrane transports these three ions from the tubular lumen into the cells, using the potential energy released by the diffusion of sodium down an electrochemical gradient into the cells. Sodium is also transported into the tubular cell by sodium-hydrogen counter-transport. The positive charge (+8 mV) of the tubular lumen relative to the interstitial fluid forces cations such as Mg^{2+} and Ca^{2+} to diffuse from the lumen to the interstitial fluid via the paracellular pathway.

which maintains a low intracellular sodium concentration. The low intracellular sodium concentration in turn provides a favorable gradient for movement of sodium from the tubular fluid into the cell.

In the thick ascending loop, movement of sodium across the luminal membrane is mediated primarily by a *1-sodium, 2-chloride, 1-potassium co-transporter (NKCC2)* (**Fig. 28.9**). This co-transport protein in the luminal membrane uses the potential energy released by downhill diffusion of sodium into the cell to drive the reabsorption of potassium into the cell against a concentration gradient.

The thick ascending limb of the loop of Henle is the site of action of the powerful *loop diuretics furosemide, ethacrynic acid*, and *bumetanide*, all of which inhibit the action of the NKCC2 co-transporter. These diuretics are discussed in Chapter 32. The thick ascending limb also has a sodium-hydrogen counter-transport mechanism in its luminal cell membrane that mediates sodium reabsorption and hydrogen secretion (**Fig. 28.9**).

There is also significant paracellular reabsorption of cations, such as Mg^{2+}, Ca^{2+}, Na^+, and K^+, in the thick ascending limb as a result of the slight positive charge of the tubular lumen relative to the interstitial fluid. Although the NKCC2 co-transporter moves equal amounts of cations and anions into the cell, there is a slight backleak of potassium ions through potassium channels into the lumen, creating a positive charge of about +8 millivolts in the tubular lumen. This positive charge forces cations such as Mg^{2+} and Ca^{2+} to diffuse from the tubular lumen through the paracellular space and into the interstitial fluid.

The thick segment of the ascending loop of Henle is virtually impermeable to water. Therefore, most of the water delivered to this segment remains in the tubule, despite reabsorption of large amounts of solute. The tubular fluid in the ascending limb becomes very dilute as it flows toward the distal tubule, a feature that is important in allowing the kidneys to dilute or concentrate the urine under different conditions, as discussed in more detail in Chapter 29.

DISTAL TUBULES

The thick segment of the ascending limb of the loop of Henle empties into the *distal tubule*. The first portion of the distal tubule forms the *macula densa*, a group of closely packed epithelial cells that is part of the *juxtaglomerular complex* and provides feedback control of GFR and blood flow in this same nephron, as discussed in Chapter 27.

The next part of the distal tubule is highly convoluted and has many of the same reabsorptive characteristics of the thick segment of the ascending limb of the loop of Henle. That is, it avidly reabsorbs most of the ions, including sodium, potassium, and chloride, but is virtually impermeable to water and urea. For this reason, it is referred to as the *diluting segment* because it also dilutes the tubular fluid.

Approximately 5% of the filtered load of sodium chloride is reabsorbed in the early distal tubule. The *sodium-chloride co-transporter* moves sodium chloride from the tubular lumen into the cell, and the Na^+-K^+ ATPase pump transports sodium out of the cell across the basolateral membrane (**Fig. 28.10**). Chloride diffuses out of cell into the renal interstitial fluid through chloride channels in the basolateral membrane.

The *thiazide diuretics*, which are widely used to treat disorders such as hypertension and heart failure, inhibit the sodium-chloride co-transporter.

LATE DISTAL TUBULES AND CORTICAL COLLECTING TUBULES

The second half of the distal tubule and subsequent cortical collecting tubule have similar functional characteristics. Anatomically, they are composed of two main cell types, the *principal cells* and *intercalated cells* (**Fig. 28.11**). The principal cells reabsorb sodium and water from the lumen and secrete potassium ions into the lumen. There are two subtypes of intercalated cells. The type A intercalated cells reabsorb potassium and bicarbonate ions and secrete hydrogen ions into the tubular lumen, whereas type B intercalated cells have the opposite effects, as discussed later.

Principal Cells Reabsorb Sodium and Secrete Potassium. Sodium *reabsorption* and potassium *secretion* by the principal cells depend on the activity of a Na^+-K^+ ATPase pump in each cell's basolateral membrane (**Fig. 28.12**). This pump maintains a low sodium concentration inside the cell and, therefore, favors sodium diffusion into the cell through special channels. Secretion of potassium by these cells from the blood into the tubular lumen involves two steps: (1) potassium enters the cell because of the Na^+-K^+ ATPase pump, which maintains a high intracellular potassium concentration; and (2) once in the cell, potassium diffuses down its concentration gradient through potassium channels in the luminal membrane into the tubular fluid, as discussed in more detail in Chapter 30.

The principal cells are the primary sites of action of the *potassium-sparing diuretics*, including spironolactone, eplerenone, amiloride, and triamterene. *Spironolactone* and *eplerenone* are *mineralocorticoid receptor antagonists* that compete with aldosterone for receptor sites in the principal cells and therefore inhibit the stimulatory effects of aldosterone on sodium reabsorption and potassium secretion. *Amiloride* and *triamterene* are *sodium channel*

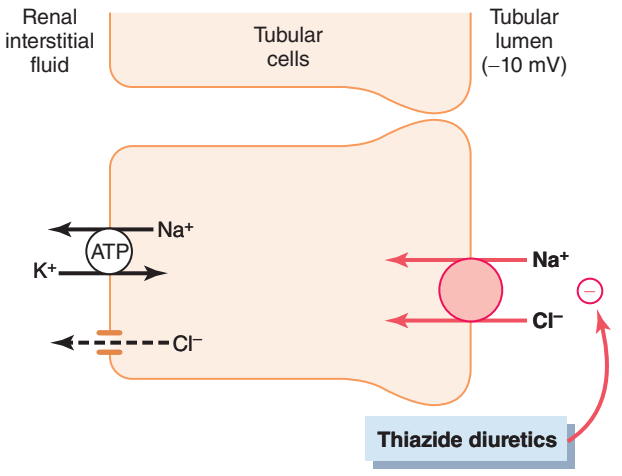

Figure 28.10 Mechanism of sodium chloride transport in the early distal tubule. Sodium and chloride are transported from the tubular lumen into the cell by a co-transporter that is inhibited by thiazide diuretics. Sodium is pumped out of the cell by Na^+-K^+ ATPase, and chloride diffuses into the interstitial fluid via chloride channels.

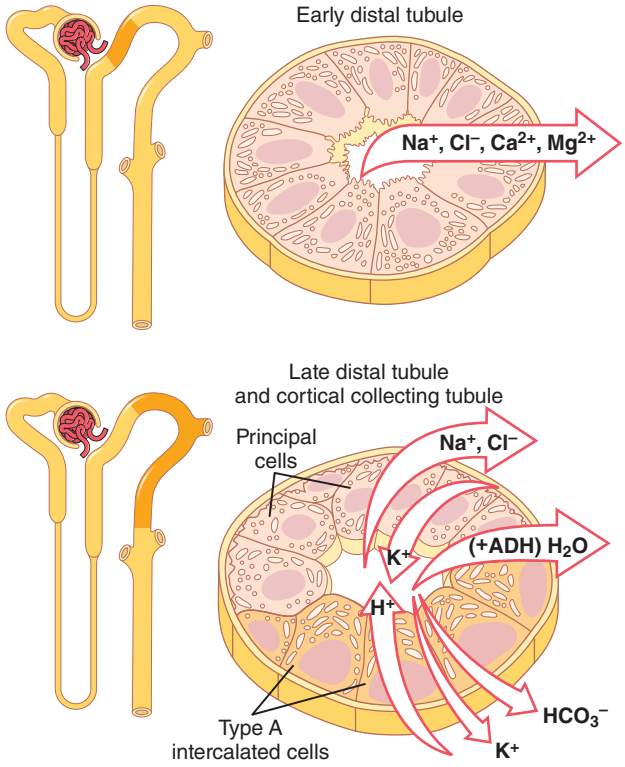

Figure 28.11 Cellular ultrastructure and transport characteristics of the early distal tubule and late distal tubule and collecting tubule. The early distal tubule has many of the same characteristics as the thick ascending loop of Henle and reabsorbs sodium, chloride, calcium, and magnesium but is virtually impermeable to water and urea. The late distal tubules and cortical collecting tubules are composed of two distinct cell types, the *principal cells* and *intercalated cells*. The principal cells reabsorb sodium from the lumen and secrete potassium ions into the lumen. Type A intercalated cells reabsorb potassium and bicarbonate ions from the lumen and secrete hydrogen ions into the lumen. The reabsorption of water from this tubular segment is controlled by the concentration of *antidiuretic hormone*.

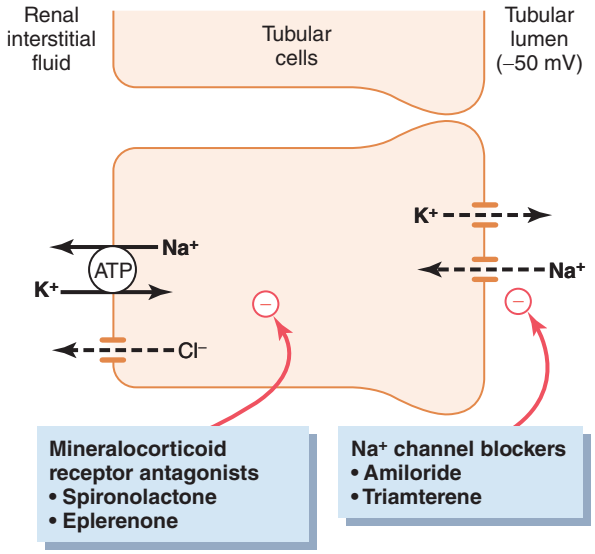

Figure 28.12 Mechanism of sodium-chloride reabsorption and potassium secretion in the principal cells of the late distal tubules and cortical collecting tubules. Sodium enters the cell through special channels and is transported out of the cell by the Na^+-K^+ ATPase pump. Aldosterone antagonists compete with aldosterone for binding sites in the cell and therefore inhibit the effects of aldosterone to stimulate sodium reabsorption and potassium secretion. Sodium channel blockers directly inhibit the entry of sodium into the sodium channels.

blockers that directly inhibit the entry of sodium into the sodium channels of the luminal membranes and therefore reduce the amount of sodium that can be transported across the basolateral membranes by the Na^+-K^+ ATPase pump. This, in turn, decreases transport of potassium into the cells and ultimately reduces potassium secretion into the tubular fluid. For this reason, sodium channel blockers, as well as aldosterone antagonists, decrease urinary excretion of potassium and act as *potassium-sparing diuretics*.

Intercalated Cells Can Secrete or Reabsorb Hydrogen, Bicarbonate, and Potassium Ions. Intercalated cells play a major role in acid–base regulation and constitute 30% to 40% of the cells in the collecting tubules and collecting ducts. Type A intercalated cells secrete hydrogen ions by a hydrogen-ATPase transporter and by a hydrogen-potassium-ATPase transporter (**Fig. 28.13**). Hydrogen is generated in this cell by the action of carbonic anhydrase on water and carbon dioxide to form carbonic acid, which then dissociates into hydrogen ions and bicarbonate ions. The hydrogen ions are then secreted into the tubular lumen and, for each hydrogen ion secreted, a bicarbonate ion becomes available for reabsorption across the basolateral membrane. Type A intercalated cells are especially important in eliminating hydrogen ions while reabsorbing bicarbonate in acidosis.

Type B intercalated cells have functions opposite to those of type A cells and secrete bicarbonate into the tubular lumen while reabsorbing hydrogen ions in alkalosis. Type B intercalated cells have hydrogen and bicarbonate

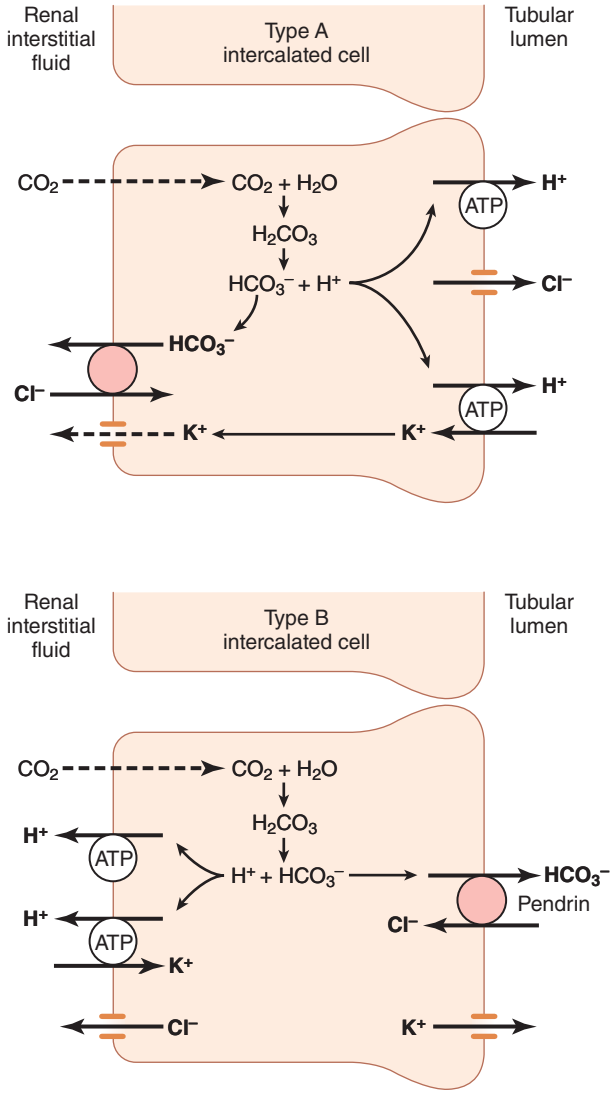

Figure 28.13 Type A and type B intercalated cells of the collecting tubule. Type A cells contain hydrogen-ATPase and hydrogen-potassium-ATPase in the luminal membrane and secrete hydrogen ions while reabsorbing bicarbonate and potassium ions in acidosis. In type B cells, the hydrogen-ATPase and hydrogen-potassium-ATPase transporters are located in the basolateral membrane and reabsorb hydrogen ions while secreting bicarbonate and potassium ions in alkalosis. The chloride-bicarbonate counter-transporter on the apical membrane of type B cells is called *pendrin* and is different from the chloride-bicarbonate transporter of type A intercalated cells.

transporters on opposite sides of the cell membrane compared with type A cells. The chloride-bicarbonate counter-transporter on the apical membrane of type B cells is called *pendrin* and is different from the chloride-bicarbonate transporter of type A cells. Hydrogen ions are actively transported out of the type B intercalated cell on the basolateral side of the cell membrane by hydrogen-ATPase, and bicarbonate is secreted into the lumen, thus eliminating excess plasma bicarbonate in alkalosis. Induction of chronic metabolic alkalosis increases the number of type B intercalated cells, which contribute to increased excretion of bicarbonate, whereas acidosis increases the number of type A cells.

A more detailed discussion of this mechanism is presented in Chapter 31. The intercalated cells can also reabsorb or secrete potassium ions, as shown in **Fig. 28.13**.

The functional characteristics of the *late distal tubule* and *cortical collecting tubule* can be summarized as follows:

1. The tubular membranes of both segments are almost completely impermeable to urea, similar to the diluting segment of the early distal tubule. Thus, almost all the urea that enters these segments passes on through and into the collecting duct to be excreted in the urine or reabsorbed in the medullary collecting ducts.
2. Both the late distal tubule and cortical collecting tubule segments reabsorb sodium, chloride, and bicarbonate ions, and the rate of reabsorption is controlled by hormones, especially aldosterone. At the same time, these segments secrete potassium and hydrogen ions from the peritubular capillary blood into the tubular lumen, a process that is also controlled by aldosterone and other factors, such as the concentration of potassium and hydrogen ions in the body fluids.
3. The type A intercalated cells of these nephron segments can avidly secrete hydrogen ions by an active hydrogen-ATPase mechanism in acidosis. This process is different from the secondary active secretion of hydrogen ions by the proximal tubule because it is capable of secreting hydrogen ions against a large concentration gradient, as much as 1000 to 1. This is in contrast to the relatively small gradient (4- to 10-fold) for hydrogen ions that can be achieved by secondary active secretion in the proximal tubule. In alkalosis, the type B intercalated cells secrete bicarbonate and actively reabsorb hydrogen ions. Thus, the intercalated cells play a key role in acid–base regulation of the body fluids.
4. The permeability of the late distal tubule and cortical collecting duct to water is controlled by the concentration of ADH, which is also called *vasopressin*. With high levels of ADH, these tubular segments are permeable to water, but in the absence of ADH they are virtually impermeable to water. This special characteristic provides an important mechanism for controlling the degree of dilution or concentration of the urine.

MEDULLARY COLLECTING DUCTS

Although the medullary collecting ducts usually reabsorb less than 5% of the filtered water and sodium, they are the final site for processing the urine and, therefore, play a critical role in determining the final urine output of water and solutes.

The epithelial cells of the collecting ducts are nearly cuboidal in shape, with smooth surfaces and relatively few mitochondria (**Fig. 28.14**). Special characteristics of this tubular segment are as follows:

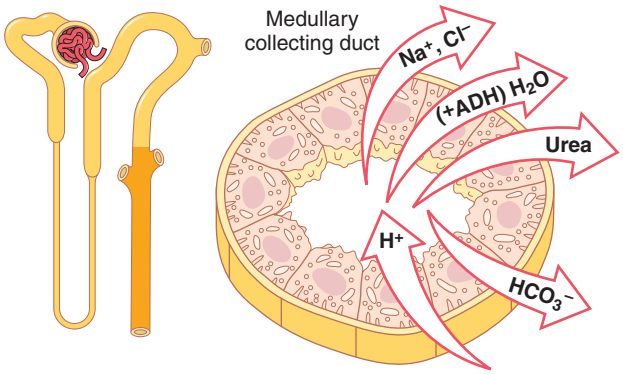

Figure 28.14 Cellular ultrastructure and transport characteristics of the medullary collecting duct. The medullary collecting ducts actively reabsorb sodium and secrete hydrogen ions and are permeable to urea, which is reabsorbed in these tubular segments. The reabsorption of water in medullary collecting ducts is controlled by the concentration of antidiuretic hormone.

1. The permeability of the medullary collecting duct to water is controlled by the level of ADH. With high levels of ADH, water is avidly reabsorbed into the medullary interstitium, thereby reducing the urine volume and concentrating most of the solutes in the urine.
2. Unlike the cortical collecting tubule, the medullary collecting duct is permeable to urea, and there are special *urea transporters* that facilitate urea diffusion across the luminal and basolateral membranes. Therefore, some of the tubular urea is reabsorbed into the medullary interstitium, helping raise the osmolality in this region of the kidneys and contributing to the kidneys' overall ability to form concentrated urine. This topic is discussed in Chapter 29.
3. The medullary collecting duct is capable of secreting hydrogen ions against a large concentration gradient, as also occurs in the cortical collecting tubule. Thus, the medullary collecting duct also plays a key role in regulating acid–base balance.

SUMMARY OF CONCENTRATIONS OF DIFFERENT SOLUTES IN DIFFERENT TUBULAR SEGMENTS

Whether a solute will become concentrated in the tubular fluid is determined by the relative degree of reabsorption of that solute versus reabsorption of water. If a greater percentage of water is reabsorbed, the substance becomes more concentrated. If a greater percentage of the solute is reabsorbed, the substance becomes more diluted.

Fig. 28.15 shows the degree of concentration of several substances in different tubular segments. All the values in this figure represent the tubular fluid concentration divided by the plasma concentration of a substance. If plasma concentration of the substance is assumed to be constant, any change in the tubular fluid/plasma concentration ratio reflects changes in tubular fluid concentration.

As the filtrate moves along the tubular system, the concentration rises progressively to higher than 1.0 if more water is reabsorbed than solute, or if there has been a net secretion of the solute into the tubular fluid. If the concentration ratio becomes progressively less than 1.0, this means that relatively more solute has been reabsorbed than water.

The substances represented at the top of **Fig. 28.15**, such as creatinine, become highly concentrated in the urine. In general, these substances are not needed by the body, and the kidneys have become adapted to reabsorb them only slightly or not at all or even to secrete them into the tubules, thereby excreting large quantities into the urine. Conversely, the substances represented at the bottom of the figure, such as glucose and amino acids, are all strongly reabsorbed. These are all substances that the body needs to conserve, and almost none of them are lost in the urine.

Tubular Fluid/Plasma Inulin Concentration Ratio Can Be Used to Assess Water Reabsorption By Renal Tubules. Inulin, a polysaccharide used to measure the GFR, is not reabsorbed or secreted by the renal tubules. Changes in inulin concentration at different points along the renal tubule, therefore, reflect changes in the amount of water present in the tubular fluid.

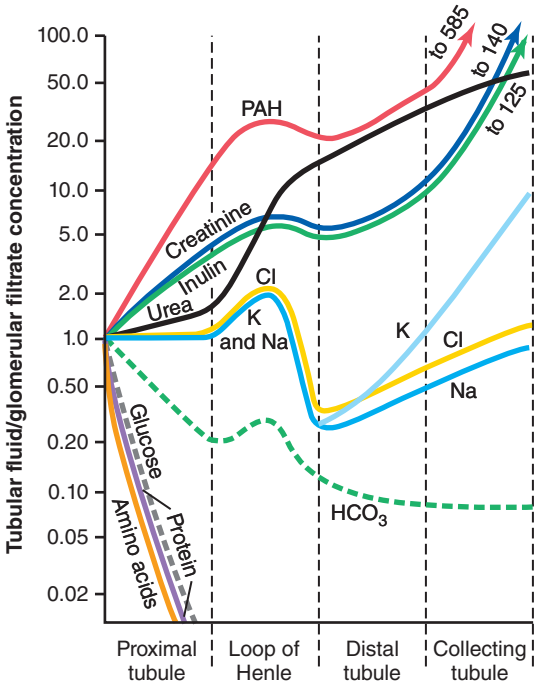

Figure 28.15 Changes in average concentrations of different substances at different points in the tubular system relative to the concentration of that substance in the plasma and glomerular filtrate. A value of 1.0 indicates that the concentration of the substance in the tubular fluid is the same as the concentration of that substance in the plasma. Values below 1.0 indicate that the substance is reabsorbed more avidly than water, whereas values above 1.0 indicate that the substance is reabsorbed to a lesser extent than water or is secreted into the tubules. *PAH*, Para-aminohippuric acid.

For example, the tubular fluid/plasma concentration ratio for inulin rises to about 3.0 at the end of the proximal tubules, indicating that inulin concentration in the tubular fluid is three times greater than in the plasma and glomerular filtrate. Because inulin is not secreted or reabsorbed from the tubules, a tubular fluid/plasma concentration ratio of 3.0 means that only one-third of the water that was filtered remains in the renal tubule and that two-thirds of the filtered water has been reabsorbed as the fluid passes through the proximal tubule. At the end of the collecting ducts, the tubular fluid/plasma inulin concentration ratio rises to about 125 (see **Fig. 28.15**), indicating that only 1/125 of the filtered water remains in the tubule and that more than 99% has been reabsorbed.

REGULATION OF TUBULAR REABSORPTION

Because it is essential to maintain a precise balance between tubular reabsorption and glomerular filtration, there are multiple nervous, hormonal, and local control mechanisms that regulate tubular reabsorption, just as there are for control of glomerular filtration. An important feature of tubular reabsorption is that reabsorption of some solutes can be regulated independently of others, especially through hormonal control mechanisms.

GLOMERULOTUBULAR BALANCE—REABSORPTION RATE INCREASES IN RESPONSE TO INCREASED TUBULAR LOAD

One of the most basic mechanisms for controlling tubular reabsorption is the intrinsic ability of the tubules to increase their reabsorption rate in response to increased tubular load (increased tubular inflow). This phenomenon is referred to as *glomerulotubular balance*. For example, if GFR increases from 125 to 150 mL/min, the absolute rate of proximal tubular reabsorption may also increase from about 81 mL/min (65% of GFR) to about 97.5 mL/min (65% of GFR). Thus, glomerulotubular balance refers to the fact that the total rate of reabsorption increases as the filtered load increases, even though the percentage of GFR reabsorbed in the proximal tubule may remain relatively constant, at about 65%.

Some degree of glomerulotubular balance also occurs in other tubular segments, especially the loop of Henle. The precise mechanisms responsible for this are not fully understood but may be due partly to changes in physical forces in the tubule and surrounding renal interstitium, as discussed later. Also, higher flow rates in the proximal tubule (and perhaps in other tubular segments) may increase the availability of ion transporters, including the sodium-hydrogen exchanger, on the luminal (apical) membrane. These mechanisms for glomerulotubular balance occur independently of hormones and can be demonstrated in completely isolated kidneys or even in completely isolated proximal tubular segments.

Glomerulotubular balance helps prevent overloading of the distal tubular segments when GFR increases. Glomerulotubular balance acts as another line of defense to buffer the effects of spontaneous changes in the GFR on urine output. (The other line of defense, discussed earlier, includes the renal autoregulatory mechanisms, especially tubuloglomerular feedback, which help prevent large changes in GFR.) Working together, the renal autoregulatory and glomerulotubular balance mechanisms prevent large changes in fluid flow in the distal tubules when the arterial pressure changes or when there are other disturbances that would otherwise upset sodium and volume homeostasis.

PERITUBULAR CAPILLARY AND RENAL INTERSTITIAL FLUID PHYSICAL FORCES

The final step in tubular reabsorption is bulk flow of water and solutes from the renal interstitium through the wall of peritubular capillaries into the blood. Hydrostatic and colloid osmotic forces govern the rate of reabsorption across the peritubular capillaries, just as they control filtration in other capillaries, including the glomerular capillaries. Changes in peritubular capillary reabsorption can in turn influence the hydrostatic and colloid osmotic pressures of the renal interstitium and, ultimately, reabsorption of water and solutes from the renal tubules.

Normal Values for Physical Forces and Reabsorption Rate. As the glomerular filtrate passes through the renal tubules, more than 99% of the water and most of the solutes are normally reabsorbed. Fluid and electrolytes are reabsorbed from the tubules into the renal interstitium and from there into the peritubular capillaries. The normal rate of peritubular capillary reabsorption is about 124 mL/min.

Reabsorption across the peritubular capillaries can be calculated as follows:

$$\text{Reabsorption} = K_f \times \text{Net reabsorptive force}$$

The net reabsorptive force represents the sum of the hydrostatic and colloid osmotic forces that favor or oppose reabsorption across the peritubular capillaries. These forces include the following: (1) hydrostatic pressure inside the peritubular capillaries (peritubular hydrostatic pressure [P_c]), which opposes reabsorption; (2) hydrostatic pressure in the renal interstitium (P_{if}) outside the capillaries, which favors reabsorption; (3) colloid osmotic pressure of the peritubular capillary plasma proteins (π_c), which favors reabsorption; and (4) colloid osmotic pressure of the proteins in the renal interstitium (π_{if}), which opposes reabsorption.

Fig. 28.16 shows the approximate normal forces that favor and oppose peritubular reabsorption. Because the normal peritubular capillary pressure averages about 13 mm Hg and the renal interstitial fluid hydrostatic pressure averages 6 mm Hg, there is a positive hydrostatic pressure gradient from the peritubular capillary to the interstitial fluid of about 7 mm Hg, which opposes fluid reabsorption. This opposition to fluid reabsorption is more than counterbalanced by the colloid osmotic pressures that favor reabsorption. The plasma colloid osmotic pressure, which favors reabsorption, is about 32 mm Hg, and the colloid osmotic pressure of the interstitium, which opposes reabsorption, is 15 mm Hg, causing a net colloid osmotic force of about 17 mm Hg, favoring reabsorption. Therefore, subtracting the net hydrostatic forces that oppose reabsorption (7 mm Hg) from the net colloid osmotic forces that favor reabsorption (17 mm Hg) gives a net reabsorptive force of about 10 mm Hg. This value is high, similar to that found in the glomerular capillaries, but in the opposite direction.

The other factor that contributes to the high rate of fluid reabsorption in the peritubular capillaries is a large filtration coefficient (K_f) because of the high hydraulic conductivity and large surface area of the capillaries. Because the reabsorption rate is normally about 124 mL/min and net reabsorption pressure is 10 mm Hg, K_f normally is about 12.4 mL/min per mm Hg.

Regulation of Peritubular Capillary Physical Forces. The two determinants of peritubular capillary reabsorption that are directly influenced by renal hemodynamic changes are the hydrostatic and colloid osmotic pressures of the peritubular capillaries. The *peritubular capillary hydrostatic pressure is influenced by the arterial pressure and resistances of the any of the blood vessels prior to the peritubular capillaries, especially the afferent and efferent arterioles*, as follows:

1. Increases in arterial pressure tend to raise peritubular capillary hydrostatic pressure and decrease the reabsorption rate. This effect is buffered to some

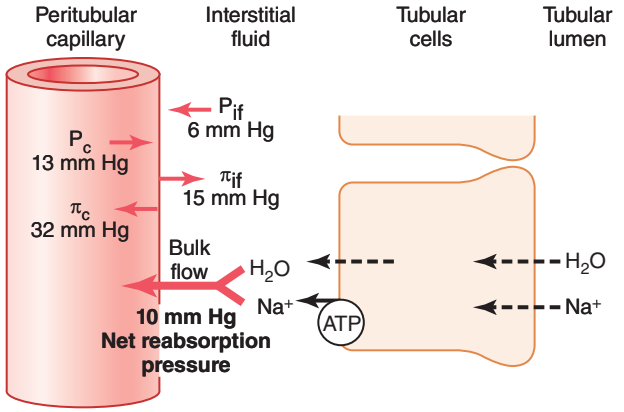

Figure 28.16 Summary of the hydrostatic and colloid osmotic forces that determine fluid reabsorption by the peritubular capillaries. The numerical values shown are estimates of the normal values for humans. The net reabsorptive pressure is normally about 10 mm Hg, causing fluid and solutes to be reabsorbed into the peritubular capillaries as they are transported across the renal tubular cells. *ATP*, Adenosine triphosphate; P_c, peritubular capillary hydrostatic pressure; P_{if}, interstitial fluid hydrostatic pressure; π_c, peritubular capillary colloid osmotic pressure; π_{if}, interstitial fluid colloid osmotic pressure.

extent by autoregulatory mechanisms that maintain relatively constant renal blood flow, as well as relatively constant hydrostatic pressures in the renal blood vessels.

2. An increase in resistance of the pre-peritubular capillary blood vessels reduces peritubular capillary hydrostatic pressure and tends to increase reabsorption rate. As discussed in Chapter 27, the afferent and efferent arterioles contribute much of the pre-peritubular vascular resistance, although the interlobar, arcuate, and interlobular arteries also provide significant resistance to blood flow. Although constriction of the efferent arterioles increases glomerular capillary hydrostatic pressure, it lowers peritubular capillary hydrostatic pressure.

The second major determinant of peritubular capillary reabsorption is the *colloid osmotic pressure* of the plasma in these capillaries; raising the colloid osmotic pressure increases peritubular capillary reabsorption. *The colloid osmotic pressure of peritubular capillaries is determined by* the following: (1) the *systemic plasma colloid osmotic pressure* (increasing the plasma protein concentration of systemic blood tends to raise peritubular capillary colloid osmotic pressure, thereby increasing reabsorption); and (2) *the filtration fraction*—the higher the filtration fraction, the greater the fraction of plasma filtered through the glomeruli and, consequently, the more concentrated the protein becomes in the plasma that remains behind. Thus, increasing the filtration fraction also tends to increase the peritubular capillary reabsorption rate. Because filtration fraction is defined as the ratio of GFR/RPF, an increased filtration fraction can occur as a result of increased GFR or decreased RPF. Some renal vasoconstrictors, such as angiotensin II, increase peritubular capillary reabsorption partly by decreasing RPF and increasing filtration fraction, as discussed later.

Changes in the peritubular capillary K_f can also influence the reabsorption rate because K_f is a measure of the permeability and surface area of the capillaries. Increases in K_f raise reabsorption, whereas decreases in K_f lower peritubular capillary reabsorption. K_f remains relatively constant in most physiological conditions. **Table 28.2** summarizes the factors that influence the peritubular capillary reabsorption rate.

Renal Interstitial Hydrostatic and Colloid Osmotic Pressures. Changes in peritubular capillary physical forces influence tubular reabsorption by changing the physical forces in the renal interstitium surrounding the tubules. For example, a decrease in the reabsorptive force across the peritubular capillary membranes, caused by increased peritubular capillary hydrostatic pressure or decreased peritubular capillary colloid osmotic pressure, reduces the uptake of fluid and solutes from the interstitium into the peritubular capillaries. This action increases renal interstitial fluid volume and hydrostatic pressure while decreasing interstitial fluid colloid osmotic pressure

Table 28.2 Factors That Can Influence Peritubular Capillary Reabsorption

- ↑ P_c → ↓ Reabsorption
  - ↓ R_A → ↑ P_c
  - ↓ R_E → ↑ P_c
  - ↑ Arterial pressure → ↑ P_c
- ↑ π_c → ↑ Reabsorption
  - ↑ π_A → ↑ π_c
  - ↑ FF → ↑ π_c
- ↑ K_f → ↑ Reabsorption

FF, Filtration fraction; K_f, peritubular capillary filtration coefficient; P_c, peritubular capillary hydrostatic pressure; π_A, arterial plasma colloid osmotic pressure; π_c, peritubular capillary colloid osmotic pressure; R_A, afferent arteriolar resistances; R_E, efferent arteriolar resistances.

because of dilution of the proteins in the renal interstitium. These changes then decrease the net reabsorption of fluid from the renal tubules into the interstitium, especially in the proximal tubules.

The mechanisms whereby changes in interstitial fluid hydrostatic and colloid osmotic pressures influence tubular reabsorption can be understood by examining the pathways through which solute and water are reabsorbed (**Fig. 28.17**). Once the solutes enter the intercellular channels or renal interstitium by active transport or passive diffusion, water is drawn from the tubular lumen into the interstitium by osmosis. Furthermore, once the water and solutes are in the interstitial spaces, they can be swept up into the peritubular capillaries or diffuse back through the epithelial junctions into the tubular lumen. The so-called tight junctions between the epithelial cells of the proximal tubule are somewhat leaky, so considerable amounts of sodium can diffuse in both directions through these junctions. With the normal high rate of peritubular capillary reabsorption, the net movement of water and solutes is into the peritubular capillaries, with little backleak into the lumen of the tubule. However, when peritubular capillary reabsorption is reduced, there is increased interstitial fluid hydrostatic pressure and a tendency for greater amounts of solute and water to leak back into the tubular lumen, thereby reducing the rate of net reabsorption (**Fig. 28.17**).

The opposite is true when peritubular capillary reabsorption increases above the normal level. An initial increase in reabsorption by the peritubular capillaries tends to reduce interstitial fluid hydrostatic pressure and raise interstitial fluid colloid osmotic pressure. Both these forces favor movement of fluid and solutes out of the tubular lumen and into the interstitium; therefore, backleak of water and solutes into the tubular lumen is reduced, and net tubular reabsorption is increased.

Thus, through changes in the hydrostatic and colloid osmotic pressures of the renal interstitium, the uptake of water and solutes by the peritubular capillaries is closely

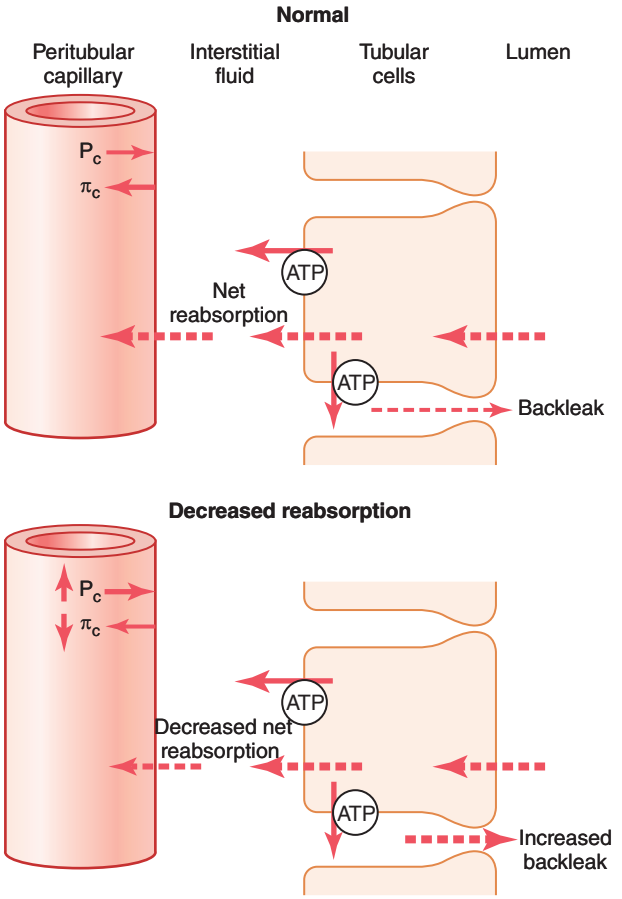

Figure 28.17 Proximal tubular and peritubular capillary reabsorption under normal conditions (*top*) and during decreased peritubular capillary reabsorption (*bottom*) caused by increasing peritubular capillary hydrostatic pressure (P_c) or decreasing peritubular capillary colloid osmotic pressure (π_c). Reduced peritubular capillary reabsorption, in turn, decreases the net reabsorption of solutes and water by increasing the amounts of solutes and water that leak back into the tubular lumen through the tight junctions of the tubular epithelial cells, especially in the proximal tubule.

matched to the net reabsorption of water and solutes from the tubular lumen into the interstitium. In general, *forces that increase peritubular capillary reabsorption also increase reabsorption from the renal tubules. Conversely, hemodynamic changes that inhibit peritubular capillary reabsorption also inhibit tubular reabsorption of water and solutes.*

EFFECT OF ARTERIAL PRESSURE ON URINE OUTPUT—PRESSURE NATRIURESIS AND PRESSURE DIURESIS

Even small increases in arterial pressure can cause marked increases in urinary excretion of sodium and water, phenomena referred to as *pressure natriuresis* and *pressure diuresis*. Because of the autoregulatory mechanisms described in Chapter 27, increasing the arterial pressure between the limits of 75 and 160 mm Hg usually has only a small effect on renal blood flow and GFR. The slight increase in GFR that does occur contributes in part to the effect of increased arterial pressure on urine output. When GFR autoregulation is impaired, as often occurs in kidney disease, increases in arterial pressure can cause much larger increases in the GFR.

A second effect of increased renal arterial pressure that raises urine output is that it decreases the percentages of the filtered loads of sodium and water that are reabsorbed by the tubules. Although the mechanisms responsible for this effect are not fully understood, they include a cascade of physical factors, as well as paracrine and hormonal effects. Increased arterial pressure causes a slight increase in peritubular capillary hydrostatic pressure, especially in the vasa recta of the renal medulla, and a subsequent *increase in the renal interstitial fluid hydrostatic pressure*. As discussed earlier, an increase in the renal interstitial fluid hydrostatic pressure enhances backleak of sodium into the tubular lumen, thereby reducing the net reabsorption of sodium and water and further increasing the rate of urine output when renal arterial pressure rises.

A third factor that contributes to pressure natriuresis and pressure diuresis is *reduced angiotensin II formation*. Angiotensin II itself increases sodium reabsorption by the tubules and stimulates aldosterone secretion, which further increases sodium reabsorption. Therefore, decreased angiotensin II formation contributes to the decreased tubular sodium reabsorption that occurs when arterial pressure is increased.

A fourth factor that may contribute to pressure natriuresis is *internalization of sodium transporter proteins* from the apical membranes to the cytoplasm of the renal tubules, thereby reducing the amount of sodium that can be transported across the cell membranes. This effect of increased arterial pressure may be mediated, in part, by decreased angiotensin II formation and other autacoid or paracrine signals.

HORMONAL CONTROL OF TUBULAR REABSORPTION

Precise regulation of body fluid volumes and solute concentrations requires the kidneys to excrete different solutes and water at variable rates, sometimes independently of one another. For example, when potassium intake is increased, the kidneys must excrete more potassium while maintaining normal excretion of sodium and other electrolytes. Likewise, when sodium intake is changed, the kidneys must adjust urinary sodium excretion appropriately without major changes in excretion of other electrolytes. Several hormones in the body provide this specificity of tubular reabsorption for different electrolytes and water. **Table 28.3** summarizes some of the most important hormones for regulating tubular reabsorption, their principal sites of action on the renal tubule, and their effects on solute and water excretion. Some of these hormones are discussed in more detail in Chapters 29 and 30, but here we briefly review their renal tubular actions.

Table 28.3 Hormones That Regulate Tubular Reabsorption

Hormone	Site of Action	Effects on Tubular Reabsorption
Aldosterone	Collecting tubule and duct	↑NaCl, H_2O, HCO_3^- reabsorption; ↑K^+ secretion; ↑H^+ secretion,
Angiotensin II	Proximal tubule, thick ascending loop of Henle, distal tubule, collecting tubule	↑NaCl, H_2O, HCO_3^- reabsorption; ↑H^+ secretion
Antidiuretic hormone	Distal tubule/collecting tubule and duct	↑H_2O reabsorption
Atrial natriuretic peptide	Distal tubule/collecting tubule and duct	↓NaCl reabsorption
Parathyroid hormone	Proximal tubule, thick ascending loop of Henle, distal tubule	↓PO_4^- reabsorption; ↑Ca^{2+} reabsorption

Aldosterone Stimulates Renal Sodium, Chloride, and Bicarbonate Reabsorption While Increasing Potassium and Hydrogen Ion Secretion. Aldosterone, secreted by the zona glomerulosa cells of the adrenal cortex, is an important regulator of sodium reabsorption and secretion of potassium and hydrogen ions by the renal tubules. *A major renal tubular site of aldosterone action is on the principal cells of the cortical collecting tubule*. One of the key mechanisms whereby aldosterone increases sodium reabsorption and potassium secretion is by stimulating the Na^+-K^+ ATPase pump on the basolateral side of the cortical collecting tubule membrane. Aldosterone also increases the sodium permeability of the luminal side of the membrane by the insertion of epithelial sodium channels. These cellular actions of aldosterone action are discussed further in Chapter 78.

Aldosterone also increases sodium chloride reabsorption in the distal convoluted tubules by stimulating the sodium-chloride co-transporter. In type B intercalated cells of the collecting tubules, aldosterone stimulates pendrin-dependent chloride reabsorption, whereas in type A intercalated cells aldosterone increases hydrogen ion secretion and bicarbonate reabsorption.

The most important stimuli for aldosterone are the following: (1) increased extracellular potassium concentration; and (2) increased angiotensin II levels, which typically occur in conditions associated with sodium and volume depletion or low blood pressure. Increased secretion of aldosterone associated with these conditions causes renal sodium and water retention, helping restore extracellular fluid volume and blood pressure toward normal.

When there is a deficit of aldosterone, as occurs with adrenal destruction or malfunction *(Addison disease)*, there is marked sodium loss from the body and accumulation of potassium. Conversely, excess aldosterone secretion, as occurs in patients with adrenal tumors *(Conn syndrome)*, is associated with sodium and chloride retention; hypertension; decreased plasma potassium concentration due, in part, to excessive potassium secretion by the kidneys; and metabolic alkalosis due to excessive hydrogen ion secretion and bicarbonate reabsorption. Although daily regulation of sodium balance can be maintained as long as minimal levels of aldosterone are present, the inability to adjust aldosterone secretion appropriately greatly impairs the regulation of renal potassium excretion and potassium concentration of the body fluids. Thus, aldosterone is even more important as a regulator of potassium concentration than for sodium concentration, as discussed in Chapter 30.

Angiotensin II Increases Renal Sodium and Water Reabsorption. Angiotensin II is perhaps the body's most powerful sodium-retaining hormone. As discussed in Chapter 19, angiotensin II formation increases in circumstances associated with low blood pressure and/or low extracellular fluid volume, such as during hemorrhage or loss of salt and water from the body fluids by excessive sweating or severe diarrhea. Increased formation of angiotensin II helps return blood pressure and extracellular volume toward normal by increasing sodium and water reabsorption from the renal tubules through three main effects:

1. *Angiotensin II stimulates aldosterone secretion*, which in turn increases sodium reabsorption.
2. *Angiotensin II constricts the efferent arterioles*, which has two effects on peritubular capillary dynamics that increase sodium and water reabsorption. First, efferent arteriolar constriction reduces peritubular capillary hydrostatic pressure, which increases net tubular reabsorption, especially from the proximal tubules. Second, efferent arteriolar constriction, by reducing renal blood flow, raises filtration fraction in the glomerulus and increases the concentration of proteins and colloid osmotic pressure in the peritubular capillaries. This mechanism also increases the reabsorptive force at the peritubular capillaries and raises tubular reabsorption of sodium and water.
3. *Angiotensin II directly stimulates sodium reabsorption in the proximal tubules, the loops of Henle, the distal tubules, and the collecting tubules*. One of the direct effects of angiotensin II is to stimulate the Na^+-K^+ ATPase pump on the tubular epithelial cell basolateral membrane. A second effect is to stimulate sodium-hydrogen exchange in the luminal membrane, especially in the proximal tubule. A third effect of angiotensin II is to stimulate sodium-bicarbonate co-transport in the basolateral membrane (**Fig. 28.18**).

Thus, angiotensin II stimulates sodium transport across the luminal and basolateral surfaces of the epithelial cell

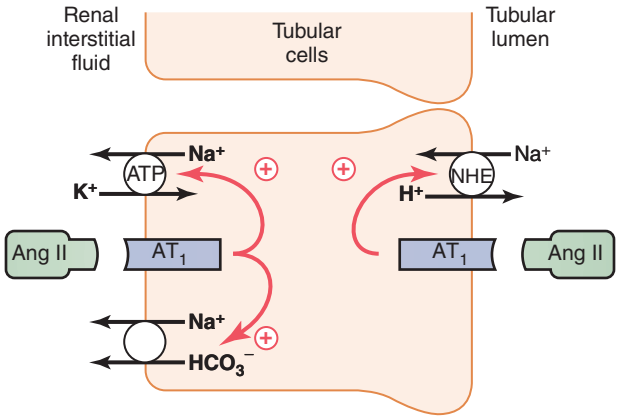

Figure 28.18 Direct effects of angiotensin II (Ang II) to increase proximal tubular sodium reabsorption. Ang II stimulates sodium-hydrogen exchange (NHE) on the luminal membrane and the Na^+-K^+ ATPase transporter, as well as sodium-bicarbonate co-transport on the basolateral membrane. Ang II also increases sodium reabsorption in several other parts of the renal tubule, including the loop of Henle, distal tubule, and collecting tubule. *AT_1*, Angiotensin II type I receptor.

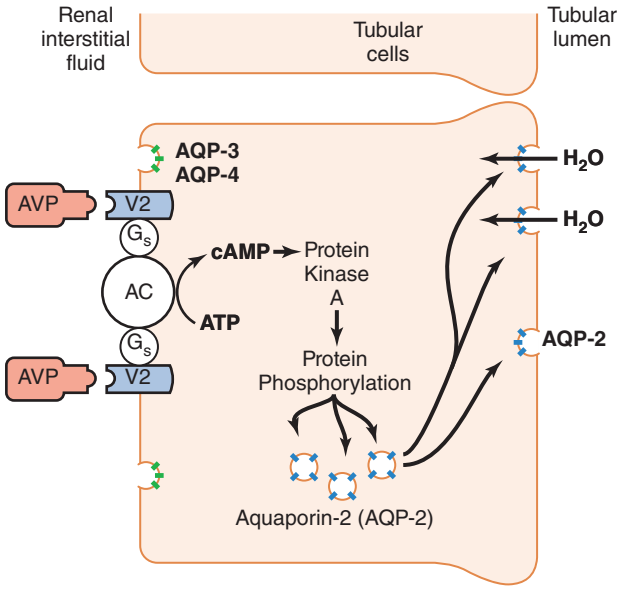

Figure 28.19 Mechanism of action of arginine vasopressin (AVP) on the epithelial cells of the late distal tubules, collecting tubules, and collecting ducts. AVP binds to its V_2 receptors, which are coupled with stimulatory G proteins (G_s) that activate adenylate cyclase (AC) and stimulate formation of cyclic adenosine monophosphate (cAMP). This, in turn, activates protein kinase A and phosphorylation of intracellular proteins, causing movement of aquaporin-2 (AQP-2) to the luminal side of the cell membrane. The molecules of AQP-2 fuse together to form water channels. On the basolateral side of the cell membrane are other aquaporins, AQP-3 and AQP-4, which permit water to flow out of the cell, although these aquaporins do not appear to be regulated by AVP.

membrane in most renal tubular segments. These multiple actions of angiotensin II cause marked sodium and water retention by the kidneys when angiotensin II levels are increased and play a critical role in permitting the body to adapt to wide variations in sodium intake without large changes in extracellular fluid volume and blood pressure, as discussed in Chapter 30.

At the same time that angiotensin II increases renal tubular sodium reabsorption, its vasoconstrictor effect on efferent arterioles also aids in the maintenance of normal excretion of metabolic waste products such as urea and creatinine that depend mainly on an adequate GFR for their excretion. Thus, increased formation of angiotensin II during reduced sodium intake, for example, permits the kidneys to retain sodium and water without causing retention of metabolic waste products.

Antidiuretic Hormone (ADH) Increases Renal Water Reabsorption. The most important renal action of ADH is to increase water permeability of the distal tubule, collecting tubule, and collecting duct epithelia. This effect helps the body conserve water in circumstances such as dehydration. In the absence of ADH, permeability of the distal tubules and collecting ducts to water is low, causing the kidneys to excrete large amounts of dilute urine, a condition called *diabetes insipidus*. Thus, the actions of ADH play a key role in controlling the degree of dilution or concentration of the urine, as discussed further in Chapters 29 and 76.

ADH binds to specific *V_2 receptors* in the late distal tubules, collecting tubules, and collecting ducts, increasing the formation of cyclic adenosine monophosphate and activating protein kinases (**Fig. 28.19**). This action, in turn, stimulates movement of *AQP-2* to the luminal side of the cell membranes. The molecules of AQP-2 cluster together and fuse with the cell membrane by exocytosis to form *water channels* that permit rapid diffusion of water through the cells. There are other aquaporins, AQP-3 and AQP-4, in the basolateral side of the cell membrane that provide a path for water to exit the cells rapidly, although these aquaporins are not regulated by ADH. Chronic increases in ADH levels also increase the formation of AQP-2 protein in the renal tubular cells by stimulating AQP-2 gene transcription. When the concentration of ADH decreases, the molecules of AQP-2 are shuttled back to the cell cytoplasm, thereby removing the water channels from the luminal membrane and reducing water permeability. These actions of ADH are discussed further in Chapters 29 and 76.

Natriuretic Peptides Secreted By the Heart Decrease Renal Sodium and Water Reabsorption. When muscle cells (myocytes) of the cardiac atria and ventricles are stretched because of plasma volume expansion and increased atrial blood pressure, they secrete a peptide called *atrial natriuretic peptide* (ANP). Increased levels of this peptide, in turn, directly inhibit reabsorption of sodium and water by the renal tubules, especially in the collecting ducts. ANP also causes renal vasodilation and decreased renin secretion and therefore angiotensin II formation, which in turn reduces renal tubular reabsorption. ANP also decreases aldosterone secretion by direct actions on the adrenal gland glomerulosa cells and by reducing angiotensin II formation. All of these effects of ANP decrease sodium and water reabsorption and increase urinary excretion, which helps return the blood volume back toward normal.

Stretch of the cardiac ventricular myocytes, associated with increased ventricular volume, stimulates release of a peptide called *brain natriuretic peptide (BNP)* that has renal actions similar to ANP. BNP was first isolated from porcine brain but originates mainly from cardiac ventricles. The primary stimulus for BNP is stretch of the ventricular myocytes associated with increased ventricular volume.

ANP and BNP both act on the same natriuretic peptide receptors (NPRs), which are *guanylyl cyclase receptors*. Activation of NPRs results in increased *cyclic guanosine monophosphate (cGMP)*, which, in turn, activates downstream kinases that lead to the multiple effects of ANP and BNP previously described. ANP and BNP levels are greatly elevated in congestive heart failure when the cardiac atria and ventricles are stretched because of impaired pumping of the ventricles. The increased ANP and BNP levels help attenuate sodium and water retention in heart failure.

Parathyroid Hormone Increases Renal Calcium Reabsorption. Parathyroid hormone (PTH) is one of the most important calcium-regulating hormones in the body. Its principal action in the kidneys is to increase tubular reabsorption of calcium, especially in the *distal tubules* and *connecting tubules*, a tubular segment that connects the distal tubules with the cortical collecting duct. PTH also has other renal actions, including inhibition of phosphate reabsorption by the proximal tubule and stimulation of magnesium reabsorption by the loop of Henle, as discussed in Chapter 30.

SYMPATHETIC NERVOUS SYSTEM ACTIVATION INCREASES SODIUM REABSORPTION

Activation of the sympathetic nervous system, if severe, can decrease sodium and water excretion by constricting the renal arterioles, thereby reducing the GFR. Even low levels of sympathetic activation, however, decrease sodium and water excretion by increasing sodium reabsorption in the proximal tubule, the thick ascending limb of the loop of Henle, and perhaps in more distal parts of the renal tubule. This occurs by activation of α-adrenergic receptors on the renal tubular epithelial cells.

Sympathetic nervous system stimulation also increases renin release and angiotensin II formation, which adds to the overall effect to increase tubular reabsorption and decrease renal excretion of sodium.

USE OF CLEARANCE METHODS TO QUANTIFY KIDNEY FUNCTION

Although there are many new methods available for assessing kidney function, the rates at which different substances are cleared from the plasma continue to provide a useful way of quantitating the effectiveness with which the kidneys excrete various substances (**Table 28.4**). By definition, the renal clearance of a substance is the volume of plasma that is completely cleared of *the substance by the kidneys per unit of time*.

Table 28.4 Use of Clearance to Quantify Kidney Function

Term	Equation	Units
Clearance rate	$C_s = \frac{U_s \times \dot{V}}{P_s}$	mL/min
Glomerular filtration rate	$GFR = \frac{U_{inulin} \times \dot{V}}{P_{inulin}}$	
Clearance ratio	$\text{Clearance ratio} = \frac{C_s}{C_{inulin}}$	None
Effective renal plasma flow	$ERPF = C_{PAH} = \frac{U_{PAH} \times \dot{V}}{P_{PAH}}$	mL/min
Renal plasma flow	$RPF = \frac{C_{PAH}}{E_{PAH}} = \frac{(U_{PAH} \times \dot{V}/P_{PAH})}{(P_{PAH} - V_{PAH})/P_{PAH}} = \frac{U_{PAH} \times \dot{V}}{P_{PAH} - V_{PAH}}$	mL/min
Renal blood flow	$RBF = \frac{RPF}{1 - \text{Hematocrit}}$	mL/min
Excretion rate	$\text{Excretion rate} = U_s \times \dot{V}$	mg/min, mmol/min, or mEq/min
Reabsorption rate	$\text{Reabsorption rate} = \text{Filtered load} - \text{Excretion rate} = (GFR \times P_s) - (U_s \times \dot{V})$	mg/min, mmol/min, or mEq/min
Secretion rate	Secretion rate = Excereton rate – Filtered load	mg/min, mmol/min, or mEq/min

C_s, Clearance rate of substance s; E_{PAH}, PAH extraction ratio; *ERPF*, effective renal plasma flow; *GFR*, glomerular filtration rate; *P*, plasma concentration; *PAH*, para-aminohippuric acid; P_{PAH}, renal arterial PAH concentration; *RBF*, renal blood flow; *RPF*, renal plasma flow; *S*, a substance; *U*, urine concentration; $\dot{V}$, urine flow rate; V_{PAH}, renal venous PAH concentration.

Although there is no single volume of plasma that is *completely* cleared of a substance, renal clearance provides a useful way of quantifying renal blood flow, GFR, tubular reabsorption, and tubular secretion. To illustrate the clearance principle, consider the following example. If the plasma passing through the kidneys contains 1 milligram of a substance in each milliliter, and if 1 milligram of this substance is also excreted into the urine each minute, then 1 mL/min of the plasma is cleared of the substance. Clearance refers to the volume of plasma that would be necessary to supply the amount of substance excreted in the urine per unit of time. Stated mathematically:

$$C_s \times P_s = U_s \times \dot{V}$$

where C_s is the clearance rate of a substance s, P_s is the plasma concentration of the substance, U_s is the urine concentration of that substance, and $\dot{V}$ is the urine flow rate. Rearranging this equation, clearance can be expressed as:

$$C_s = \frac{U_s \times \dot{V}}{P_s}$$

Thus, renal clearance of a substance is calculated from urinary excretion rate ($U_s \times \dot{V}$) of that substance divided by its plasma concentration.

Inulin Clearance Can Be Used to Estimate Glomerular Filtration Rate

If a substance is freely filtered (filtered as freely as water) and is not reabsorbed or secreted by the renal tubules, then the rate at which that substance is excreted in the urine ($U_s \times \dot{V}$) is equal to the filtration rate of the substance by the kidneys (GFR × P_s). Thus:

$$GFR \times P_s = U_s \times \dot{V}$$

The GFR, therefore, can be calculated as the clearance of the substance as follows:

$$GFR = \frac{U_s \times \dot{V}}{P_s} = C_s$$

A substance that fits these criteria is *inulin*, a polysaccharide molecule with a molecular weight of about 5200. Inulin, which is not produced in the body, is found in the roots of certain plants and must be administered intravenously to measure GFR.

Fig. 28.20 illustrates the renal handling of inulin. In this example, the plasma concentration is 1 mg/mL, urine concentration is 125 mg/mL, and urine flow rate is 1 mL/min. Therefore, 125 mg/min of inulin passes into the urine. Then, inulin clearance is calculated as the urine excretion rate of inulin divided by the plasma concentration, which yields a value of 125 mL/min. Thus, 125 mL of plasma flowing through the kidneys must be filtered to deliver the inulin that appears in the urine.

Inulin is not the only substance that can be used for determining the GFR. Other substances that have been used clinically to estimate the GFR include *iothalamate, chromium ethylenediaminetetraacetic acid* (EDTA), *cystatin C*, and *creatinine*.

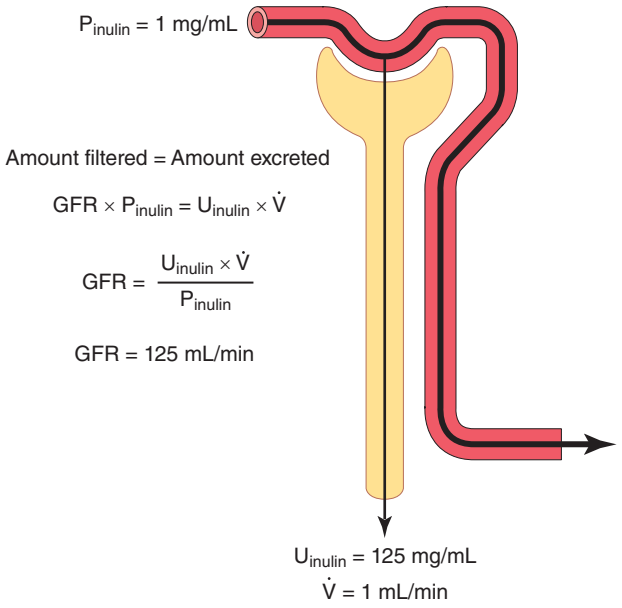

Figure 28.20 Measurement of glomerular filtration rate (*GFR*) from the renal clearance of inulin. Inulin is freely filtered by the glomerular capillaries but is not reabsorbed by the renal tubules. P_{inulin}, Plasma inulin concentration; U_{inulin}, urine inulin concentration; $\dot{V}$, urine flow rate.

Creatinine Clearance and Plasma Creatinine Concentration Can Be Used to Estimate Glomerular Filtration Rate

Creatinine is a by-product of muscle metabolism and is cleared from the body fluids almost entirely by glomerular filtration. Therefore, creatinine clearance can also be used to assess GFR. Because measurement of creatinine clearance does not require intravenous infusion into the patient, this method is much more widely used than inulin clearance for estimating GFR clinically. However, creatinine clearance is not a perfect marker of GFR because a small amount of it is secreted by the tubules, so the amount of creatinine excreted slightly exceeds the amount filtered. However, there is normally a slight error in measuring plasma creatinine that leads to an overestimation of plasma creatinine concentration; fortuitously, these two errors tend to cancel each other, and creatinine clearance provides a reasonable estimate of GFR.

In some cases, it may not be practical to collect urine in a patient for measuring creatinine clearance (C_{Cr}). An approximation of *changes* in GFR, however, can be obtained by simply measuring plasma creatinine concentration (P_{Cr}), which is inversely proportional to the GFR:

$$GFR \approx C_{Cr} = \frac{U_{Cr} \times \dot{V}}{P_{Cr}}$$

If GFR suddenly decreases by 50%, the kidneys will transiently filter and excrete only half as much creatinine, causing accumulation of creatinine in the body fluids and raising plasma concentration. Plasma concentration of creatinine will continue to rise until the filtered load of creatinine (P_{Cr} × GFR) and creatinine excretion ($U_{Cr} \times \dot{V}$) return to normal, and a balance between

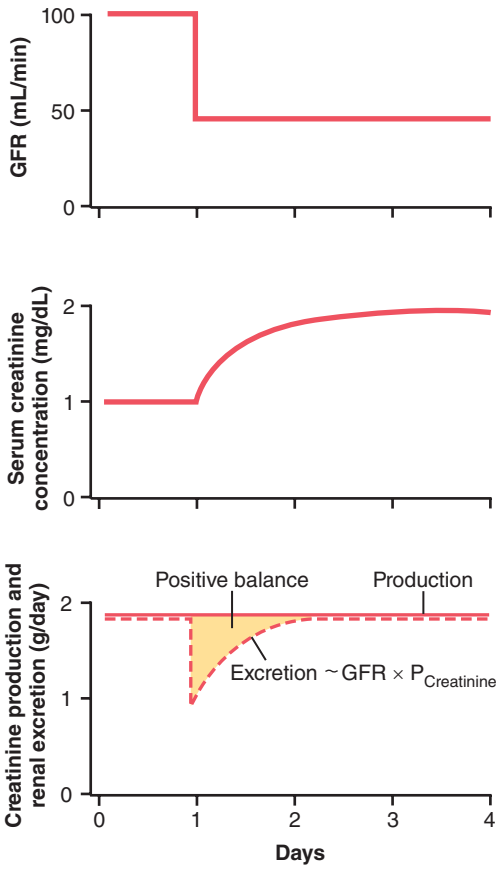

Figure 28.21 Effect of reducing glomerular filtration rate (*GFR*) by 50% on the serum creatinine concentration and on creatinine excretion rate when the production rate of creatinine remains constant. $P_{Creatinine}$, Plasma creatinine concentration.

creatinine production and creatinine excretion is reestablished. This balance will occur when the plasma creatinine level increases to approximately twice normal, as shown in **Fig. 28.21**.

If GFR falls to one-fourth normal, plasma creatinine level would increase to about four times normal, and a decrease of GFR to one-eighth normal would raise plasma creatinine level to eight times normal. Thus, under steady-state conditions, creatinine excretion rate equals the rate of creatinine production, despite reductions in GFR. However, this normal rate of creatinine excretion occurs at the expense of an elevated plasma creatinine concentration, as shown in **Fig. 28.22**.

Para-Aminohippuric Acid Clearance Can Be Used to Estimate Renal Plasma Flow

Theoretically, if a substance is *completely* cleared from the plasma, the clearance rate of that substance is equal to the total RPF. In other words, the amount of the substance delivered to the kidneys in the blood (RPF × P_s) would be equal to the amount excreted in the urine ($U_s \times \dot{V}$). Thus, RPF can be calculated as follows:

$$RPF = \frac{U_s \times \dot{V}}{P_s} = C_s$$

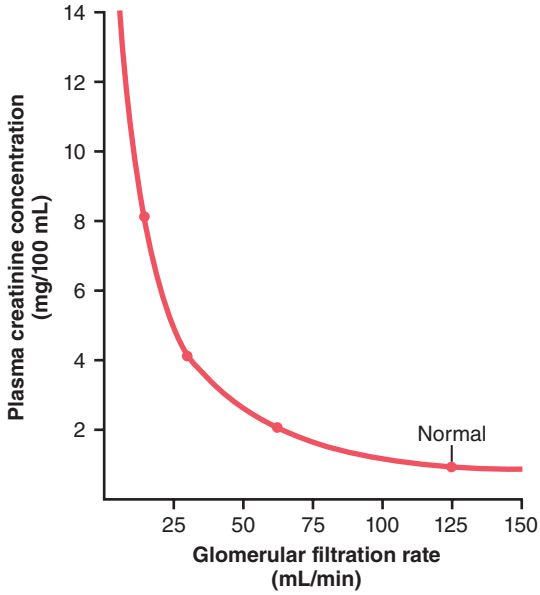

Figure 28.22 Approximate relationship between glomerular filtration rate (GFR) and plasma creatinine concentration under steady-state conditions. Decreasing GFR by 50% will increase plasma creatinine level to twice normal if creatinine production by the body remains constant.

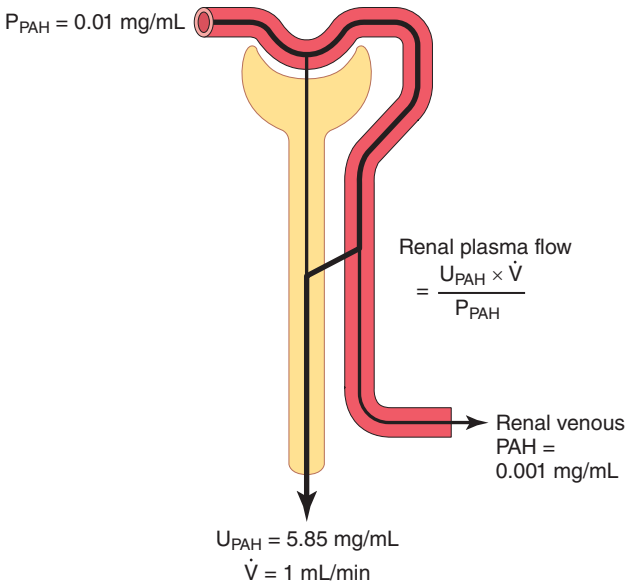

Figure 28.23 Measurement of renal plasma flow from the renal clearance of para-aminohippuric acid (PAH). PAH is freely filtered by the glomerular capillaries and is also secreted from the peritubular capillary blood into the tubular lumen. The amount of PAH in the plasma of the renal artery is about equal to the amount of PAH excreted in the urine. Therefore, the renal plasma flow can be calculated from the clearance of PAH. To be more accurate, one can correct for the percentage of PAH that is still in the blood when it leaves the kidneys. P_{PAH}, Arterial plasma PAH concentration; U_{PAH}, urine PAH concentration; $\dot{V}$, urine flow rate.

Because the GFR is only about 20% of the total plasma flow, a substance that is completely cleared from the plasma must be excreted by tubular secretion, as well as by glomerular filtration (**Fig. 28.23**). There is no known substance that is *completely* cleared by the kidneys. One

substance, PAH, is about 90% cleared from the plasma. Therefore, clearance of PAH can be used to approximate RPF. To be more accurate, one can correct for the percentage of PAH that is still in the blood when it leaves the kidneys. The percentage of PAH removed from the blood is known as the *extraction ratio of PAH* and averages about 90% in normal kidneys. In diseased kidneys, this extraction ratio may be reduced because of the inability of damaged tubules to secrete PAH into the tubular fluid.

The calculation of RPF can be demonstrated by the following example. Assume that the plasma concentration of PAH is 0.01 mg/mL, urine concentration is 5.85 mg/mL, and urine flow rate is 1 mL/min. PAH clearance can be calculated from the rate of urinary PAH excretion (5.85 [mg/mL] × 1 [mL/min]) divided by plasma PAH concentration (0.01 mg/mL). Thus, clearance of PAH is calculated to be 585 mL/min.

If the extraction ratio for PAH is 90%, the actual RPF can be calculated by dividing 585 mL/min by 0.9, yielding a value of 650 mL/min. Thus, total RPF can be calculated as follows:

$$\text{Total renal plasma flow} = \frac{\text{PAH clearance}}{\text{PAH extraction ratio}}$$

The extraction ratio (E_{PAH}) is calculated as the difference between renal arterial PAH (P_{PAH}) and renal venous PAH (V_{PAH}) concentrations, divided by renal arterial PAH concentration:

$$E_{PAH} = \frac{P_{PAH} - V_{PAH}}{P_{PAH}}$$

One can calculate total blood flow through the kidneys from total RPF and hematocrit (the percentage of red blood cells in the blood). If hematocrit is 0.45 and total RPF is 650 mL/min, total blood flow through both kidneys is 650/(1 − 0.45), or 1182 mL/min.

Filtration Fraction Is Calculated From GFR Divided By RPF

To calculate the filtration fraction, which is the fraction of plasma filtered through the glomerular membrane, one must first know the RPF (PAH clearance) and the GFR (inulin clearance). If RPF is 650 mL/min and GFR is 125 mL/min, filtration fraction (FF) is calculated as follows:

$$FF = \frac{GFR}{RPF} = \frac{125}{650} = 0.19$$

CALCULATION OF TUBULAR REABSORPTION OR SECRETION

If the rates of glomerular filtration and renal excretion of a substance are known, one can calculate whether there is a net reabsorption or net secretion of that substance by the renal tubules. For example, if the rate of excretion of the substance ($U_s \times \dot{V}$) is less than the filtered load of the substance ($GFR \times P_s$), then some of the substance must have been reabsorbed from the renal tubules. Conversely, if the excretion rate of the substance is greater than its filtered load, then the rate at which it appears in the urine represents the sum of the rate of glomerular filtration plus tubular secretion.

The following example demonstrates the calculation of tubular reabsorption. Assume that the following laboratory values for a patient were obtained:

- Urine flow rate ($\dot{V}$) = 1 mL/min
- Urine concentration of sodium (U_{Na}) = 70 mEq/L = 70 μEq/mL
- Plasma sodium concentration (P_{Na}) = 140 mEq/L = 140 μEq/mL
- GFR (inulin clearance) = 100 mL/min

In this example, the filtered sodium load is $GFR \times P_{Na}$, or 100 mL/min × 140 μEq/mL = 14,000 μEq/min. Urinary sodium excretion ($U_{Na} \times \dot{V}$) is 70 μEq/min. Therefore, tubular reabsorption of sodium is the difference between the filtered load and urinary excretion, or 14,000 μEq/min − 70 μEq/min = 13,930 μEq/min

Comparisons of Inulin Clearance With Clearances of Different Solutes. The following generalizations can be made by comparing the clearance of a substance with the clearance of inulin, the gold standard for measuring GFR: (1) if the clearance rate of the substance equals that of inulin, the substance is only filtered and not reabsorbed or secreted; (2) if the clearance rate of a substance is less than inulin clearance, the substance must have been reabsorbed by the nephron tubules; and (3) if the clearance rate of a substance is greater than that of inulin, the substance must be secreted by the nephron tubules. Listed below are the approximate clearance rates for some of the substances normally handled by the kidneys:

Substance	Clearance Rate (mL/min)
Glucose	0
Sodium	0.9
Chloride	1.3
Potassium	12.0
Phosphate	25.0
Inulin	125.0
Creatinine	140.0

CHAPTER 29

Urine Concentration and Dilution; Regulation of Extracellular Fluid Osmolarity and Sodium Concentration

Normal function of the cells requires that they be bathed in extracellular fluid with a relatively constant concentration of electrolytes and other solutes. The *total concentration* of solutes in the extracellular fluid—and therefore osmolarity—must also be precisely regulated to prevent the cells from shrinking or swelling. The osmolarity is determined by the amount of solute (mainly sodium chloride) divided by the volume of the extracellular fluid. Thus, to a large extent, extracellular fluid osmolarity and sodium chloride concentration are regulated by the amount of extracellular water. The total body water is controlled by (1) fluid intake, which is regulated by factors that determine thirst; and (2) renal water excretion, which is controlled by multiple factors that influence glomerular filtration and tubular reabsorption.

In this chapter, we discuss the following: (1) renal mechanisms for eliminating excess water through excretion of dilute urine; (2) renal mechanisms for conserving water through excretion of concentrated urine; (3) feedback mechanisms that control extracellular fluid sodium concentration and osmolarity; and (4) thirst and salt appetite mechanisms that determine the intakes of water and salt, which also help control extracellular fluid volume, osmolarity, and sodium concentration.

KIDNEYS EXCRETE EXCESS WATER BY FORMING DILUTE URINE

Normal kidneys have a tremendous capability to vary the relative proportions of solutes and water in the urine in response to various challenges. When there is excess water in the body and body fluid osmolarity is reduced, the kidneys can excrete urine with an osmolarity as low as 50 mOsm/L, a concentration that is only about one-sixth the osmolarity of normal extracellular fluid. Conversely, when there is a deficit of water in the body and extracellular fluid osmolarity is high, the kidneys can excrete highly concentrated urine with an osmolarity of 1200 to 1400 mOsm/L. Equally important, the kidneys can excrete a large volume of dilute urine or a small volume of concentrated urine without major changes in rates of excretion of solutes such as sodium and potassium. This ability to regulate water excretion independently of solute excretion is necessary for survival, especially when fluid intake is limited.

ANTIDIURETIC HORMONE CONTROLS URINE CONCENTRATION

The body has a powerful feedback system for regulating plasma osmolarity and sodium concentration that operates by altering renal excretion of water independently of solute excretion rate. A primary effector of this feedback is *antidiuretic hormone* (ADH), also called *vasopressin*.

When osmolarity of the body fluids increases above normal (i.e., the solutes in the body fluids become too concentrated), the posterior pituitary gland secretes more ADH, which increases the permeability of the distal tubules and collecting ducts to water, as discussed in Chapter 28. This mechanism increases water reabsorption and decreases urine volume but does not markedly alter the rate of renal excretion of solutes.

When there is excess water in the body and extracellular fluid osmolarity is reduced, secretion of ADH by the posterior pituitary decreases, thereby reducing the permeability of the distal tubule and collecting ducts to water, which causes increased amounts of dilute urine to be excreted. Thus, the rate of ADH secretion determines, to a large extent, whether the kidney excretes dilute or concentrated urine.

RENAL MECHANISMS FOR EXCRETING DILUTE URINE

When there is a large excess of water in the body, the kidneys can excrete as much as 20 L/day of dilute urine, with a concentration as low as 50 mOsm/L. The kidneys perform this impressive feat by continuing to reabsorb solutes without reabsorbing large amounts of water in the distal parts of the nephron, including the late distal tubule and collecting ducts.

Fig. 29.1 shows the approximate renal responses in a human after ingestion of 1 liter of water. Note that urine volume increased to about six times normal within 45 minutes after the water had been ingested. However, the total amount of solute excreted remained relatively constant because the urine formed became dilute, and urine osmolarity decreased from 600 to about 100 mOsm/L. Thus, after ingestion of excess water, the kidney rids the body of the excess water but does not excrete substantially greater amounts of solutes.

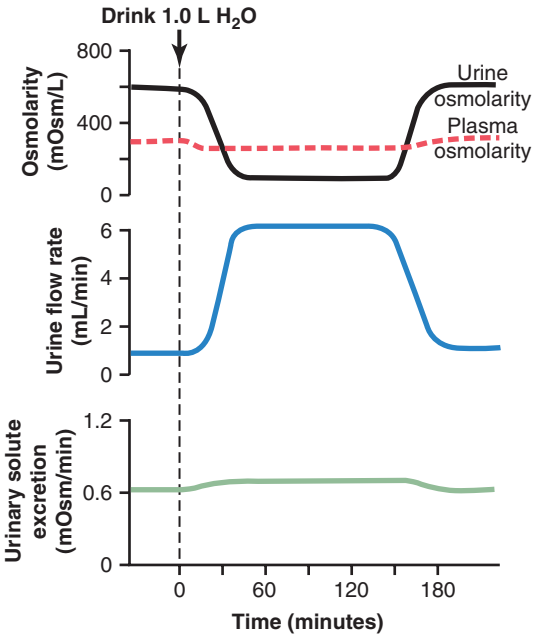

Figure 29.1 Water diuresis in a person after ingestion of 1 liter of water. After water ingestion, urine volume increases and urine osmolarity decreases, causing excretion of a large volume of dilute urine; however, the total amount of solute excreted by the kidneys remains relatively constant. These responses of the kidneys help prevent plasma osmolarity from decreasing markedly during increased water ingestion.

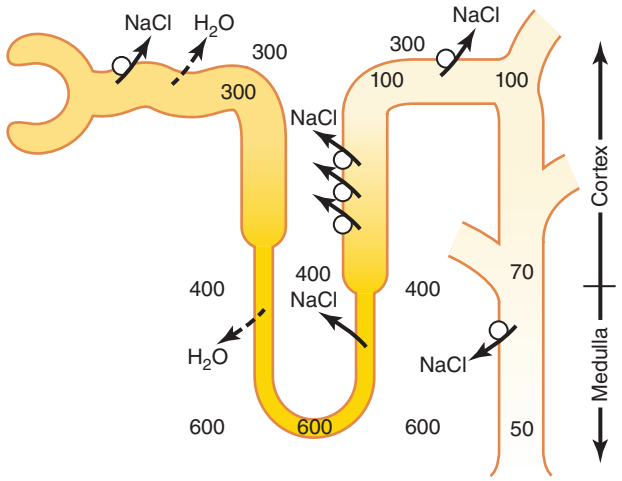

Figure 29.2 Formation of dilute urine when antidiuretic hormone (ADH) levels are very low. Note that in the ascending loop of Henle, the tubular fluid becomes very dilute. In the distal tubules and collecting tubules, the tubular fluid is further diluted by the reabsorption of sodium chloride and the failure to reabsorb water when ADH levels are very low. The failure to reabsorb water and continued reabsorption of solutes lead to a large volume of dilute urine. (Numerical values are in milliosmoles per liter.)

When the glomerular filtrate is initially formed, its osmolarity is about the same as that of plasma (300 mOsm/L). To excrete excess water, the filtrate is diluted as it passes along the tubule by reabsorbing solutes to a greater extent than water, as shown in **Fig. 29.2**. This dilution, however, occurs only in certain segments of the tubular system, as described in the following sections.

Tubular Fluid Remains Isosmotic in Proximal Tubules. As fluid flows through the proximal tubule, solutes and water are reabsorbed in equal proportions, so little change in osmolarity occurs. Thus, the proximal tubule fluid remains isosmotic to the plasma, with an osmolarity of about 300 mOsm/L. As fluid passes down the descending loop of Henle, water is reabsorbed by osmosis and the tubular fluid reaches equilibrium with the surrounding interstitial fluid of the renal medulla, which is very hypertonic—about two to four times the osmolarity of the original glomerular filtrate. Therefore, the tubular fluid becomes more concentrated as it flows into the inner medulla.

Tubular Fluid Is Diluted in the Ascending Loop of Henle. In the ascending limb of the loop of Henle, especially in the thick segment, sodium, potassium, and chloride are avidly reabsorbed. However, this portion of the tubular segment is impermeable to water, even in the presence of large amounts of ADH. Therefore, the tubular fluid becomes more dilute as it flows up the ascending loop of Henle into the early distal tubule, with the osmolarity decreasing progressively to about 100 mOsm/L by the time the fluid enters the early distal tubular segment. *Thus, regardless of whether ADH is present or absent, fluid leaving the early distal tubular segment is hypo-osmotic, with an osmolarity of only about one-third the osmolarity of plasma.*

Tubular Fluid in Distal and Collecting Tubules Is Further Diluted in the Absence of ADH. As the dilute fluid in the early distal tubule passes into the late distal convoluted tubule, cortical collecting duct, and medullary collecting duct, there is additional reabsorption of sodium chloride. In the absence of ADH, this portion of the tubule is also impermeable to water, and the additional reabsorption of solutes causes the tubular fluid to become even more dilute, decreasing its osmolarity to as low as 50 mOsm/L. The failure to reabsorb water and continued reabsorption of solutes lead to a large volume of dilute urine.

To summarize, the mechanism for forming dilute urine is to continue reabsorbing solutes from the distal segments of the tubular system while reducing water reabsorption. In healthy kidneys, fluid leaving the ascending loop of Henle and early distal tubule is always dilute, regardless of the level of ADH. In the absence of ADH, the urine is further diluted in the late distal tubule and collecting ducts, and a large volume of dilute urine is excreted.

KIDNEYS CONSERVE WATER BY EXCRETING CONCENTRATED URINE

The ability of the kidneys to form concentrated urine is essential for survival of mammals that live on land, including humans. Water is continuously lost from the body through various routes, including the lungs by

evaporation into the expired air, the gastrointestinal tract by way of the feces, the skin through evaporation and perspiration, and the kidneys through excretion of urine. Fluid intake is required to match this loss, but the ability of the kidneys to form a small volume of concentrated urine minimizes the fluid intake required to maintain homeostasis, a function that is especially important when water is in short supply.

When there is a water deficit in the body, the kidneys form concentrated urine by continuing to excrete solutes while increasing water reabsorption and decreasing urine volume. The human kidney can produce a maximal urine concentration of 1200 to 1400 mOsm/L, four to five times the osmolarity of plasma.

Some desert animals, such as the Australian hopping mouse, can concentrate urine to as high as 10,000 mOsm/L. This ability allows the mouse to survive in the desert without drinking water; sufficient water can be obtained through the ingested food and water produced in the body by metabolism of the food. Animals adapted to freshwater environments usually have minimal urine-concentrating ability. Beavers, for example, can concentrate the urine only to about 500 mOsm/L.

Obligatory Urine Volume

The maximal concentrating ability of the kidney dictates how much urine volume must be excreted each day to rid the body of metabolic waste products and electrolytes that are ingested. A 70-kg person with a normal diet must excrete about 600 milliosmoles of solute each day. If the maximal urine concentrating ability is 1200 mOsm/L, the *minimal* volume of urine that must be excreted, called the *obligatory urine volume*, can be calculated as follows:

$$\frac{600\ \text{mOsm/day}}{1200\ \text{mOsm/L}} = 0.5\ \text{L/day}$$

This minimal loss of volume in the urine contributes to dehydration, along with water loss from the skin, respiratory tract, and gastrointestinal tract, when water is not available to drink.

The limited ability of the human kidney to concentrate the urine to only about 1200 mOsm/L explains why severe dehydration occurs if one attempts to drink seawater. Sodium chloride concentration in the ocean averages about 3.0% to 3.5%, with an osmolarity between about 1000 and 1200 mOsm/L. Drinking 1 liter of seawater with a concentration of 1200 mOsm/L would provide a total sodium chloride intake of 1200 milliosmoles. If the maximal urine concentrating ability is 1200 mOsm/L, the amount of urine volume needed to excrete 1200 milliosmoles would be 1.0 liter. Why then does drinking seawater cause dehydration? The answer is that the kidney must also excrete other solutes, especially urea, which contribute about 600 mOsm/L when the urine is maximally concentrated. Therefore, the maximum concentration of sodium chloride that can be excreted by the kidneys is about 600 mOsm/L. Thus, for every liter of seawater ingested, 1.5 liters of urine volume would be required to rid the body of 1200 mOsm of sodium chloride ingested in addition to 600 mOsm of other solutes, such as urea. This would result in a net fluid loss of 0.5 liter for every liter of seawater, explaining the rapid dehydration that occurs in shipwreck victims who drink seawater.

Urine Specific Gravity

Urine *specific gravity* is often used in clinical settings to provide a rapid estimate of urine solute concentration. The more concentrated the urine, the higher the urine specific gravity. In most cases, urine specific gravity increases linearly with increasing urine osmolarity (**Fig. 29.3**). Urine specific gravity, however, is a measure of the weight of solutes in a given volume of urine and is therefore determined by the number and size of the solute molecules. In contrast, osmolarity is determined only by the number of solute molecules in a given volume.

Urine specific gravity is generally expressed in grams per milliliter (g/mL) and, in humans, normally ranges from 1.002 to 1.028 g/mL, rising by 0.001 for every 35- to 40-mOsm/L increase in urine osmolarity. This relationship between specific gravity and osmolarity is altered when there are significant amounts of large molecules in the urine, such as glucose, radiocontrast media used for diagnostic purposes, or some antibiotics. In these cases, urine specific gravity measurements may falsely suggest a highly concentrated urine, despite a normal urine osmolality.

Dipsticks are available that measure approximate urine specific gravity, but most laboratories measure specific gravity with a *refractometer*.

Excreting Concentrated Urine Requires High ADH Levels and Hyperosmotic Renal Medulla

The basic requirements for forming a concentrated urine are (1) a *high level of ADH*, which increases the

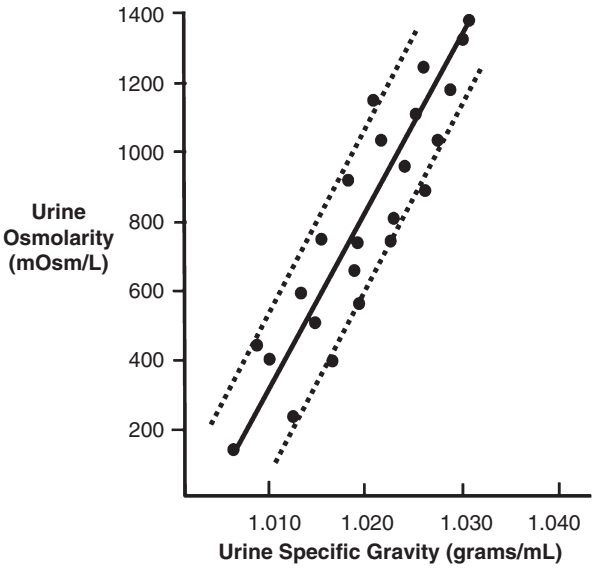

Figure 29.3 Relationship between specific gravity and osmolarity of the urine.

permeability of the distal tubules and collecting ducts to water, thereby allowing these tubular segments to avidly reabsorb water; and (2) *a high osmolarity of the renal medullary interstitial fluid*, which provides the osmotic gradient necessary for water reabsorption to occur in the presence of high levels of ADH.

The renal medullary interstitium surrounding the collecting ducts is normally hyperosmotic, so when ADH levels are high, water moves through the tubular membrane by osmosis into the renal interstitium; from there it is carried away by the vasa recta back into the blood. Thus, the urine-concentrating ability is limited by the level of ADH and by the degree of hyperosmolarity of the renal medulla. We discuss the factors that control ADH secretion later, but for now, what is the process whereby renal medullary interstitial fluid becomes hyperosmotic? This process involves the operation of the *countercurrent multiplier mechanism*.

COUNTERCURRENT MULTIPLIER MECHANISM

The countercurrent multiplier mechanism depends on the special anatomical arrangement of the loops of Henle and vasa recta, the specialized peritubular capillaries of the renal medulla. In humans, about 25% of the nephrons are *juxtamedullary nephrons*, with loops of Henle and vasa recta that go deeply into the medulla before returning to the cortex. Some of the loops of Henle dip all the way to the tips of the renal papillae that project from the medulla into the renal pelvis. Paralleling the long loops of Henle are the vasa recta, which also loop down into the medulla before returning to the renal cortex. And finally, the collecting ducts, which carry urine through the hyperosmotic renal medulla before it is excreted, also play a critical role in the countercurrent mechanism.

Countercurrent Multiplier Produces Hyperosmotic Renal Medullary Interstitium

The osmolarity of interstitial fluid in almost all parts of the body is about 300 mOsm/L, which is similar to the plasma osmolarity. (As discussed in Chapter 25, the *corrected osmolar activity*, which accounts for intermolecular attraction, is about 282 mOsm/L.) The osmolarity of the interstitial fluid in the medulla of the kidney is much higher and may increase progressively to about 1200 to 1400 mOsm/L in the pelvic tip of the medulla. This means that the renal medullary interstitium has accumulated solutes in great excess of water. Once the high solute concentration in the medulla is achieved, it is maintained by a balanced inflow and outflow of solutes and water in the medulla.

The major factors that contribute to the buildup of solute concentration into the renal medulla are as follows:

1. Active transport of sodium ions and co-transport of potassium, chloride, and other ions out of the thick portion of the ascending limb of the loop of Henle into the medullary interstitium
2. Active transport of ions from the collecting ducts into the medullary interstitium
3. Facilitated diffusion of urea from the inner medullary collecting ducts into the medullary interstitium
4. Diffusion of only small amounts of water from the medullary tubules into the medullary interstitium—far less than the reabsorption of solutes into the medullary interstitium

Loop of Henle Pumps Solutes Into the Renal Medulla

The transport characteristics of the loops of Henle are summarized in **Table 29.1**, along with the properties of the proximal tubules, distal tubules, cortical collecting tubules, and inner medullary collecting ducts.

A major reason for the high medullary osmolarity is active transport of sodium and co-transport of potassium, chloride, and other ions from the thick ascending loop of Henle into the interstitium. This pump is capable of establishing about a 200-mOsm/L concentration gradient between the tubular lumen and interstitial fluid. Because the thick ascending limb is virtually impermeable to water, the solutes pumped out are not followed by osmotic flow of water into the interstitium. Thus, the active transport of sodium and other ions out of the thick ascending loop adds solutes in excess of water to the renal medullary interstitium. There is some passive reabsorption of sodium chloride from the thin ascending limb of the loop of Henle, which is also essentially impermeable to water, adding further to the high solute concentration of the renal medullary interstitium.

Table 29.1 Summary of Tubule Characteristics—Urine Concentration

Structure	Active NaCl Transport	Permeability		
		H_2O	NaCl	Urea
Proximal tubule	++	++	+	+
Thin descending limb, loop of Henle	0	++	+	+
Thin ascending limb, loop of Henle	0	0	+	+
Thick ascending limb, loop of Henle	++	0	0	0
Distal tubule	+	+ADH	0	0
Cortical collecting tubule	+	+ADH	0	0
Inner medullary collecting duct	+	+ADH	0	+ADH

ADH, Antidiuretic hormone; *NaCl*, sodium chloride; *0*, low level of active transport or permeability; +, moderate level of active transport or permeability; ++, high level of active transport or permeability; *+ADH*, permeability to water or urea is increased by ADH.

The descending limb of the loop of Henle, in contrast to the ascending limb, is very permeable to water, and the tubular fluid osmolarity quickly becomes equal to the renal medullary osmolarity. Therefore, water diffuses out of the descending limb of the loop of Henle into the interstitium, and the tubular fluid osmolarity gradually rises as it flows toward the tip of the loop of Henle.

Steps Involved in Causing Hyperosmotic Renal Medullary Interstitium. Keeping in mind these characteristics of the loop of Henle, let us now discuss how the renal medulla becomes hyperosmotic (**Video 29.1**). First, assume that the loop of Henle is filled with fluid having a concentration of 300 mOsm/L, the same as that leaving the proximal tubule (**Fig. 29.4, step 1**). Next, the active ion pump of the *thick ascending limb* on the loop of Henle reduces the concentration of electrolytes inside the tubule and raises the interstitial concentration; this pump establishes a 200-mOsm/L concentration gradient between the tubular fluid and interstitial fluid (**Fig. 29.4, step 2**). The limit to the gradient is about 200 mOsm/L because paracellular diffusion of ions back into the tubule eventually counterbalances the transport of ions out of the lumen when the 200-mOsm/L concentration gradient is achieved.

Step 3 is that the tubular fluid in the *descending limb of the loop of Henle* and interstitial fluid quickly reaches osmotic equilibrium due to osmosis of water out of the descending limb. The interstitial osmolarity is maintained at 400 mOsm/L because of continued transport of ions out of the thick ascending loop of Henle. Thus, by itself, active transport of sodium chloride out of the thick ascending limb is capable of establishing only a 200-mOsm/L concentration gradient, which is much less than that achieved by the countercurrent multiplier system.

Step 4 is the additional flow of fluid into the loop of Henle from the proximal tubule, which causes the hyperosmotic fluid previously formed in the descending limb to flow into the ascending limb. Once this fluid is in the ascending limb, additional ions are pumped into the interstitium and water remains in the tubular fluid until a 200-mOsm/L osmotic gradient is established, and the interstitial fluid osmolarity rises to 500 mOsm/L (**step 5**). Then, once again, fluid in the descending limb reaches equilibrium with the hyperosmotic medullary interstitial fluid (**step 6**) and, as the hyperosmotic tubular fluid from the descending limb of the loop of Henle flows into the ascending limb, still more solute is continuously pumped out of the tubules and deposited into the medullary interstitium.

These steps are repeated over and over, with the net effect of adding more and more solute to the medulla in excess of water. With sufficient time, *this process gradually concentrates solutes in the medulla and multiplies the concentration gradient established by the active pumping of ions out of the thick ascending loop of Henle, eventually raising the interstitial fluid osmolarity to 1200 to 1400 mOsm/L, as shown in* ***step 7***.

Thus, the repetitive reabsorption of sodium chloride by the thick ascending loop of Henle and continued inflow of new sodium chloride from the proximal tubule into the loop of Henle is called the *countercurrent multiplier*. The sodium chloride reabsorbed from the ascending loop of Henle keeps adding to the newly arrived sodium chloride, thus "multiplying" its concentration in the medullary interstitium.

After the high solute concentration in the renal medulla is achieved and the countercurrent multiplier has reached its limit, inflow and outflow of solutes and water from the renal medullary interstitium are balanced and no further increases in renal medullary interstitial fluid osmolarity occur.

Role of Distal Tubules and Collecting Ducts in Excreting Concentrated Urine

Tubular fluid leaving the loop of Henle and flowing into the distal convoluted tubule in the renal cortex is dilute,

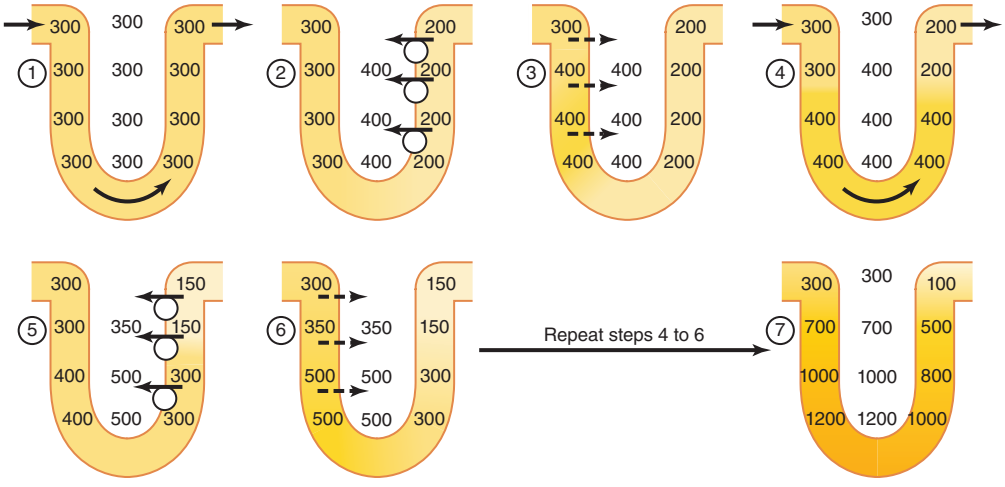

Figure 29.4 Countercurrent multiplier system in the loop of Henle for producing a hyperosmotic renal medulla. (Numerical values are in milliosmoles per liter.)

with an osmolarity of only about 100 to 140 mOsm/L (**Fig. 29.5**). The early distal tubule further dilutes the tubular fluid because this segment, like the ascending loop of Henle, actively transports sodium chloride out of the tubule but is relatively impermeable to water.

As fluid flows into the cortical collecting tubule, the amount of water reabsorbed depends on the concentration of ADH. In the absence of ADH, this segment is almost impermeable to water and fails to reabsorb water but continues to reabsorb solutes and further dilutes the urine. When there is a high concentration of ADH, the cortical collecting tubule becomes highly permeable to water, so large amounts of water are now reabsorbed from the tubule into the cortex interstitium, where it is carried away by the peritubular capillaries. *The reabsorption of much larger amounts of water in the cortex than in the renal medulla helps preserve the high medullary interstitial fluid osmolarity*.

As the tubular fluid flows along the medullary collecting ducts, there is further water reabsorption from the tubular fluid into the medullary interstitium, but the total amount of water is relatively small compared with that added to the cortex interstitium. The reabsorbed water is carried away by the vasa recta into the venous blood. When high levels of ADH are present, the collecting ducts become permeable to water, so the fluid at the end of the collecting ducts has essentially the same osmolarity as the interstitial fluid of the renal medulla—about 1200 mOsm/L (**Fig. 29.4**). Thus, by reabsorbing as much water as possible, the kidneys form highly concentrated urine, excreting normal amounts of solutes in the urine while adding water back to the extracellular fluid and compensating for deficits of body water.

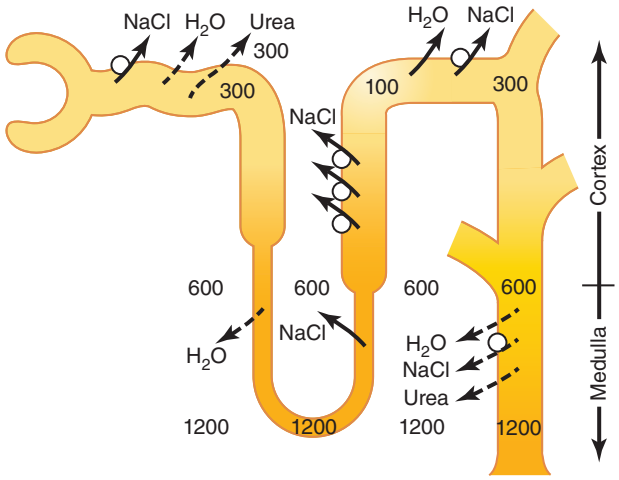

Figure 29.5 Formation of a concentrated urine when antidiuretic hormone (ADH) levels are high. Note that the fluid leaving the loop of Henle is dilute but becomes concentrated as water is absorbed from the distal tubules and collecting tubules. With high ADH levels, the osmolarity of the urine is about the same as the osmolarity of the renal medullary interstitial fluid in the papilla, which is about 1200 mOsm/L. (Numerical values are in milliosmoles per liter.)

Urea Contributes to Hyperosmotic Renal Medullary Interstitium and Formation of Concentrated Urine

Urea contributes about 40% to 50% of the osmolarity (500–600 mOsm/L) of the renal medullary interstitium when the kidney is forming a maximally concentrated urine. Unlike sodium chloride, urea is passively reabsorbed from the tubule. When there is a water deficit and blood concentration of ADH is high, large amounts of urea are passively reabsorbed from the inner medullary collecting ducts into the interstitium.

The mechanism for urea reabsorption into the renal medulla is as follows. As water flows up the ascending loop of Henle and into the distal and cortical collecting tubules, little urea is reabsorbed because these segments have low urea permeabilities (**Table 29.1**). In the presence of high concentrations of ADH, water is reabsorbed rapidly from the cortical collecting tubule, and the urea concentration increases rapidly because urea permeability is low in this part of the tubule.

As the tubular fluid flows into the inner medullary collecting ducts, still more water reabsorption takes place, resulting in an even higher concentration of urea in the tubular fluid. This high concentration of urea in the fluid of the inner medullary collecting duct causes urea to diffuse out of the tubule into the renal interstitial fluid. This diffusion is greatly facilitated by specific *urea transporters—UT-A1*, expressed mainly in the luminal (apical) membrane, and *UT-A3*, expressed mainly in the basolateral membrane. Accumulation of these urea transporters is stimulated by ADH, facilitating urea transport out of the inner medullary collecting duct even more when ADH levels are elevated. The simultaneous movement of water and urea out of the inner medullary collecting ducts maintains a high concentration of urea in the tubular fluid and, eventually, in the urine, even though urea is being reabsorbed.

The fundamental role of urea in contributing to urine-concentrating ability is evidenced by the fact that people who ingest a high-protein diet, yielding large amounts of urea as a nitrogenous waste product, can concentrate their urine much better than people whose protein intake and urea production are low. Malnutrition is associated with a low urea concentration in the medullary interstitium and considerable impairment of urine-concentrating ability.

Recirculation of Urea From Collecting Duct to Loop of Henle Contributes to Hyperosmotic Renal Medulla. A healthy person usually excretes about 20% to 60% of the filtered load of urea, depending on urine flow rate and state of hydration. In general, the rate of urea excretion is determined mainly by the following: (1) concentration of urea in the plasma; (2) glomerular filtration rate (GFR); and (3) renal tubular urea reabsorption. In patients with renal disease who have large reductions in GFR, the plasma urea concentration increases markedly, returning the filtered urea load and urea excretion rate to

the normal level (equal to the rate of urea production), despite reduced GFR.

In the proximal tubule, 40% to 50% of the filtered urea is reabsorbed; even so, the tubular fluid urea concentration increases because urea is not nearly as permeant as water. The concentration of urea continues to rise as the tubular fluid flows into the thin segments of the loop of Henle, partly because of water reabsorption out of the descending loop of Henle but also because of some *secretion* of urea into the thin loop of Henle from the medullary interstitium (**Fig. 29.6**). The passive secretion of urea into the thin loops of Henle is facilitated by the *urea transporter UT-A2*.

The thick limb of the loop of Henle, distal tubule, and cortical collecting tubule are all less permeable to urea, and only small amounts of urea reabsorption normally occur in these tubular segments. When the kidney is forming concentrated urine and high levels of ADH are present, reabsorption of water from the distal tubule and cortical collecting tubule further raises the tubular fluid concentration of urea. As this urea flows into the inner medullary collecting duct, the high tubular fluid concentration of urea and urea transporters UT-A1 and UT-A3 facilitate urea diffusion into the medullary interstitium. A moderate share of the urea that moves into the medullary interstitium eventually diffuses into the thin loop of Henle and then passes upward through the ascending loop of Henle, distal tubule, and cortical collecting tubule and back down into the medullary collecting duct again. In this way, urea can recirculate through these terminal parts of the tubular system several times before it is excreted. Each time around the circuit contributes to a higher concentration of urea.

This urea recirculation provides an additional mechanism for forming a hyperosmotic renal medulla. Because urea is one of the most abundant waste products that must be excreted by the kidneys, this mechanism for concentrating urea before it is excreted is essential to the economy of the body fluid when water is in short supply.

When there is excess water in the body, urine flow rate increases and the concentration of urea in the inner medullary collecting ducts decreases, causing less diffusion of urea into the renal medullary interstitium. ADH levels are also reduced when there is excess body water, and this reduction, in turn, decreases permeability of the inner medullary collecting ducts to both water and urea, and more urea is excreted in the urine.

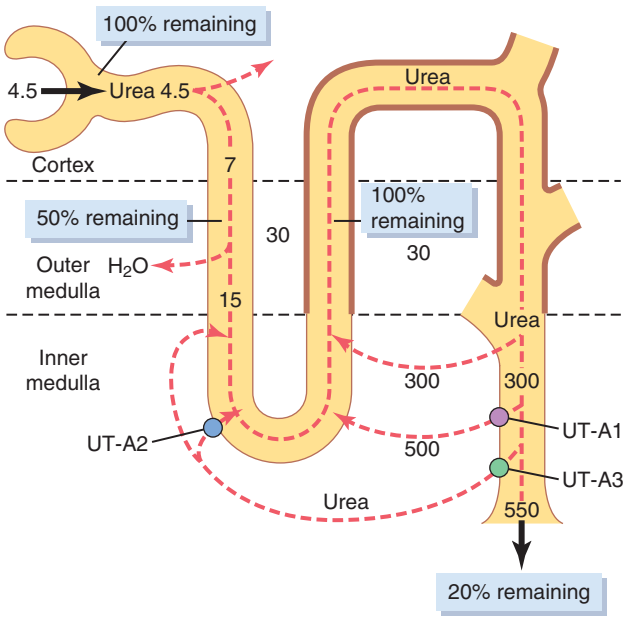

Figure 29.6 Recirculation of urea absorbed from the inner medullary collecting duct into the interstitial fluid. This urea diffuses into the thin loop of Henle, then passes through the distal tubules, and finally passes back into the collecting duct. The recirculation of urea helps concentrate urea in the renal medulla and contributes to the hyperosmolarity of the renal medulla. The *heavy lines*, from the thick ascending loop of Henle to the medullary collecting ducts, indicate that these segments are not very permeable to urea. The urea transporters UT-A1 and UT-A3 facilitate diffusion of urea out of the inner medullary collecting ducts while UT-A2 facilitates urea diffusion into the thin descending loop of Henle. (Numerical values are in milliosmoles per liter of urea during antidiuresis, when large amounts of antidiuretic hormone [ADH] are present. Percentages of the filtered load of urea that remain in the tubules are indicated in the boxes.)

Countercurrent Exchange in Vasa Recta Preserves Hyperosmolarity of Renal Medulla

Blood flow must be provided to the renal medulla to supply the metabolic needs of the cells in this part of the kidney. Without a special medullary blood flow system, however, the solutes pumped into the renal medulla by the countercurrent multiplier system would be rapidly dissipated.

Two special features of the renal medullary blood flow contribute to the preservation of the high solute concentrations:

1. The medullary blood flow is low, accounting for less than 5% of the total renal blood flow. This sluggish blood flow is sufficient to supply the metabolic needs of the tissues but helps minimize solute loss from the medullary interstitium.
2. The vasa recta serve as *countercurrent exchangers*, minimizing the washout of solutes from the medullary interstitium.

The countercurrent exchange mechanism operates as follows (**Fig. 29.7**). Blood enters and leaves the medulla via the vasa recta at the boundary of the cortex and renal medulla. The vasa recta, like other capillaries, are highly permeable to solutes in the blood, except for the plasma proteins. As blood descends into the medulla toward the papillae, it becomes progressively more concentrated, partly by solute entry from the interstitium and partly by loss of water into the interstitium. By the time the blood reaches the tips of the vasa recta, it has a concentration of about 1200 mOsm/L, the same as that of the medullary interstitium. As blood ascends back toward the cortex, it becomes progressively less concentrated as solutes diffuse

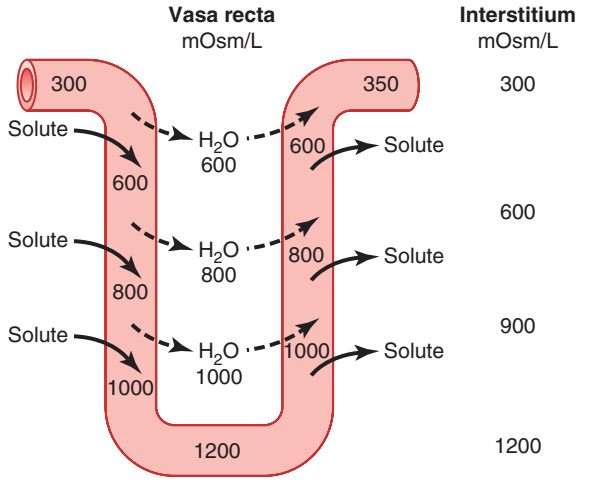

Figure 29.7 Countercurrent exchange in the vasa recta. Plasma flowing down the descending limb of the vasa recta becomes more hyperosmotic because of diffusion of water out of the blood and diffusion of solutes from the renal interstitial fluid into the blood. In the ascending limb of the vasa recta, solutes diffuse back into the interstitial fluid, and water diffuses back into the vasa recta. Large amounts of solutes would be lost from the renal medulla without the U shape of the vasa recta capillaries. (Numerical values are in milliosmoles per liter.)

back out into the medullary interstitium and as water moves into the vasa recta.

Although large amounts of fluid and solute are exchanged across the vasa recta, there is little net dilution of the concentration of the interstitial fluid at each level of the renal medulla because of the U shape of the vasa recta capillaries, which act as countercurrent exchangers. *Thus, the vasa recta do not create the medullary hyperosmolarity, but they do prevent it from being dissipated.*

The U-shaped structure of the vessels minimizes loss of solute from the interstitium but does not prevent bulk flow of fluid and solutes into the blood through the usual colloid osmotic and hydrostatic pressures that favor reabsorption in these capillaries. Under steady-state conditions, the vasa recta carry away only as much solute and water as is absorbed from the medullary tubules, and the high concentration of solutes established by the countercurrent mechanism is preserved.

Increased Medullary Blood Flow Reduces Urine-Concentrating Ability. Certain vasodilators can markedly increase renal medullary blood flow, thereby washing out some of the solutes from the renal medulla and reducing the maximum urine-concentrating ability. Large increases in arterial pressure may also increase the blood flow of the renal medulla to a greater extent than in other regions of the kidney and tend to wash out the hyperosmotic interstitium, thereby reducing urine-concentrating ability. As discussed previously, maximum concentrating ability of the kidney is determined not only by ADH concentration but also by the osmolarity of the renal medulla interstitial fluid. Even with maximal ADH levels, the urine-concentrating ability will be reduced if medullary blood flow increases enough to reduce the hyperosmolarity in the renal medulla.

Summary of Urine-Concentrating Mechanism and Changes in Osmolarity in Different Tubular Segments

The changes in osmolarity and volume of the tubular fluid as it passes through the different parts of the nephron are shown in **Fig. 29.8**.

Proximal Tubule. About 65% of most filtered electrolytes is reabsorbed in the proximal tubule. However, the proximal tubular membranes are highly permeable to water, so whenever solutes are reabsorbed, water also diffuses through the tubular membrane by osmosis. Water diffusion across the proximal tubular epithelium is aided by the water channel *aquaporin 1* (AQP-1). Therefore, the osmolarity of the fluid remains about the same as the glomerular filtrate—300 mOsm/L.

Descending Loop of Henle. As fluid flows down the descending loop of Henle, water is absorbed into the medulla. The descending limb also contains AQP-1 and is highly permeable to water but much less permeable to sodium chloride and urea. During antidiuretic conditions passive urea secretion into the thin loops of Henle is facilitated by the urea transporter UT-A2. Therefore, the osmolarity of the fluid flowing through the descending loop gradually increases until it is nearly equal to that of the surrounding interstitial fluid, which is about 1200 mOsm/L when the blood concentration of ADH is high.

When dilute urine is being formed, as a result of low ADH concentrations, the medullary interstitial osmolarity is less than 1200 mOsm/L; consequently, the descending loop tubular fluid osmolarity also becomes less concentrated. This decrease in concentration is due partly to the fact that less urea is absorbed into the medullary interstitium from the inner medullary collecting ducts when ADH levels are low, and the kidney is forming a large volume of dilute urine.

Thin Ascending Loop of Henle. The thin ascending limb is essentially impermeable to water but reabsorbs some sodium chloride. Because of the high concentration of sodium chloride in the tubular fluid as a result of water removal from the descending loop of Henle, there is some passive diffusion of sodium chloride from the thin ascending limb into the medullary interstitium. Thus, the tubular fluid becomes more dilute as the sodium chloride diffuses out of the tubule and water remains in the tubule.

Some of the urea absorbed into the medullary interstitium from the inner medullary collecting ducts also diffuses into the ascending limb, thereby returning the urea to the tubular system and helping prevent its washout from the renal medulla. This *urea recycling* is an additional mechanism that contributes to the hyperosmotic renal medulla.

Thick Ascending Loop of Henle. The thick part of the ascending loop of Henle is also virtually impermeable to water, but large amounts of sodium, chloride, potassium,

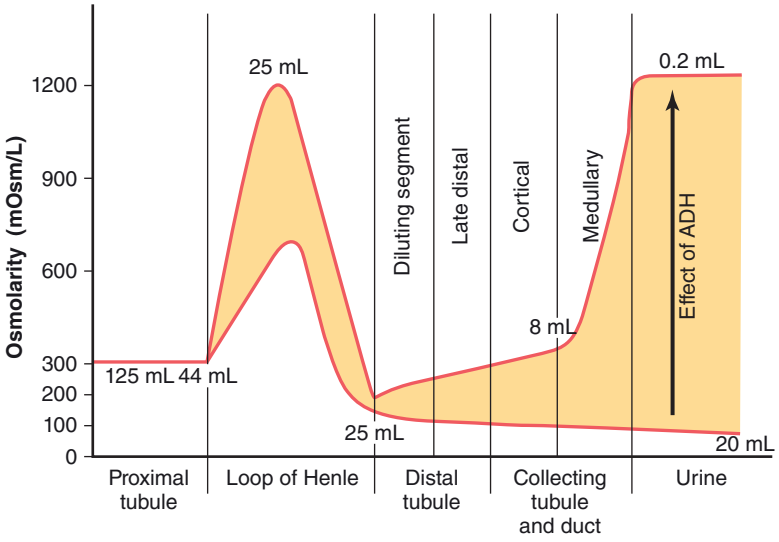

Figure 29.8 Changes in osmolarity of the tubular fluid as it passes through the different tubular segments in the presence of high levels of antidiuretic hormone (ADH) and absence of ADH. (Numerical values indicate the approximate volumes in milliliters per minute or osmolarities in milliosmoles per liter of fluid flowing along the different tubular segments.)

and other ions are actively transported from the tubule into the medullary interstitium. Therefore, fluid in the thick ascending limb of the loop of Henle becomes very dilute, falling to a concentration of about 140 mOsm/L.

Early Distal Tubule. The early distal tubule has properties similar to those of the thick ascending loop of Henle, so further dilution of the tubular fluid to about 100 mOsm/L occurs as solutes are reabsorbed while water remains in the tubule.

Late Distal Tubule and Cortical Collecting Tubules. In the late distal tubule and cortical collecting tubules, the osmolarity of the fluid depends on the level of ADH. With high ADH levels, these tubules are highly permeable to water, and significant amounts of water are reabsorbed. However, this part of the nephron is not very permeable to urea, and urea concentration increases as water is reabsorbed. This process allows most of the urea delivered to the distal tubules and collecting tubules to pass into the inner medullary collecting ducts, from which it is eventually reabsorbed or excreted in the urine.

In the absence of ADH, little water is reabsorbed in the late distal tubule and cortical collecting tubule; therefore, osmolarity decreases even further because of continued active reabsorption of ions from these segments.

Inner Medullary Collecting Ducts. The concentration of fluid in the inner medullary collecting ducts also depends on the following: (1) ADH; and (2) the surrounding medullary interstitium osmolarity established by the countercurrent mechanism and urea reabsorption. In the presence of large amounts of ADH, these ducts are highly permeable to water, and water diffuses from the tubule into the interstitial fluid until osmotic equilibrium is reached, with the tubular fluid having about the same concentration as the renal medullary interstitium (1200–1400 mOsm/L). Thus, a small volume of concentrated urine is produced when ADH levels are high.

Because water reabsorption increases urea concentration in the tubular fluid, and because the inner medullary collecting ducts have specific urea transporters (UTA-1 and UTA-3) that greatly facilitate diffusion, much of the highly concentrated urea in the ducts diffuses out of the tubular lumen into the medullary interstitium. This absorption of the urea into the renal medulla contributes to the high osmolarity of the medullary interstitium and high concentrating ability of the kidney.

Several important points to consider may not be obvious from this discussion. First, although sodium chloride is one of the principal solutes that contribute to the hyperosmolarity of the medullary interstitium, *the kidney can, when needed, excrete a highly concentrated urine that contains little sodium chloride*. The hyperosmolarity of the urine in these circumstances is due to high concentrations of other solutes, especially waste products such as urea. One condition in which this occurs is dehydration accompanied by low sodium intake. As discussed in Chapter 30, a low sodium intake stimulates formation of angiotensin II and aldosterone, which together cause avid sodium reabsorption from the tubules while leaving urea and other solutes to maintain the highly concentrated urine.

Second, *large quantities of dilute urine can be excreted without increasing sodium excretion*. This feat is accomplished by decreasing ADH secretion, which reduces water reabsorption in the more distal tubular segments without substantially altering sodium reabsorption.

Finally, there is an *obligatory urine volume* dictated by the maximum concentrating ability of the kidney and amounts of solutes that must be excreted. Therefore, if large amounts of solutes must be excreted, they must be accompanied by the minimal amount of water necessary to excrete them. For example, if 600 milliosmoles of solutes must be excreted each day, this requires *at least* 0.5 liter of urine if the maximal urine concentrating ability is 1200 mOsm/L.

Quantifying Renal Urine Concentration and Dilution: Free Water and Osmolar Clearances

The process of concentrating or diluting the urine requires the kidneys to excrete water and solutes somewhat independently. When the urine is dilute, water is excreted in excess of solutes. Conversely, when the urine is concentrated, solutes are excreted in excess of water.

The total clearance of solutes from the blood can be expressed as the *osmolar clearance* (C_{osm}). This is the calculated volume of plasma cleared of solutes each minute, in the same way that clearance of a single substance is calculated:

$$C_{osm} = \frac{U_{osm} \times \dot{V}}{P_{osm}}$$

where U_{osm} is the urine osmolarity, $\dot{V}$ is the urine flow rate, and P_{osm} is plasma osmolarity. For example, if the plasma osmolarity is 300 mOsm/L, urine osmolarity is 600 mOsm/L, and urine flow rate is 1 mL/min (0.001 L/min), the osmolar excretion rate is 0.6 mOsm/min (600 mOsm/L × 0.001 L/min), and osmolar clearance is 0.6 mOsm/min divided by 300 mOsm/L, or 0.002 L/min (2.0 mL/min). This means that 2 mL of plasma are being cleared of solute each minute.

Free Water Clearance—Relative Rates at Which Solutes and Water Are Excreted. *Free water clearance* (C_{H_2O}) is calculated as the difference between water excretion (urine flow rate) and osmolar clearance:

$$C_{H_2O} = \dot{V} - C_{osm} = \dot{V} - \frac{(U_{osm} \times \dot{V})}{P_{osm}}$$

Thus, the rate of free water clearance represents the rate at which solute-free water is excreted by the kidneys. When free water clearance is positive, excess water is being excreted by the kidneys; when free water clearance is negative, excess solutes are excreted by the kidneys, and water is being conserved.

Using the example discussed earlier, if urine flow rate is 1 mL/min and osmolar clearance is 2 mL/min, free water clearance would be –1 mL/min. This means that instead of water being cleared from the kidneys in excess of solutes, the kidneys are actually returning water to the systemic circulation, as occurs during water deficits. *Thus, whenever urine osmolarity is greater than plasma osmolarity, free water clearance is negative, indicating water conservation.*

When the kidneys are forming a dilute urine (i.e., urine osmolarity < plasma osmolarity), free water clearance will be a positive value, denoting that water is being removed from the plasma by the kidneys in excess of solutes. Thus, water free of solutes, called *free water*, is being lost from the body, and the plasma is being concentrated when free water clearance is positive.

Disorders of Urinary Concentrating Ability

Impairment in the kidneys' ability to concentrate or dilute the urine appropriately can occur with one or more of the following abnormalities:

1. *Inappropriate secretion of ADH.* Either too much or too little ADH secretion results in abnormal water excretion by the kidneys.
2. *Impairment of the countercurrent mechanism.* A hyperosmotic medullary interstitium is required for maximal urine-concentrating ability. No matter how much ADH is present, maximal urine concentration is limited by the degree of hyperosmolarity of the medullary interstitium.
3. *Inability of the distal tubules, collecting tubules, and collecting ducts to respond to ADH.*

Central Diabetes Insipidus: Failure to Produce ADH. Inability to produce or release ADH from the posterior pituitary can be caused by head injuries or infections, or it can be congenital. Because the distal tubular segments cannot effectively reabsorb water in the absence of ADH, this condition is called *central diabetes insipidus* (or *arginine vasopressin deficiency*) and results in formation of a large volume of dilute urine, with urine volumes that can exceed 15 L/day in severe cases. The thirst mechanisms, discussed later in this chapter, are activated when excessive water is lost from the body; therefore, as long as the person drinks enough water, large decreases in body fluid water do not occur.

The primary abnormalities observed clinically in people with central diabetes insipidus are the large volumes of dilute urine and *polydipsia* (increased thirst and elevated level of water intake). However, if water intake is restricted, as can occur in a hospital setting when fluid intake is restricted or the patient is unconscious (e.g., because of a head injury), severe dehydration and hypernatremia can rapidly occur.

The treatment for central diabetes insipidus is administration of *desmopressin*, a synthetic analogue of ADH that acts selectively on V_2 receptors to increase water permeability in the late distal and collecting tubules. Desmopressin can be given by injection, as a nasal spray, or orally, and it rapidly restores urine output toward normal.

Nephrogenic Diabetes Insipidus: Inability of Kidneys to Respond to ADH. In some circumstances, normal or elevated levels of ADH are present but the renal tubular segments cannot respond appropriately. This condition is referred to as *nephrogenic diabetes insipidus* (or *arginine vasopressin resistance*) because the abnormality resides in the kidneys. This abnormality can be due to failure of the countercurrent mechanism to form a hyperosmotic renal medullary interstitium or failure of the distal and collecting tubules and collecting ducts to respond to ADH. In either case, large volumes of dilute urine are formed, which causes dehydration unless fluid intake is increased by the same amount as urine volume is increased.

Several types of renal diseases can impair the concentrating mechanism, especially those that damage the renal medulla (see Chapter 32 for further discussion). Also, impairment of the function of the loop of Henle, as occurs with diuretics that inhibit electrolyte reabsorption by this segment, such as furosemide, can compromise urine-concentrating ability. Furthermore, certain drugs such as lithium (used to treat manic-depressive disorders) and tetracyclines (used as antibiotics) can impair the ability of the distal nephron segments to respond to ADH. Genetic causes of nephrogenic diabetes insipidus include vasopressin V_2 receptor mutations and aquaporin-2 gene mutations.

Patients with nephrogenic diabetes insipidus also typically present with polyuria and polydipsia. However, nephrogenic diabetes insipidus can be distinguished from central

diabetes insipidus by administration of desmopressin, the synthetic analogue of ADH. Lack of a prompt decrease in urine volume and an increase in urine osmolarity within 2 hours after injection of desmopressin is strongly suggestive of nephrogenic diabetes insipidus.

The appropriate treatment for nephrogenic diabetes insipidus is to correct, if possible, the underlying renal disorder. The hypernatremia can also be attenuated by a low-sodium diet and administration of a diuretic that enhances renal sodium excretion, such as a thiazide diuretic.

CONTROL OF EXTRACELLULAR FLUID OSMOLARITY AND SODIUM CONCENTRATION

Regulation of extracellular fluid osmolarity and sodium concentration are closely linked because sodium is the most abundant ion in the extracellular compartment. Plasma sodium concentration is normally regulated at 135 to 145 mEq/L, with an average concentration of about 142 mEq/L. Osmolarity averages about 300 mOsm/L (~282 mOsm/L when corrected for interionic attraction) and seldom changes more than ±2% to 3%. As discussed in Chapter 25, these variables must be precisely controlled because they determine the distribution of fluid between the intracellular and extracellular compartments.

Estimating Plasma Osmolarity From Plasma Sodium Concentration

In most clinical laboratories, plasma osmolarity is not routinely measured. However, because sodium and its associated anions account for about 94% of the solute in the extracellular compartment, plasma osmolarity (P_{osm}) can be roughly estimated from the plasma sodium concentration (P_{Na^+}) as follows:

$$P_{osm} = 2.1 \times P_{Na^+} \text{ (mmol/L)}$$

For example, with a plasma sodium concentration of 142 mEq/L, the plasma osmolarity would be estimated from this formula to be about 298 mOsm/L. To be more exact, especially in conditions associated with renal disease, the contribution of the plasma concentrations (in units of mmol/L) of two other solutes, glucose and urea, is usually included:

$$P_{osm} = 2 \times [P_{Na^+}, \text{ mmol/L}] + [P_{glucose}, \text{ mmol/L}] + [P_{urea}, \text{ mmol/L}]$$

Such estimates of plasma osmolarity are usually accurate within a few percent of those measured directly.

Normally, sodium ions and associated anions (primarily bicarbonate and chloride) represent about 94% of the extracellular osmoles, with glucose and urea contributing about 3% to 5% of the total osmoles. However, because urea easily permeates most cell membranes, it exerts little *effective* osmotic pressure under steady-state conditions. Therefore, sodium ions in the extracellular fluid and associated anions are the principal determinants of fluid movement across the cell membrane. Consequently, we can discuss the control of osmolarity and control of sodium ion concentration at the same time.

Although multiple mechanisms control the *amount* of sodium and water excretion by the kidneys, two primary systems are especially involved in regulating the *concentration* of sodium and osmolarity of extracellular fluid: (1) the osmoreceptor-ADH system; and (2) the thirst mechanism.

OSMORECEPTOR-ADH FEEDBACK SYSTEM

Fig. 29.9 shows the basic components of the osmoreceptor-ADH feedback system for control of extracellular fluid sodium concentration and osmolarity. When osmolarity increases above normal because of water deficit, for example, this feedback system operates as follows:

1. An increase in extracellular fluid osmolarity (which in practical terms means an increase in plasma sodium concentration) causes the special nerve cells called *osmoreceptor cells*, located in the *anterior hypothalamus* near the supraoptic nuclei, to shrink.
2. Shrinkage of the osmoreceptor cells stimulates them to fire, sending nerve signals to additional nerve cells in the supraoptic nuclei, which then relay these signals down the stalk of the pituitary gland to the posterior pituitary.

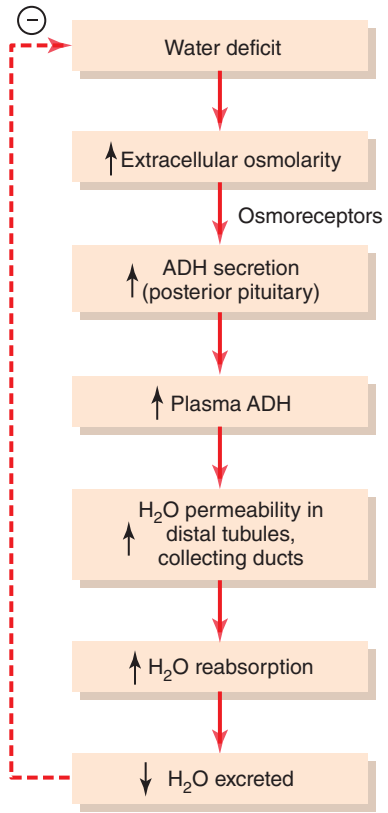

Figure 29.9 Osmoreceptor-antidiuretic hormone (ADH) feedback mechanism for regulating extracellular fluid osmolarity in response to a water deficit.

3. These action potentials conducted to the posterior pituitary stimulate release of ADH, which is stored in secretory granules (or vesicles) in the nerve endings.
4. ADH enters the bloodstream and is transported to the kidneys, where it increases water permeability of the late distal tubules, cortical collecting tubules, and medullary collecting ducts.
5. The increased water permeability in the distal nephron segments causes increased water reabsorption and excretion of a smaller volume of concentrated urine.

Thus, water is conserved while sodium and other solutes continue to be excreted in the urine. This causes dilution of the solutes in the extracellular fluid, thereby correcting the initial excessively concentrated extracellular fluid.

The opposite sequence of events occurs when the extracellular fluid becomes too dilute (hypo-osmotic). For example, with excess water ingestion and a decrease in extracellular fluid osmolarity, less ADH is formed, the renal tubules decrease their permeability for water, less water is reabsorbed, and a larger volume of dilute urine is formed. This in turn concentrates the body fluids and returns plasma osmolarity toward normal.

ADH Is Synthesized in Supraoptic and Paraventricular Nuclei of Hypothalamus and Released From the Posterior Pituitary

Fig. 29.10 shows the neuroanatomy of the hypothalamus and the pituitary gland, where ADH is synthesized and released. The hypothalamus contains two types of *magnocellular* (large) *neurons that synthesize ADH in the supraoptic and paraventricular nuclei of the hypothalamus*, about five-sixths in the supraoptic nuclei and about one-sixth in the paraventricular nuclei. Both of these nuclei have axonal extensions to the posterior pituitary. Once ADH is synthesized, it is transported down the axons of the neurons to their tips, terminating in the posterior pituitary gland. When the supraoptic and paraventricular nuclei are stimulated by increased osmolarity or other factors, nerve impulses pass down these nerve endings, changing their membrane permeability and increasing calcium entry. ADH stored in the secretory granules (*vesicles*) of the nerve endings is released in response to increased calcium entry. The released ADH is then carried away in the capillary blood of the posterior pituitary into the systemic circulation. Secretion of ADH in response to an osmotic stimulus is rapid, and plasma ADH levels can increase severalfold within minutes, thereby providing a rapid means for altering renal excretion of water.

A second neuronal area important in controlling osmolarity and ADH secretion is located along the *anteroventral region of the third ventricle*, called the *AV3V region*. At the upper part of this region is a structure called the *subfornical organ*, and at the inferior part is another structure called the *organum vasculosum* of the *lamina terminalis*. Between these two organs is the *median preoptic nucleus*, which has multiple nerve connections with the two organs, as well as with the supraoptic nuclei and

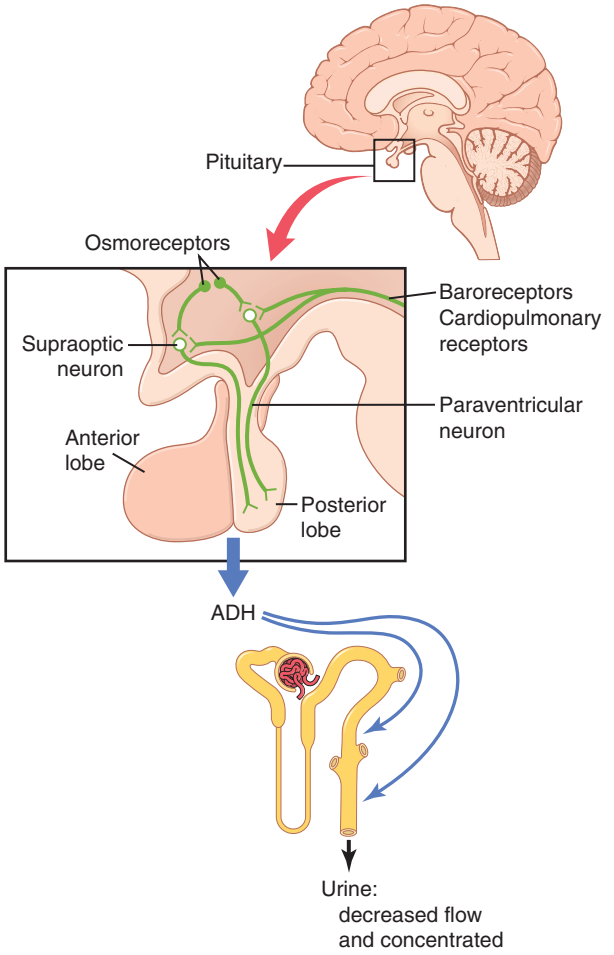

Figure 29.10 Neuroanatomy of the hypothalamus, where antidiuretic hormone (ADH) is synthesized, and the posterior pituitary gland, where ADH is released.

blood pressure control centers in the medulla of the brain. Lesions of the AV3V region cause multiple deficits in the control of ADH secretion, thirst, sodium appetite, and blood pressure regulation. Electrical stimulation of this region or stimulation by angiotensin II can increase ADH secretion, thirst, and sodium appetite.

In the vicinity of the AV3V region and supraoptic nuclei are neuronal cells that are excited by small increases in extracellular fluid osmolarity—hence, the term *osmoreceptors* has been used to describe these neurons. These cells send nerve signals to the supraoptic nuclei to control their firing and secretion of ADH. It is also likely that they induce thirst in response to increased extracellular fluid osmolarity.

The subfornical organ and organum vasculosum of the lamina terminalis have vascular supplies that lack the typical blood–brain barrier that impedes diffusion of most ions from the blood into brain tissue. This characteristic makes it possible for ions and other solutes to cross between the blood and local interstitial fluid in this region. As a result, the osmoreceptors rapidly respond to changes in osmolarity of the extracellular fluid, exerting

powerful control over ADH secretion and thirst, as discussed later.

Stimulation of ADH Release By Decreased Arterial Pressure and/or Decreased Blood Volume

ADH release is also controlled by cardiovascular reflexes that respond to decreases in blood pressure and/or blood volume, including the following: (1) the *arterial baroreceptor reflexes*; and (2) *the cardiopulmonary reflexes*, both of which are discussed in Chapter 18. These reflex pathways originate in high-pressure regions of the circulation, such as the aortic arch and carotid sinus, and in low-pressure regions, especially in the cardiac atria. Afferent stimuli are carried by the vagus and glossopharyngeal nerves, with synapses in the nuclei of the tractus solitarius. Projections from these nuclei relay signals to the hypothalamic nuclei that control ADH synthesis and secretion.

Thus, in addition to increased osmolarity, two other stimuli increase ADH secretion: (1) decreased arterial pressure; and (2) decreased blood volume. Whenever blood pressure and blood volume are reduced, such as during hemorrhage, increased ADH secretion causes increased fluid reabsorption by the kidneys, helping restore blood pressure and blood volume toward normal.

Quantitative Importance of Osmolarity and Cardiovascular Reflexes in Stimulating ADH Secretion

As shown in **Fig. 29.11**, a decrease in effective blood volume or an increase in extracellular fluid osmolarity stimulates ADH secretion. However, ADH is considerably more sensitive to small changes in osmolarity than to similar percentage changes in blood volume. For example, a change in plasma osmolarity of only 1% is sufficient to increase ADH levels. By contrast, after blood loss, plasma ADH levels do not change appreciably until blood volume is reduced by about 10%. With further decreases in blood volume, ADH levels rapidly increase. Thus, with severe decreases in blood volume, the cardiovascular reflexes play a major role in stimulating ADH secretion. The usual daily regulation of ADH secretion during simple dehydration is mediated mainly by changes in plasma osmolarity. Decreases in blood volume and blood pressure, however, greatly enhance the ADH response to increased osmolarity.

Other Stimuli for ADH Secretion

ADH secretion can also be increased or decreased by other stimuli to the central nervous system, as well as by various drugs and hormones, as shown in **Table 29.2**. For example, *nausea* is a potent stimulus for ADH release, which may increase to as much as 100 times normal after vomiting. Also, drugs such as *nicotine* and *morphine* stimulate ADH release, whereas some drugs, such as *alcohol*, inhibit ADH release. The marked diuresis that occurs after ingestion of alcohol is partly due to the inhibition of ADH release.

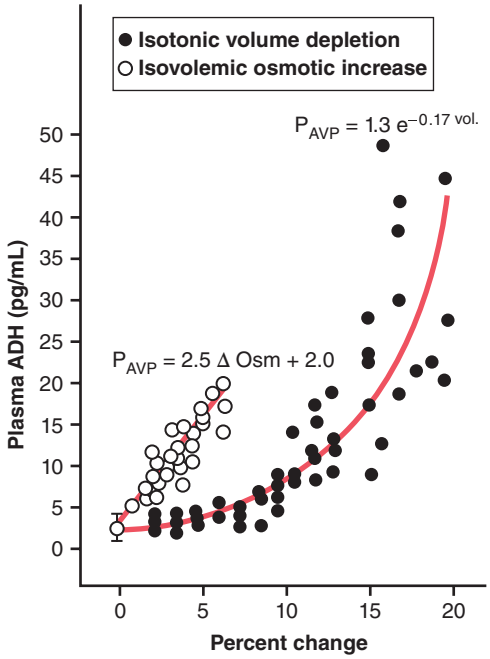

Figure 29.11 Effect of increased plasma osmolarity or decreased blood volume on the level of plasma (P) antidiuretic hormone (ADH), also called arginine vasopressin (AVP). *(Modified from Dunn FL, Brennan TJ, Nelson AE, et al. The role of blood osmolality and volume in regulating vasopressin secretion in the rat.* J Clin Invest. *1973;52[12]:3212.)*

Nicotine	Clonidine (antihypertensive)
Cyclophosphamide	Haloperidol (dopamine blocker)

IMPORTANCE OF THIRST IN CONTROLLING EXTRACELLULAR FLUID OSMOLARITY AND SODIUM CONCENTRATION

The kidneys minimize fluid loss during water deficits through the osmoreceptor-ADH feedback system. Adequate fluid intake, however, is necessary to counterbalance fluid losses that occur through sweating and breathing and through the gastrointestinal tract. Fluid intake is regulated by the thirst mechanism, which, together with the osmoreceptor-ADH mechanism, maintains precise control of extracellular fluid osmolarity and sodium concentration.

Many of the same factors that stimulate ADH secretion also increase thirst, which is defined as the conscious desire for water.

Central Nervous System Centers for Thirst

Referring again to **Fig. 29.10**, the same area along the anteroventral wall of the third ventricle that promotes ADH release also stimulates thirst. Located anterolaterally in the preoptic nucleus is another small area that when stimulated electrically, causes immediate drinking that continues as long as the stimulation lasts. All these areas together are called the *thirst center*.

The thirst center neurons respond to increased extracellular fluid sodium concentration by stimulating drinking behavior. These cells almost certainly function as osmoreceptors to stimulate thirst in the same way that the osmoreceptors stimulate ADH release.

Increased osmolarity of the cerebrospinal fluid in the third ventricle has essentially the same effect to promote drinking. It is likely that the *organum vasculosum of the lamina terminalis*, which lies immediately beneath the ventricular surface at the inferior end of the AV3V region, is intimately involved in mediating this response.

Stimuli for Thirst

Table 29.3 summarizes some of the known stimuli for thirst.

1. *Increased extracellular fluid osmolarity, which causes intracellular dehydration in the thirst centers*, thereby stimulating the sensation of thirst.

   The value of this response is obvious: it helps dilute extracellular fluids and returns osmolarity toward normal.
2. *Decreases in extracellular fluid volume and arterial pressure also stimulate thirst* by a pathway that is different from the one stimulated by increased plasma osmolarity.

   Thus, blood volume loss by hemorrhage stimulates thirst, even though there might be no change in plasma osmolarity. This stimulation probably occurs because of neural input from cardiopulmonary and systemic arterial baroreceptors in the circulation.
3. *Angiotensin II is an important stimulus for thirst.*

   Studies in animals have shown that angiotensin II acts on the subfornical organ and on the organum vasculosum of the lamina terminalis. These regions are outside the blood–brain barrier, and peptides such as angiotensin II diffuse into the tissues. Because angiotensin II is also stimulated by factors associated with hypovolemia and low blood pressure, its effect on thirst helps restore blood volume and blood pressure toward normal along with the other actions of angiotensin II on the kidneys to decrease fluid excretion.
4. *Dryness of the mouth and mucous membranes of the esophagus can elicit the sensation of thirst.*

   As a result, a thirsty person may receive relief from thirst almost immediately after drinking water, even though the water has not been absorbed from the gastrointestinal tract and has not yet had an effect on extracellular fluid osmolarity.
5. *Gastrointestinal and pharyngeal stimuli influence thirst.*

   In animals that have an esophageal opening to the exterior so that water is never absorbed into the blood, partial relief of thirst occurs after drinking, although the relief is only temporary. Also, gastrointestinal distention may partially alleviate thirst; for example, simple inflation of a balloon in the stomach can relieve thirst. However, relief of thirst sensations through gastrointestinal or pharyngeal mechanisms is short-lived; the desire to drink is completely satisfied only when plasma osmolarity and/or blood volume returns to normal.

   The ability of animals and humans to "meter" fluid intake is important because it prevents overhydration. After a person drinks water, 30 to 60 minutes may be required for the water to be reabsorbed and distributed throughout the body. If the thirst sensation were not temporarily relieved after drinking water, continued drinking could occur, eventually leading to overhydration and excess dilution of the body fluids.

Table 29.3 Control of Thirst

Increase Thirst	Decrease Thirst
↑ Plasma osmolarity	↓ Plasma osmolarity
↓ Blood volume	↑ Blood volume
↓ Blood pressure	↑ Blood pressure
↑ Angiotensin II	↓ Angiotensin II
Dry mouth	Gastric distention

Threshold for Osmolar Stimulus of Drinking

The kidneys must continually excrete an obligatory amount of water, even in a dehydrated person, to rid the body of excess solutes that are ingested or produced by metabolism. Water is also lost by evaporation from the lungs and the gastrointestinal tract and by evaporation and sweating from the skin. Therefore, there is always a tendency for dehydration, with resultant increased extracellular fluid sodium concentration and osmolarity.

When sodium concentration increases only about 2 mEq/L above normal, the thirst mechanism is activated, causing a desire to drink water. This is called the *threshold for drinking*. Thus, even small increases in plasma osmolarity are normally followed by drinking, which restores extracellular fluid osmolarity and volume toward normal. In this way, the extracellular fluid osmolarity and sodium concentration are precisely controlled.

Disorders of Thirst and Water Intake

Increased thirst occurs in various medical disorders associated with increased urine volume (*polyuria*) and reductions in extracellular fluid volume, such as poorly controlled diabetes

mellitus or diabetes insipidus. In these cases, increased water intake serves as a compensatory response for increased plasma osmolarity and/or extracellular fluid volume depletion.

Polydipsia, or excessive thirst, occasionally occurs in the absence of known physiological stimuli for thirst. *Psychogenic polydipsia*, for example, may be caused by mental illnesses such as schizophrenia or obsessive-compulsive disorders and can lead to significant *hyponatremia*. In contrast, *adipsia*, the absence of thirst even in the presence of hypernatremia or volume depletion, is rare but usually results from lesions to the hypothalamic thirst centers caused by trauma, infection, or surgery. Partial deficiency of the thirst mechanism, causing inadequate water intake (*hypodipsia*), or an inability to access fluid may occur in patients who have suffered stroke, in older patients with dementia, or in critically ill patients. In the absence of adequate water intake, dehydration and hypernatremia occur, despite large increases in ADH levels.

INTEGRATED RESPONSES OF OSMORECEPTOR-ADH AND THIRST MECHANISMS

In a healthy person, the osmoreceptor-ADH and thirst mechanisms work in parallel to regulate extracellular fluid osmolarity and sodium concentration precisely, despite the constant challenges of dehydration. Even with additional challenges, such as high salt intake, these feedback systems are usually able to keep plasma osmolarity reasonably constant. **Fig. 29.12** shows that an increase in sodium intake to as high as six times normal has only a small effect on plasma sodium concentration as long as the ADH and thirst mechanisms are both functioning normally.

When the ADH or thirst mechanism fails, ordinarily the other can still control extracellular osmolarity and sodium concentration with reasonable effectiveness as long as there is enough fluid intake to balance the daily obligatory urine volume and water losses caused by respiration, sweating, or gastrointestinal losses. However, if both the ADH and thirst mechanisms fail simultaneously, plasma sodium concentration and osmolarity are poorly controlled. Thus, when sodium intake is increased after blocking the total ADH-thirst system, relatively large changes in plasma sodium concentration occur. In the absence of the ADH-thirst mechanisms, no other feedback mechanism is capable of adequately regulating plasma sodium concentration and osmolarity.

Role of Angiotensin II and Aldosterone in Controlling Extracellular Fluid Osmolarity and Sodium Concentration

As discussed in Chapter 28, angiotensin II and aldosterone play important roles in regulating sodium reabsorption by the renal tubules. When sodium intake is low, increased levels of these hormones stimulate sodium reabsorption by the kidneys and prevent large sodium losses, even though sodium intake may be reduced to as low as 10% of normal.

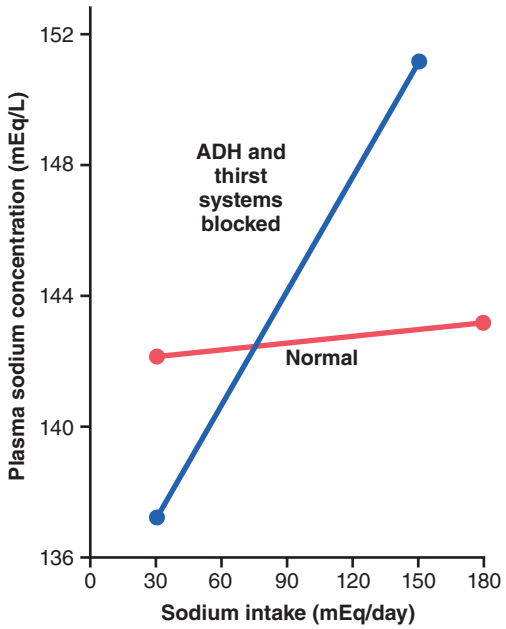

Figure 29.12 Effect of large changes in sodium intake on extracellular fluid sodium concentration in dogs under normal conditions (*red line*) and after the antidiuretic hormone (ADH) and thirst feedback systems were blocked (*blue line*). Note that control of extracellular fluid sodium concentration was poor in the absence of these feedback systems. *(Courtesy Dr. David B. Young.)*

Conversely, with high sodium intake, decreased formation of these hormones permits the kidneys to excrete large amounts of sodium.

Because of the importance of angiotensin II and aldosterone in regulating sodium excretion by the kidneys, one might mistakenly infer that they also play a major role in regulating extracellular fluid sodium concentration. Although these hormones increase the *amount* of sodium in the extracellular fluid, they also increase the extracellular fluid volume by increasing reabsorption of water along with the sodium. Therefore, *angiotensin II and aldosterone have little effect on sodium concentration, except under extreme conditions.*

This relative unimportance of aldosterone in normal regulation of extracellular fluid sodium concentration is shown by the experiment depicted in **Fig. 29.13**. This figure shows the effect on plasma sodium concentration of changing sodium intake more than 6-fold under two conditions: (1) under normal conditions; and (2) after the aldosterone feedback system was blocked by removing the adrenal glands and infusing the animals with aldosterone at a constant rate so that plasma levels could not increase or decrease. Note that when sodium intake was increased 6-fold, plasma concentration changed only about 1% to 2% in either case. This finding indicates that even without a functional aldosterone feedback system, plasma sodium concentration can be well regulated. The same type of experiment has been conducted after blocking angiotensin II formation, with the same result.

There are two primary reasons why changes in angiotensin II and aldosterone do not have a major effect on plasma sodium concentration. First, as discussed earlier,

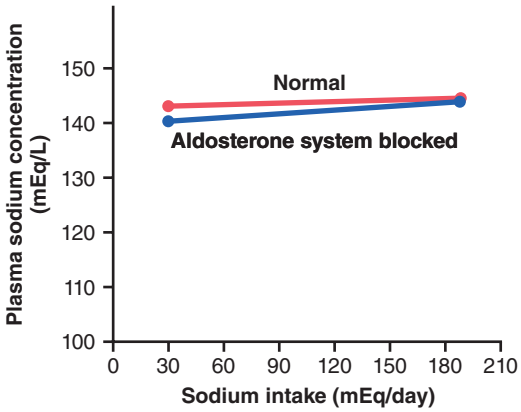

Figure 29.13 Effect of large changes in sodium intake on extracellular fluid sodium concentration in dogs under normal conditions (*red line*) and after the aldosterone feedback system was blocked (*blue line*). Note that the sodium concentration was maintained relatively constant over this wide range of sodium intakes, with or without aldosterone feedback control. *(Courtesy Dr. David B. Young.)*

angiotensin II and aldosterone increase both sodium and water reabsorption by the renal tubules, leading to increases in extracellular fluid volume and sodium *quantity* but little change in sodium *concentration*. Second, as long as the ADH-thirst mechanism is functional, any tendency toward increased plasma sodium concentration is compensated for by increased water intake or increased plasma ADH secretion, which tends to dilute the extracellular fluid back toward normal. The ADH-thirst system far overshadows the angiotensin II and aldosterone systems for regulating sodium concentration under normal conditions. Even in patients with *primary aldosteronism*, who have extremely high levels of aldosterone, plasma sodium concentration usually increases only about 3 to 5 mEq/L above normal.

Under extreme conditions caused by complete loss of aldosterone secretion as a result of adrenalectomy or in patients with *Addison disease* (severely impaired secretion or total lack of aldosterone), there is tremendous loss of sodium by the kidneys, which can lead to a marked reduction in plasma sodium concentration. One reason for this is that large losses of sodium eventually cause severe volume depletion and decreased blood pressure, which can activate the thirst mechanism through the cardiovascular reflexes. This activation leads to a further dilution of the plasma sodium concentration, even though the increased water intake helps minimize the decrease in body fluid volumes under these conditions.

Thus, there are extreme situations in which the plasma sodium concentration may change significantly, even with a functional ADH-thirst mechanism. Even so, the ADH-thirst mechanism is the most powerful feedback system in the body for controlling extracellular fluid osmolarity and sodium concentration.

Salt-Appetite Mechanism for Controlling Extracellular Fluid Sodium Concentration and Volume

The maintenance of a normal extracellular fluid volume and sodium concentration requires a balance between sodium excretion and sodium intake. In most people, sodium intake is substantially greater than necessary for homeostasis. In fact, the average sodium intake for persons in industrialized cultures who eat processed foods usually ranges between 100 and 200 mEq/day, even though humans can survive and function normally while ingesting only 10 to 20 mEq/day. Current evidence indicates that our usual high sodium intake may contribute to cardiovascular disorders such as hypertension.

Salt appetite is due in part to the fact that animals and humans like salt and eat it regardless of whether they are salt-deficient. However, salt appetite also has a regulatory component in which there is a behavioral drive to obtain salt when a sodium deficiency exists in the body. This behavioral drive is particularly important in herbivores, which naturally eat a low-sodium diet, but salt craving may also be important in humans, especially in those who have an extreme deficiency of sodium, such as occurs in Addison disease. In this case, there is a deficiency of aldosterone secretion, which causes excessive loss of sodium in the urine and leads to decreased extracellular fluid volume and decreased sodium concentration; both of these changes elicit the desire for salt.

In general, the primary stimuli that increase salt appetite are those associated with sodium deficits and decreased blood volume or decreased blood pressure associated with circulatory insufficiency.

The neuronal mechanism for salt appetite is analogous to that of the thirst mechanism. Some of the same neuronal centers in the AV3V region of the brain seem to be involved because lesions in this region frequently affect both thirst and salt appetite simultaneously in experimental animals. Also, circulatory reflexes elicited by low blood pressure or decreased blood volume affect both thirst and salt appetite at the same time.

CHAPTER 30

Renal Regulation of Potassium, Calcium, Phosphate, and Magnesium; Integration of Renal Mechanisms for Control of Blood Volume and Extracellular Fluid Volume

Extracellular fluid potassium concentration normally is regulated at about 4.2 mEq/L, seldom rising or falling more than ±0.3 mEq/L. This precise control is necessary because many cell functions are sensitive to changes in extracellular fluid potassium concentration. For example, an increase in plasma potassium concentration of only 3 to 4 mEq/L can cause cardiac arrhythmias, and higher concentrations can lead to cardiac arrest or fibrillation.

A special difficulty in regulating extracellular potassium concentration is the fact that less than 2% of the total body potassium is contained in the extracellular fluid and more than 98% is contained in the cells (**Fig. 30.1**). For a 70-kg lean adult, who has about 28 liters of intracellular fluid (40% of body weight) and 14 liters of extracellular fluid (20% of body weight), only about 59 mEq are in the extracellular fluid and about 3920 mEq of potassium are inside the cells. Since a single meal may contain as much as 50 mEq of potassium, and the daily potassium intake usually ranges between 50 and 200 mEq/day, failure to rapidly rid the extracellular fluid of the ingested potassium could cause life-threatening *hyperkalemia* (increased plasma potassium concentration). Likewise, a small loss of potassium from the extracellular fluid could cause severe *hypokalemia* (low plasma potassium concentration) in the absence of rapid and appropriate compensatory responses.

Maintenance of a balance between intake and output of potassium depends primarily on excretion by the kidneys because the amount excreted in the feces is only about 5% to 10% of the potassium intake. Thus, the maintenance of a normal potassium balance requires the kidneys to adjust their potassium excretion rapidly and precisely in response to wide variations in intake, as is true for most electrolytes.

Control of potassium distribution between the extracellular and intracellular compartments also plays a critical role in potassium homeostasis. Because more than 98% of the total body potassium is contained in the cells, they can serve as an overflow site for excess extracellular fluid potassium during hyperkalemia or as a source of potassium during hypokalemia. Thus, potassium redistribution between the intracellular and extracellular fluid compartments provides a first line of defense against changes in extracellular fluid potassium concentration.

The skeletal muscles provide an especially important reservoir for potassium, normally containing 60% to 75% of the body's potassium, depending on various factors, such as sex, age, and physical activity, that influence muscle mass.

REGULATION OF INTERNAL POTASSIUM DISTRIBUTION

After ingestion of a potassium-rich meal, extracellular fluid potassium concentration would rise to a dangerous level if the ingested potassium did not move rapidly into the cells. For example, absorption of 42 mEq of potassium (the amount contained in a meal rich in vegetables and fruit) into an extracellular fluid volume of 14 liters would raise plasma potassium concentration by about 3.0 mEq/L if all the potassium remained in the extracellular compartment. Fortunately, most of the ingested potassium rapidly moves into the cells until the kidneys can eliminate the excess. Between meals, plasma potassium concentration also remains nearly constant as potassium is released by the cells to balance the extracellular fluid potassium excreted by the kidneys.

Table 30.1 summarizes some of the factors that can influence the distribution of potassium between the intracellular and extracellular compartments.

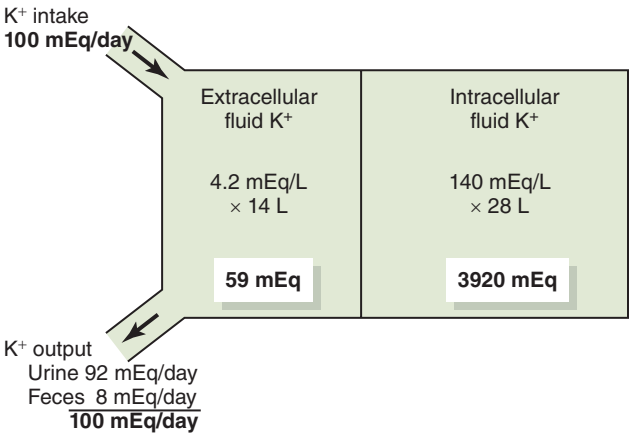

Figure 30.1 Normal potassium intake, distribution of potassium in the body fluids, and potassium output from the body.

Table 30.1 Factors That Can Alter Potassium Distribution Between Intracellular and Extracellular Fluids

Factors That Shift K^+ Into Cells (Decrease Extracellular Fluid [K^+])	Factors That Shift K^+ Out of Cells (Increase Extracellular Fluid [K^+])
Insulin	Insulin deficiency (diabetes mellitus)
Aldosterone	Aldosterone deficiency (Addison disease)
β-Adrenergic stimulation	β-Adrenergic blockade
Alkalosis	Acidosis
	Cell lysis
	Strenuous exercise
	Increased extracellular fluid osmolarity

Insulin Stimulates Potassium Uptake Into Cells. Insulin stimulates sodium-potassium adenosine triphosphatase (Na^+-K^+ ATPase) activity in many tissues, including skeletal muscle, which in turn transports potassium into the cells. Insulin is important for increasing cell potassium uptake after a meal. In people who have insulin-deficient diabetes mellitus, the rise in plasma potassium concentration after eating a meal is much greater than normal. Injections of insulin can help correct the hyperkalemia, although excessive insulin administration in patients with diabetes mellitus can cause profound hypokalemia.

Aldosterone Increases Potassium Uptake Into Cells. Increased potassium intake stimulates secretion of aldosterone, which increases Na^+-K^+ ATPase activity and cell potassium uptake in multiple extrarenal tissues, including skeletal muscle, in addition to stimulating potassium secretion by the kidneys. Thus, increases in aldosterone and insulin synergize to enhance cellular uptake of potassium after a potassium-rich meal.

Excess aldosterone secretion (*Conn syndrome*) is almost invariably associated with hypokalemia, due in part to movement of extracellular potassium into the cells. Conversely, patients with deficient aldosterone production (*Addison disease*) often have clinically significant hyperkalemia due to accumulation of potassium in the extracellular space, as well as renal retention of potassium.

β-Adrenergic Stimulation Increases Cellular Uptake of Potassium. Increased secretion of catecholamines, especially epinephrine, can cause movement of potassium from the extracellular to the intracellular fluid, mainly by activation of β_2-adrenergic receptors, which, in turn, stimulates Na^+-K^+ ATPase. Conversely, treatment of hypertension with β-adrenergic receptor blockers, such as propranolol, causes potassium to move out of the cells and creates a tendency toward hyperkalemia.

Acid–Base Abnormalities Can Cause Changes in Potassium Distribution. Metabolic acidosis generally increases extracellular potassium concentration, in part by causing loss of potassium from the cells, whereas metabolic alkalosis decreases extracellular fluid potassium concentration. One effect of increased hydrogen ion concentration is to reduce activity of the Na^+-K^+ ATPase pump. This reduction, in turn, decreases cellular uptake of potassium and raises extracellular potassium concentration. Alkalosis has the opposite effect, shifting potassium from the extracellular fluid into the cells and tending to cause hypokalemia.

Cell Lysis Causes Increased Extracellular Potassium Concentration. As cells are destroyed, the large amounts of potassium contained in the cells are released into the extracellular fluid. This release of potassium can cause significant hyperkalemia if large amounts of tissue are destroyed, as occurs with severe muscle injury or with red blood cell lysis.

Strenuous Exercise Can Cause Hyperkalemia By Releasing Potassium From Skeletal Muscle. During prolonged exercise, potassium is released from skeletal muscle into the extracellular fluid. Usually the hyperkalemia is mild, but because skeletal muscles constitute the body's major reservoir for potassium, high-intensity muscle exercise may cause clinically significant increases in extracellular fluid potassium, especially in patients treated with β-adrenergic blockers or in individuals with insulin deficiency. In rare cases, hyperkalemia after exercise may be severe enough to cause cardiac toxicity.

Dehydration and Increased Extracellular Fluid Osmolarity Causes Redistribution of Potassium From Cells to Extracellular Fluid. Dehydration and increased extracellular fluid osmolarity causes osmotic flow of water out of the cells. The cellular dehydration increases intracellular potassium concentration, thereby promoting diffusion of potassium out of the cells and increasing extracellular fluid potassium concentration. Decreased extracellular fluid osmolarity has the opposite effect.

REGULATION OF RENAL POTASSIUM EXCRETION

Although redistribution of potassium plays a major role in buffering changes in extracellular fluid potassium concentration, a balance between potassium intake and excretion of potassium is required for homeostasis. Renal potassium excretion is determined by the sum of three processes: (1) the rate of potassium filtration (glomerular filtration rate [GFR] multiplied by the plasma potassium concentration); (2) the rate of potassium reabsorption by the tubules; and (3) the rate of potassium secretion by the tubules. The normal average rate of potassium filtration by the glomerular capillaries is about 756 mEq/day (GFR, 180 L/day, multiplied by plasma potassium concentration, 4.2 mEq/L). This rate of filtration is relatively constant in healthy persons because of the autoregulatory mechanisms for GFR discussed previously and the precision

with which plasma potassium concentration is regulated. Severe decreases in GFR in certain renal diseases, however, can cause serious potassium accumulation and hyperkalemia.

Fig. 30.2 summarizes the tubular handling of potassium under normal conditions. About 65% of the filtered potassium is reabsorbed in the proximal tubule. Another 25% to 30% of the filtered potassium is reabsorbed in the thick ascending loop of Henle, where potassium is actively co-transported along with sodium and chloride. In the proximal tubule and loop of Henle, a relatively constant fraction of the filtered potassium load is reabsorbed. Although changes in potassium reabsorption in these segments can influence potassium excretion, most of the daily variation of potassium excretion is not due to changes in reabsorption in the proximal tubule or loop of Henle. The distal and collecting tubules and collecting ducts can reabsorb or secrete potassium at variable rates, depending on the potassium intake.

Variable Potassium Secretion in Distal and Collecting Tubules Mediates Most Daily Changes in Potassium Excretion. The most important sites for regulating potassium excretion are the late distal tubules and cortical collecting tubules. In these tubular segments, potassium can at times be reabsorbed or at other times can be secreted, depending on the needs of the body. With a normal potassium intake of 100 mEq/day, the kidneys must excrete about 92 mEq/day (the remaining 8 mEq are lost in the feces). About 60 mEq/day of potassium are secreted into the distal and collecting tubules, accounting for most of the excreted potassium.

With a high potassium intake, the required extra excretion of potassium is achieved almost entirely by increasing the secretion of potassium into the late distal and collecting tubules. In fact, in those who consume extremely high-potassium diets, the rate of potassium excretion can exceed the amount of potassium in the glomerular filtrate, indicating a powerful mechanism for secreting potassium.

When potassium intake is reduced, secretion of potassium in the distal and collecting tubules decreases, causing a reduction in urinary potassium excretion. There is also increased reabsorption of potassium by the intercalated cells in the distal segments of the nephron, and potassium excretion can fall to less than 1% of the potassium in the glomerular filtrate (to <10 mEq/day). With potassium intakes below this level, severe hypokalemia can develop.

Thus, most of the daily regulation of potassium excretion occurs in the late distal and cortical collecting tubules and collecting ducts, where potassium can be reabsorbed or secreted, depending on the needs of the body. In the next section, we consider the basic mechanisms of potassium secretion and the factors that regulate this process.

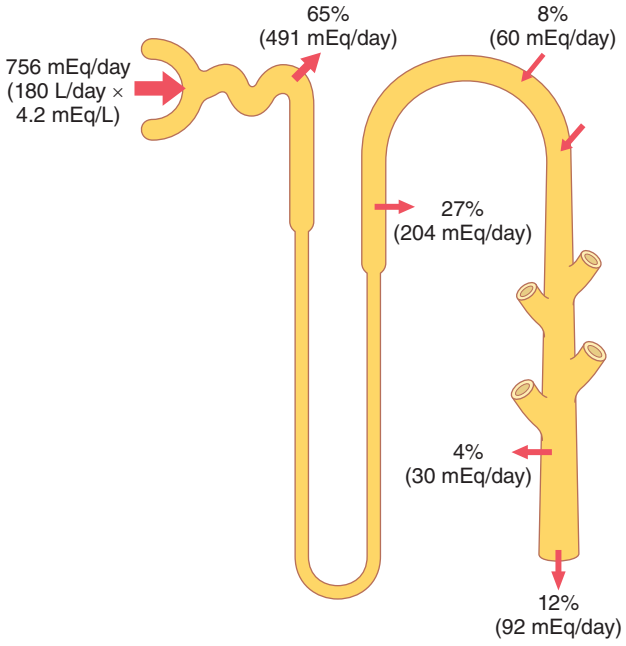

Figure 30.2 Renal tubular sites of potassium reabsorption and secretion. Potassium is reabsorbed in the proximal tubule and ascending loop of Henle, so only about 8% of the filtered load is normally delivered to the distal tubule. Secretion of potassium by the principal cells of the late distal tubules and collecting ducts adds to the amount delivered, but there is some additional reabsorption by the intercalated cells; therefore, the daily excretion is normally about 12% of the potassium filtered at the glomerular capillaries. The percentages indicate how much of the filtered load is reabsorbed or secreted into the different tubular segments.

Principal Cells of Late Distal and Cortical Collecting Tubules Secrete Potassium

The cells in the late distal and cortical collecting tubules that secrete potassium are called *principal cells* and make up most of the epithelial cells in these regions. **Fig. 30.3** shows the basic cellular mechanisms of potassium secretion by the principal cells.

Secretion of potassium from the interstitial fluid into the tubular lumen is a two-step process, beginning with uptake from the interstitium into the cell by the Na^+-K^+ ATPase pump in the basolateral cell membrane. This pump moves sodium out of the cell into the interstitium and, at the same time, moves potassium to the interior of the cell.

The second step of the process is passive diffusion of potassium from the interior of the cell into the tubular fluid. The Na^+-K^+ ATPase pump creates a high intracellular potassium concentration, which provides the driving force for passive diffusion of potassium from the cell into the tubular lumen. The luminal membrane of the principal cells is highly permeable to potassium because of special channels that allow potassium ions to diffuse across the membrane rapidly: (1) the *renal outer medullary potassium* (ROMK) *channels*, and (2) high-conductance, *"big" potassium* (BK) *channels*. Both types of potassium channels are required for efficient renal potassium excretion, and their abundance in the luminal membrane is increased during high potassium intake.

Control of Potassium Secretion By Principal Cells. The primary factors that control potassium secretion by the principal cells of the late distal and cortical collecting tubules are the following: (1) the activity of the Na^+-K^+ ATPase pump; (2) the electrochemical gradient for potassium secretion from the blood to the tubular lumen; and (3) the permeability of the luminal membrane for potassium. These three determinants of potassium secretion are, in turn, regulated by several factors, discussed later.

Intercalated Cells Can Reabsorb or Secrete Potassium. In circumstances associated with severe potassium depletion, there is a cessation of potassium secretion and a net reabsorption of potassium in the late distal and collecting tubules. This reabsorption occurs through *type A intercalated cells*. One mechanism that contributes to this reabsorption is a *hydrogen-potassium ATPase* transport mechanism located in the luminal membrane (see Chapter 28, **Fig. 28.13**). This transporter reabsorbs potassium in exchange for hydrogen ions secreted into the tubular lumen, and the potassium then diffuses through basolateral membrane potassium channels into the interstitial fluid. This abundance of intercalated cell hydrogen-potassium ATPase transporters is enhanced with potassium depletion and hypokalemia, causing increased hydrogen ion secretion and alkalosis. Under normal conditions, however, potassium reabsorption by intercalated cells plays only a small role in controlling potassium excretion.

When there is excess potassium in the body fluids, *type B intercalated cells* in the late distal tubules and collecting tubules actively secrete potassium into the tubular lumen and have functions that are opposite to those of type A cells (see Chapter 28, **Fig. 28.13**). Potassium is pumped into the type B intercalated cell by a hydrogen-potassium ATPase transporter on the basolateral membrane, and it then diffuses into the tubular lumen through potassium channels.

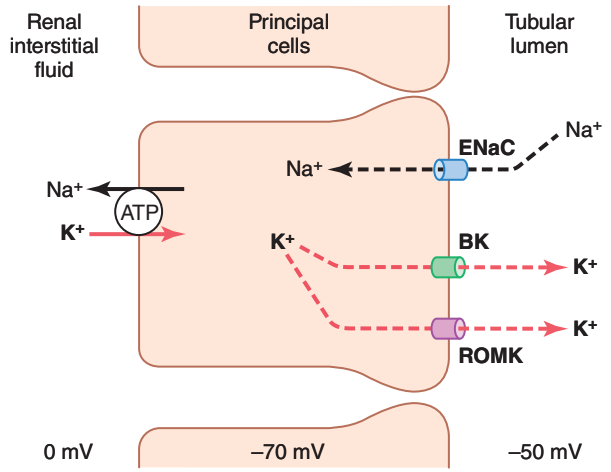

Figure 30.3 Mechanisms of potassium secretion and sodium reabsorption by the principal cells of the late distal and collecting tubules. *BK*, "Big" potassium channel; *ENaC*, epithelial sodium channel; *ROMK*, renal outer medullary potassium channel.

Summary of Major Factors That Regulate Potassium Secretion

Because the normal regulation of potassium excretion occurs mainly as a result of changes in potassium secretion by the principal cells of the late distal and collecting tubules, in this chapter we discuss the primary factors that influence secretion by these cells. The most important factors that *increase* potassium secretion by the principal cells include the following: (1) increased extracellular fluid potassium concentration; (2) increased aldosterone; and (3) increased tubular flow rate.

One factor that *decreases* potassium secretion is an increased hydrogen ion concentration (acidosis).

Increased Extracellular Fluid Potassium Concentration Stimulates Potassium Secretion. Potassium secretion rate in the late distal and cortical collecting tubules is directly stimulated by increased extracellular fluid potassium concentration, leading to increases in potassium excretion, as shown in **Fig. 30.4**. This effect is especially pronounced when extracellular fluid potassium concentration rises above about 4.1 mEq/L, slightly less than the normal concentration. Increased plasma potassium concentration, therefore, serves as one of the most important mechanisms for increasing potassium secretion and regulating extracellular fluid potassium ion concentration.

Increased dietary potassium intake and increased extracellular fluid potassium concentration stimulate potassium secretion by at least four mechanisms:

1. Increased extracellular fluid potassium concentration stimulates the Na^+-K^+ ATPase pump, thereby increasing cell potassium uptake across the basolateral membrane. Increased potassium uptake in turn increases intracellular potassium ion concentration,

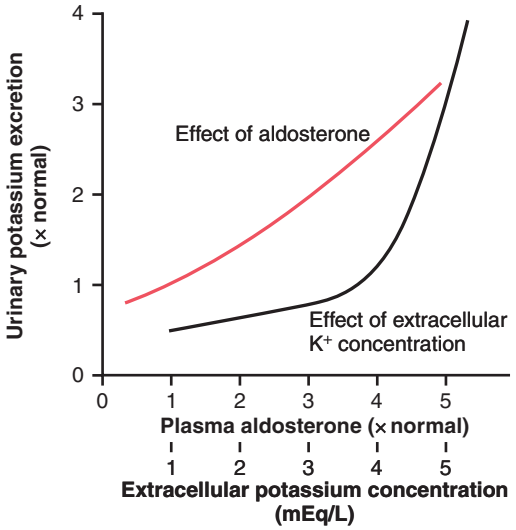

Figure 30.4 Effect of plasma aldosterone concentration (*red line*) and extracellular potassium ion concentration (*black line*) on the rate of urinary potassium excretion. These factors stimulate potassium secretion by the principal cells of the cortical collecting tubules. *(Data from Young DB, Paulsen AW. Interrelated effects of aldosterone and plasma potassium on potassium excretion.* Am J Physiol. *1983;244:F28.)*

causing potassium to diffuse across the luminal membrane into the tubule.

2. Increased extracellular potassium concentration increases the potassium gradient from the renal interstitial fluid to the epithelial cell interior, which reduces backleak of potassium ions from inside the cells through the basolateral membrane.
3. Increased potassium intake stimulates synthesis of potassium channels and their translocation from the cytosol to the luminal membrane, which, in turn, increases the ease of potassium diffusion through the membrane.
4. Increased potassium concentration stimulates aldosterone secretion by the adrenal cortex, which further stimulates potassium secretion, as discussed next.

Aldosterone Stimulates Potassium Secretion. Aldosterone has powerful effects to stimulate active reabsorption of sodium ions and secretion of potassium ions by the principal cells of the late distal tubules and collecting ducts (see Chapter 28). This effect is mediated through a Na^+-K^+ ATPase pump that transports sodium outward through the basolateral membrane of the cell and into the renal interstitial fluid at the same time that it pumps potassium into the cell.

A second effect of aldosterone is to increase the number of potassium channels in the luminal membrane and therefore its permeability for potassium, further adding to the effectiveness of aldosterone in stimulating potassium secretion. Therefore, aldosterone has a powerful effect to increase potassium excretion, as shown in **Fig. 30.4**.

Increased Extracellular Potassium Ion Concentration Stimulates Aldosterone Secretion. In negative feedback control systems, the factor that is controlled usually has a feedback effect on the controller. In the case of the aldosterone-potassium control system, the rate of aldosterone secretion by the adrenal gland is controlled strongly by extracellular fluid potassium ion concentration. **Fig. 30.5** shows that an increase in plasma potassium concentration of about 3 mEq/L can increase the plasma aldosterone concentration from nearly 0 to as high as 60 ng/100 mL, a concentration almost 10 times normal.

The effect of potassium ion concentration to stimulate aldosterone secretion is part of a powerful feedback system for regulating potassium excretion, as shown in **Fig. 30.6**. In this feedback system, an increase in plasma potassium concentration stimulates aldosterone secretion and, therefore, increases plasma aldosterone concentration (block 1). The increase in plasma aldosterone then causes a marked increase in potassium secretion and excretion by the kidneys (block 2). The increased potassium excretion then reduces the extracellular fluid potassium concentration back toward normal (circle 3 and block 4). Thus, this feedback mechanism acts synergistically, with the direct effect of increased extracellular potassium concentration to elevate potassium excretion when potassium intake is raised (**Fig. 30.7**).

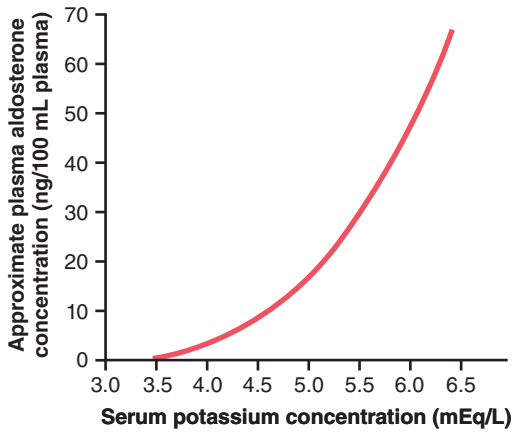

Figure 30.5 Effect of extracellular fluid potassium ion concentration on plasma aldosterone concentration. Note that small changes in potassium concentration cause large changes in aldosterone concentration.

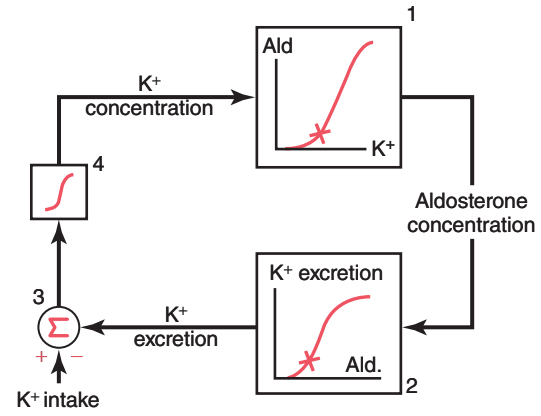

Figure 30.6 Basic feedback mechanism for control of extracellular fluid potassium concentration by aldosterone (Ald).

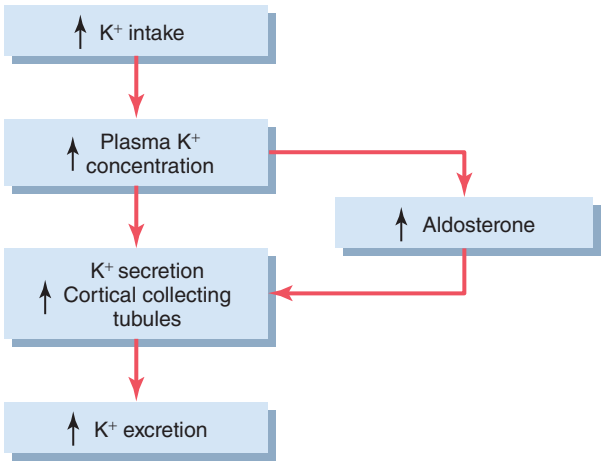

Figure 30.7 Primary mechanisms whereby high potassium intake raises potassium excretion. Note that increased plasma potassium concentration directly raises potassium secretion by the cortical collecting tubules and indirectly increases potassium secretion by raising plasma aldosterone concentration.

Blockade of Aldosterone Feedback System Greatly Impairs Potassium Regulation. In the absence of adequate aldosterone secretion, as occurs in patients with *Addison disease*, renal secretion of potassium is impaired,

thus causing the extracellular fluid potassium concentration to rise to dangerously high levels. Conversely, with excess aldosterone secretion (e.g., *primary aldosteronism*), potassium secretion becomes greatly increased, causing potassium loss by the kidneys, thus leading to hypokalemia.

In addition to its stimulatory effect on renal secretion of potassium, aldosterone also increases cellular uptake of potassium. This contributes to the powerful aldosterone-potassium feedback system, as discussed previously.

The quantitative importance of the aldosterone feedback system in controlling potassium concentration is shown in **Fig. 30.8**. In this experiment, potassium intake was increased almost 7-fold in dogs under two conditions: (1) normal conditions; and (2) after the aldosterone feedback system had been blocked by removing the adrenal glands and placing the animals on a fixed rate of aldosterone infusion so that plasma aldosterone concentration was maintained at a normal level and could neither increase nor decrease as potassium intake was altered.

Note that in normal animals, a 7-fold increase in potassium intake caused only a slight increase in plasma potassium concentration, from 4.2 to 4.3 mEq/L. Thus, when the aldosterone feedback system is functioning normally, potassium concentration is precisely controlled, despite large changes in potassium intake.

When the aldosterone feedback system was blocked, the same increases in potassium intake caused a much larger increase in plasma potassium concentration. Thus, control of potassium concentration is greatly impaired when the aldosterone feedback system is blocked. A similar impairment of potassium regulation is observed in people with poorly functioning aldosterone feedback systems, such as occurs in patients with primary aldosteronism (too much aldosterone) or Addison disease (too little aldosterone).

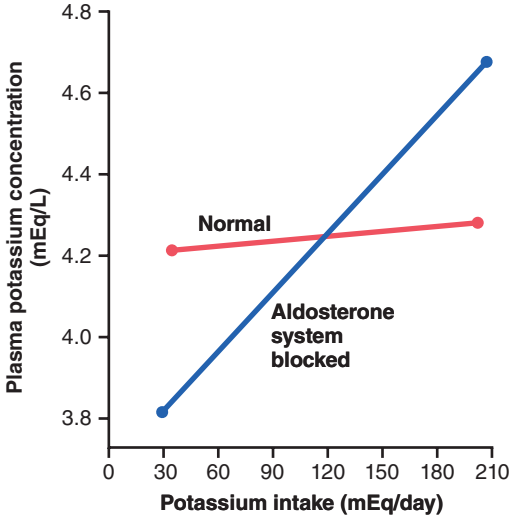

Figure 30.8 Effect of large changes in potassium intake on plasma potassium concentration under normal conditions (*red line*) and after the aldosterone feedback was blocked (*blue line*). Note that after blockade of the aldosterone system, regulation of potassium concentration was greatly impaired. *(Courtesy Dr. David B. Young.)*

Increased Distal Tubular Flow Rate Stimulates Potassium Secretion. Increased distal tubular flow rate, as occurs with volume expansion, high sodium intake, or treatment with some diuretics, stimulates potassium secretion (**Fig. 30.9**). Conversely, decreased distal tubular flow rate, as caused by sodium depletion, reduces potassium secretion.

The effect of the tubular flow rate on potassium secretion in the distal and collecting tubules is strongly influenced by potassium intake. When potassium intake is high, increased tubular flow rate has a much greater effect to stimulate potassium secretion than when potassium intake is low (**Fig. 30.9**).

There are two main effects of a high-volume flow rate that increase potassium secretion:

1. When potassium is secreted into the tubular fluid, the luminal potassium concentration increases, thereby reducing the driving force for potassium diffusion across the luminal membrane. With increased tubular flow rate, the secreted potassium is continuously flushed down the tubule, minimizing the rise in tubular potassium concentration and increasing net potassium secretion.
2. A high tubular flow rate also increases the number of high-conductance BK channels in the luminal membrane. Although the BK channels are normally quiescent, they become active in response to increases in flow rate, thereby greatly increasing potassium conductance across the luminal membrane.

The effect of increased tubular flow rate is especially important in helping preserve normal potassium excretion during changes in sodium intake. For example, with a

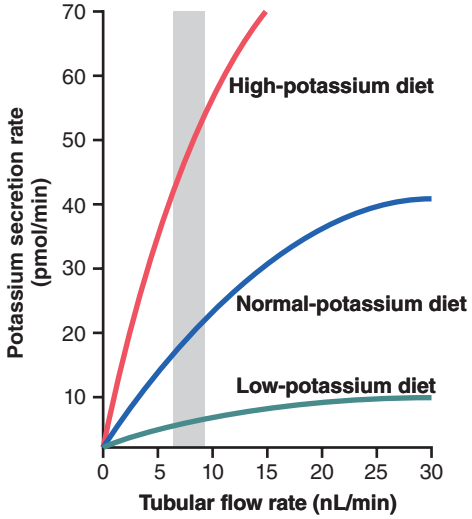

Figure 30.9 Relationship between flow rate in the cortical collecting tubules and potassium secretion and the effect of changes in potassium intake. Note that a high dietary potassium intake greatly enhances the effect of increased tubular flow rate to increase potassium secretion. The *shaded bar* shows the approximate normal tubular flow rate under most physiological conditions. *(Data from Malnic G, Berliner RW, Giebisch G. Flow dependence of K^+ secretion in cortical distal tubes of the rat.* Am J Physiol. *1989;256:F932.)*

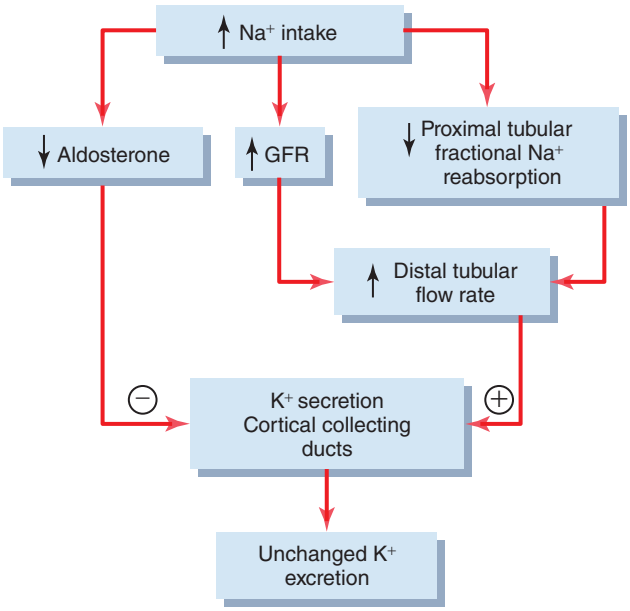

Figure 30.10 Effect of high sodium intake on renal excretion of potassium. Note that a high-sodium diet decreases plasma aldosterone, which tends to decrease potassium secretion by the cortical collecting tubules. However, the high-sodium diet simultaneously increases fluid delivery to the cortical collecting duct, which tends to increase potassium secretion. These opposing effects of a high-sodium diet counterbalance each other, so there is little change in potassium excretion. *GFR*, Glomerular filtration rate.

high sodium intake, there is decreased aldosterone secretion, which by itself would tend to decrease the rate of potassium secretion and urinary excretion of potassium. However, the high distal tubular flow rate that occurs with a high sodium intake tends to increase potassium secretion (**Fig. 30.10**). Therefore, the two effects of a high sodium intake—decreased aldosterone secretion and high tubular flow rate—counterbalance each other, so there is little change in potassium excretion. Likewise, with a low sodium intake, there is little change in potassium excretion because of the counterbalancing effects of increased aldosterone secretion and decreased tubular flow rate on potassium secretion.

Acute Acidosis Decreases Potassium Secretion. Acute increases in extracellular fluid hydrogen ion concentration (acidosis) reduce potassium secretion, whereas decreased hydrogen ion concentration (alkalosis) increases potassium secretion. Although acid-base disturbances have complex effects of potassium excretion, one key mechanism whereby increased hydrogen ion concentration inhibits potassium secretion is by reducing activity of the Na^+-K^+ ATPase pump. This reduction in turn decreases intracellular potassium concentration and subsequent passive diffusion of potassium across the luminal membrane into the tubule. Acidosis may also reduce the number of potassium channels in the luminal membrane. In intercalated cells of the late distal and collecting tubules, acidosis stimulates hydrogen-ATPase and hydrogen-potassium ATPase, which enhances potassium reabsorption and therefore reduces the net potassium secretion.

With more prolonged acidosis, lasting over a period of several days, there is an increase in urinary potassium excretion. The mechanism for this effect is due in part to an effect of chronic acidosis to reduce proximal tubular Na^+-K^+ ATPase activity and therefore to inhibit sodium chloride and water reabsorption, which increases distal volume delivery, thereby stimulating potassium secretion. This effect overrides the inhibitory effect of hydrogen ions on the Na^+-K^+ ATPase pump. *Thus, chronic acidosis leads to a loss of potassium, whereas acute acidosis leads to decreased potassium excretion.*

Beneficial Effects of Diet High in Potassium and Low in Sodium Content

For most of human history, the typical diet has been one that is relatively low in sodium and high in potassium content, compared with the typical modern diet. In isolated populations that have not experienced industrialization, such as the Yanomamo tribe living in the Amazon region of Northern Brazil, sodium intake may be as low as 10 to 20 mmol/day, and potassium intake may be as high as 200 mmol/day. This intake is due to their diet containing large amounts of fruits and vegetables and no processed foods. Populations consuming this type of diet typically do not experience age-related increases in blood pressure and cardiovascular diseases.

With industrialization and increased consumption of processed foods, which often have high sodium and low potassium content, there have been dramatic increases in sodium intake and decreases in potassium intake. In most industrialized countries, potassium consumption averages only 30 to 70 mmol/day, and sodium intake averages 140 to 180 mmol/day.

Experimental and clinical studies have shown that the combination of a high-sodium and low-potassium diet increases the risk for hypertension and associated cardiovascular and kidney diseases. A diet rich in potassium, however, seems to protect against the adverse effects of a high-sodium diet, reducing blood pressure and the risk for stroke, coronary artery disease, and kidney disease. The beneficial effects of increasing potassium intake are especially apparent when combined with a low-sodium diet.

Dietary guidelines published by various organizations have recommended reducing the dietary intake of sodium chloride to about 65 to 100 mmol/day (corresponding to 1.5–2.3 g/day of sodium or 3.8–5.8 g/day sodium chloride) while increasing potassium intake to 120 mmol/day (4.7 g/day) for healthy adults.

REGULATION OF RENAL CALCIUM EXCRETION AND EXTRACELLULAR CALCIUM ION CONCENTRATION

The mechanisms for regulating calcium ion concentration are discussed in detail in Chapter 80, along with the endocrinology of the calcium-regulating hormones, parathyroid

hormone (PTH), and calcitonin. Therefore, calcium ion regulation is discussed only briefly in this chapter.

The extracellular fluid calcium ion concentration normally remains tightly controlled within a few percent of its normal level, 2.4 mEq/L. When calcium ion concentration falls to low levels (*hypocalcemia*), the excitability of nerve and muscle cells increases markedly and can, in extreme cases, result in *hypocalcemic tetany*, which is characterized by spastic skeletal muscle contractions. *Hypercalcemia* (increased calcium concentration) depresses neuromuscular excitability and can lead to cardiac arrhythmias.

About 50% of the *total* calcium in the plasma (~5 mg/dL) exists in the ionized form, which is the form that has biological activity at cell membranes. The remainder is bound to plasma proteins (~40%) or complexed in the nonionized form with anions such as phosphate and citrate (~10%).

Changes in plasma hydrogen ion concentration influence calcium binding to plasma proteins. With acidosis, less calcium is bound to the plasma proteins. Conversely, with alkalosis, a greater amount of calcium is bound to the plasma proteins. Therefore, *patients with alkalosis are more susceptible to hypocalcemic tetany*.

Intestinal Calcium Absorption and Secretion Play a Major Role in Calcium Homeostasis. As with other substances in the body, calcium intake must be balanced with the net loss of calcium over the long term. Unlike ions such as sodium and chloride, however, much of the calcium excretion occurs in the feces. The usual rate of dietary calcium intake is about 1000 mg/day, with about 800 mg/day of calcium excreted in the feces. Under certain conditions, fecal calcium excretion can exceed calcium ingestion because calcium can also be secreted into the intestinal lumen. Therefore, the gastrointestinal tract and regulatory mechanisms that influence intestinal calcium absorption and secretion play a major role in calcium homeostasis, as discussed in Chapter 80.

Most of the Body's Calcium Is Stored in Bones and Regulated By Parathyroid Hormone (PTH). Almost all the calcium in the body (99%) is stored in the bone, with only about 0.1% in the extracellular fluid and 1.0% in the intracellular fluid and cell organelles. The bone, therefore, acts as a large reservoir for calcium and as a source of calcium when extracellular fluid calcium concentration tends to decrease.

One of the most important regulators of bone uptake and release of calcium is PTH. When extracellular fluid calcium concentration falls below normal, activity of *calcium-sensing receptors* (CSRs) on the cell membrane of the parathyroid glands is reduced, promoting increased secretion of PTH. This hormone then acts directly on the bones to increase resorption of bone salts (release of salts from the bones) and release large amounts of calcium into the extracellular fluid, thereby returning calcium levels back toward normal. When calcium ion concentration is elevated, CSR activity of the parathyroid cells is stimulated, causing a reduction in PTH secretion, so almost no bone resorption occurs; instead, excess calcium is deposited in the bones. Thus, the daily regulation of calcium ion concentration is mediated in large part by the effects of PTH on bone resorption.

The bones, however, do not have an inexhaustible supply of calcium. Therefore, over the long term, intake of calcium must be balanced with calcium excretion by the gastrointestinal tract and kidneys. The most important regulator of calcium at both these sites is PTH, which regulates the plasma calcium concentration through three main effects: *(1) by stimulating bone resorption; (2) by stimulating activation of vitamin D, which then increases intestinal absorption of calcium; and (3) by increasing renal tubular calcium reabsorption* (**Fig. 30.11**). The control of gastrointestinal calcium absorption and calcium exchange in the bones is discussed in Chapter 80; the remainder of this section focuses on the mechanisms that control renal calcium excretion.

CONTROL OF CALCIUM EXCRETION BY THE KIDNEYS

Calcium is filtered and reabsorbed in the kidneys but is not secreted. Therefore, the rate of renal calcium excretion is calculated as follows:

$$\text{Renal calcium excretion} = \text{Calcium filtered} - \text{Calcium reabsorbed}$$

Only about 50% of the plasma calcium is ionized, with 40% being bound to the plasma proteins and 10% complexed with anions such as phosphate. Only the calcium that is ionized and complexed with anions is filtered by the glomerular capillaries. Therefore, only about 60% of the plasma calcium is filtered at the glomerulus. Normally, about 98% to 99% of the filtered calcium is reabsorbed by the tubules, with only about 1% to 2% of the filtered calcium being excreted. About 60% to 70% of the filtered calcium is reabsorbed in the proximal tubule, 20% to 25% is reabsorbed in the loop of Henle, and 5% to 10% is reabsorbed in the distal and collecting tubules. This pattern of reabsorption is similar to that for sodium.

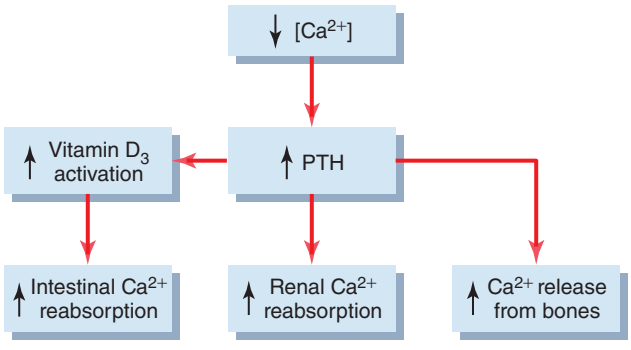

Figure 30.11 Compensatory responses to decreased plasma ionized calcium concentration mediated by parathyroid hormone (PTH) and vitamin D.

As is true with the other ions, calcium excretion is adjusted to meet the body's needs. With increased calcium intake, there is also increased renal calcium excretion, although much of the increase of calcium intake is eliminated in the feces. With calcium depletion, calcium excretion by the kidneys decreases as a result of enhanced tubular reabsorption.

Proximal Tubular Calcium Reabsorption. At least 80% to 90% of the calcium reabsorption in the proximal tubule occurs through the paracellular pathway **Fig. 30.12**; it is dissolved in water and carried with the reabsorbed fluid as it flows between the cells.

Only a small amount of proximal tubular calcium reabsorption occurs through the transcellular pathway in two steps;

1. Calcium diffuses from the tubular lumen into the cell down an electrochemical gradient due to the much higher concentration of calcium in the tubular lumen, compared with the epithelial cell cytoplasm, and because the cell interior has a negative charge relative to the tubular lumen.
2. Calcium exits the cell across the basolateral membrane by a calcium-ATPase pump and by the sodium-calcium counter-transporter (**Fig. 30.12**).

Loop of Henle and Distal Tubule Calcium Reabsorption. In the loop of Henle, calcium reabsorption is restricted to the thick ascending limb. Most of the calcium reabsorption in the thick ascending limb occurs through the paracellular route by passive diffusion due to the slight positive charge of the tubular lumen relative to the interstitial fluid (**Fig. 30.12**).

Claudins, a family of tight junction membrane proteins, regulate paracellular permeability of epithelia cells throughout the renal tubule. In the thick ascending loop of Henle, claudins play a critical role in paracellular reabsorption of calcium, as well as other cations such as magnesium and sodium, and are regulated by CSRs.

A small amount of calcium reabsorption in the thick ascending limb also occurs through the transcellular pathway, a process that is stimulated by PTH.

In the distal tubule, calcium reabsorption occurs almost entirely by transcellular reabsorption coupled to active

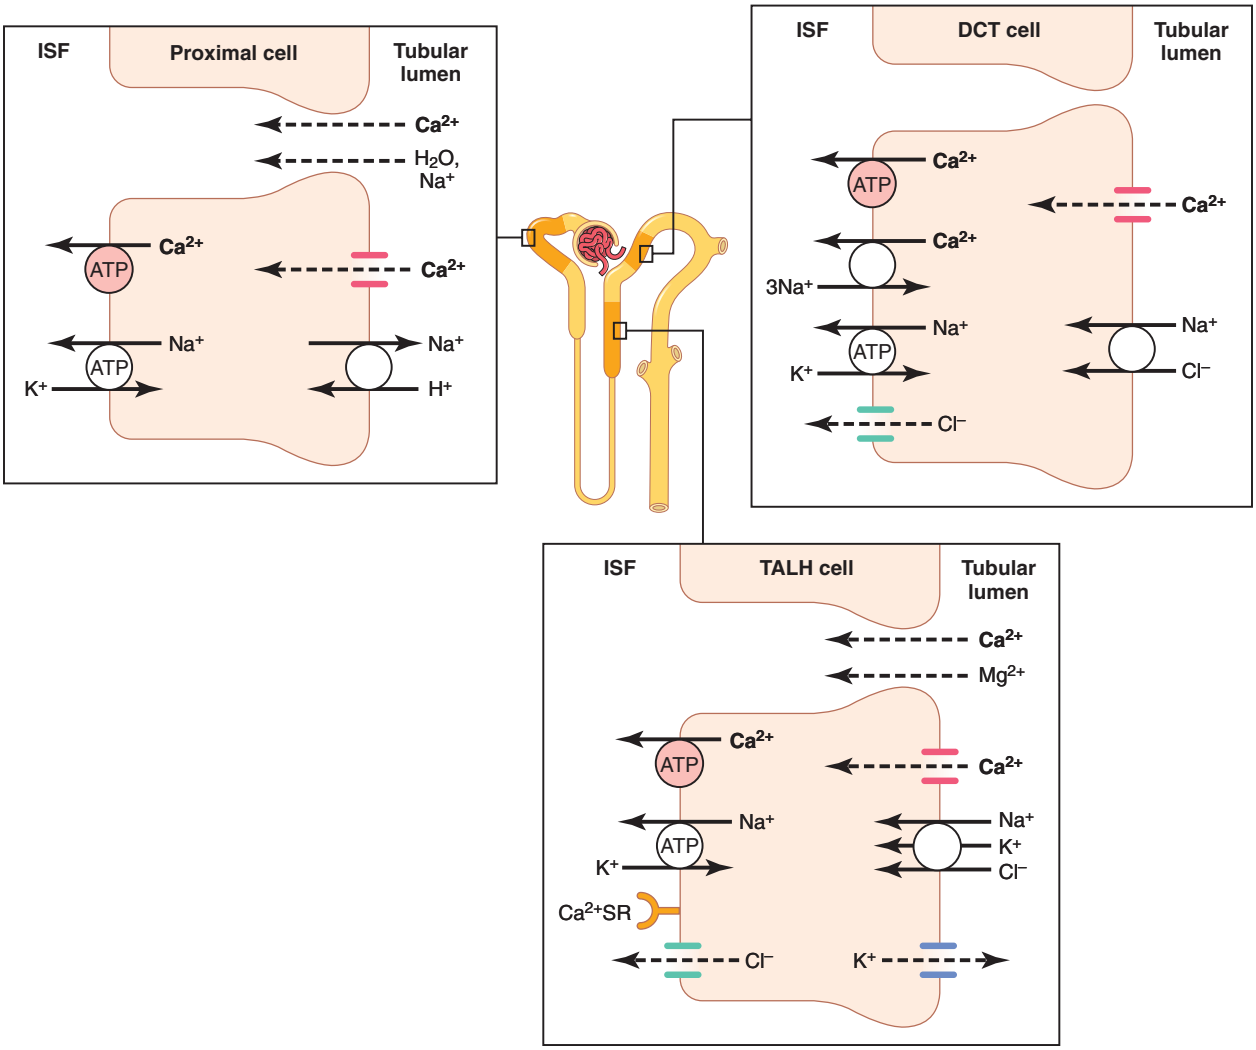

Figure 30.12 Mechanisms of calcium reabsorption by paracellular and transcellular pathways in the proximal tubule, thick ascending loop of Henle (TALH), and distal convoluted tubule (DCT). *ISF*, Interstitial fluid; *Ca^{2+}SR*, calcium sensing receptor.

transport through the cell membrane. The mechanism for this active transport involves diffusion across the luminal membrane through calcium channels and exit across the basolateral membrane by a calcium-ATPase pump, as well as a sodium-calcium counter-transport mechanism. In this segment, as well as in the loops of Henle, PTH stimulates calcium reabsorption. Vitamin D (calcitriol) and calcitonin also stimulate calcium reabsorption in the thick ascending limb of the loop of Henle and in the distal tubule, although these hormones are not as important quantitatively as PTH in reducing renal calcium excretion.

Regulation of Tubular Calcium Reabsorption. One of the primary controllers of renal tubular calcium reabsorption is PTH. Increased levels of PTH stimulate calcium reabsorption in the thick ascending loops of Henle and distal tubules, which reduces urinary excretion of calcium. Conversely, reduction of PTH promotes calcium excretion by decreasing reabsorption in the loops of Henle and distal tubules.

Increased extracellular fluid calcium ion concentration also directly stimulates CSRs, which inhibit calcium reabsorption in the thick ascending loops of Henle. Conversely, reductions in calcium concentration decrease CSR activity and increase calcium reabsorption in the thick ascending loop of Henle.

In the proximal tubule, calcium reabsorption usually parallels sodium and water reabsorption and is independent of PTH. Therefore, in cases of extracellular volume expansion or increased arterial pressure—both of which decrease proximal sodium and water reabsorption—there is also reduction in calcium reabsorption and, consequently, increased urinary calcium excretion. Conversely, with reduced extracellular volume or decreased blood pressure, calcium excretion decreases primarily because of increased proximal tubular reabsorption.

Another factor that influences calcium reabsorption is the plasma phosphate concentration. Increased plasma phosphate tends to reduce ionized calcium concentration and therefore stimulates secretion of PTH, which increases calcium reabsorption by the renal tubules, thereby reducing calcium excretion. The opposite occurs with a reduction in plasma phosphate concentration.

Calcium reabsorption is also inhibited by metabolic acidosis and stimulated by metabolic alkalosis. Thus, acidosis tends to increase calcium excretion, whereas alkalosis tends to reduce calcium excretion. Most of the effect of increased hydrogen ion concentration on calcium excretion results from inhibition of active calcium reabsorption in the distal tubule.

A summary of the major factors that influence calcium excretion is shown in **Table 30.2**.

REGULATION OF RENAL PHOSPHATE EXCRETION

Phosphate excretion by the kidneys is controlled primarily by an overflow mechanism that can be explained as follows. The renal tubules have a normal transport maximum for reabsorbing phosphate of about 0.1 mmol/min. When less than this amount of phosphate is present in the glomerular filtrate, essentially *all* the filtered phosphate is reabsorbed. When more than this amount is present, the *excess* is excreted. Therefore, phosphate normally begins to spill into the urine when its concentration in the extracellular fluid rises above a threshold of about 0.8 mM/L, which gives a tubular load of phosphate of about 0.1 mmol/min, assuming a GFR of 125 mL/min. Because most people ingest large quantities of phosphate in milk products and meat, the concentration of phosphate is usually maintained above 1 mM/L; at this level, there is continual excretion of phosphate into the urine.

The proximal tubule normally reabsorbs 75% to 80% of the filtered phosphate. The distal tubule reabsorbs about 10% of the filtered load, and only small amounts are reabsorbed in the loop of Henle, collecting tubules, and collecting ducts. Approximately 10% of the filtered phosphate is excreted in the urine.

In the proximal tubule, phosphate reabsorption occurs mainly through the transcellular pathway. Phosphate enters the cell from the lumen by at least three sodium-phosphate co-transporters, driven by the inward gradient for sodium that is generated by activity of the basolateral Na^+-K^+ ATPase pump. Phosphate exits the cell across the basolateral membrane by a process that is not fully understood but may involve a counter-transport mechanism in which phosphate is exchanged for an anion.

Changes in tubular phosphate reabsorptive capability can also occur in different conditions and influence phosphate excretion. For example, a diet low in phosphate can, over time, increase the reabsorptive transport maximum for phosphate, thereby reducing the tendency for phosphate to spill over into the urine.

PTH can play a significant role in regulating phosphate concentration through two effects: (1) PTH promotes bone resorption, thereby releasing large amounts of phosphate into the extracellular fluid from the bone salts; and (2) PTH decreases the abundance of sodium-phosphate co-transporters in the apical membrane, which in turn reduces phosphate reabsorption by the renal tubules. *Thus, whenever plasma PTH is increased, tubular phosphate reabsorption is decreased, and more phosphate is excreted.*

Table 30.3 Factors That Alter Renal Phosphate Excretion

↓ Phosphate Excretion	↑ Phosphate Excretion
↓ Dietary phosphate	↑ Dietary phosphate

Thyroid hormone	Hypertension

These interrelationships among phosphate, PTH, and calcium are discussed in more detail in Chapter 80.

Table 30.3 summarizes some of the factors that influence renal phosphate excretion.

REGULATION OF RENAL MAGNESIUM EXCRETION AND EXTRACELLULAR MAGNESIUM ION CONCENTRATION

More than half of the body's magnesium is stored in the bones. Most of the rest is within the cells, with less than 1% located in the extracellular fluid. Although the total plasma magnesium concentration is about 1.8 mEq/L, more than half of this is bound to plasma proteins. Therefore, the free ionized concentration of magnesium is only about 0.8 mEq/L.

The normal daily intake of magnesium is about 250 to 300 mg/day, but only about half of this intake is absorbed by the gastrointestinal tract. To maintain magnesium balance, the kidneys must excrete this absorbed magnesium, about half the daily intake of magnesium, or 125 to 150 mg/day. The kidneys normally excrete about 10% to 15% of the magnesium in the glomerular filtrate.

Renal excretion of magnesium can increase markedly during magnesium excess or decrease to almost zero during magnesium depletion. Because magnesium is involved in many biochemical processes in the body, including activation of many enzymes, its concentration must be closely regulated.

Regulation of magnesium excretion is achieved mainly by changing tubular reabsorption. The proximal tubule usually reabsorbs only about 25% of the filtered magnesium. The primary site of reabsorption is the thick ascending loop of Henle, where about 65% of the filtered load of magnesium is reabsorbed, mainly through the paracellular pathway. The driving force for paracellular magnesium reabsorption is the lumen-positive positive voltage in the thick ascending loop of Henle. In the thick ascending loop of Henle, claudins also play a critical role in paracellular magnesium reabsorption.

Only a small amount (usually <5%) of filtered magnesium is reabsorbed in the distal and collecting tubules, mainly through the transcellular pathway by active transport.

Table 30.4 summarizes some of the most important factors that influence renal magnesium excretion. Note that several factors that alter renal calcium excretion have similar effects on magnesium excretion.

INTEGRATION OF RENAL MECHANISMS FOR CONTROL OF EXTRACELLULAR FLUID

Extracellular fluid volume is determined mainly by the balance between intake and output of water and salt. In many cases, salt and fluid intakes are dictated by a person's habits rather than by physiological control mechanisms. Therefore, the burden of extracellular volume regulation is often placed on the kidneys, which must adapt their excretion of salt and water to match intake under steady-state conditions.

In discussing the regulation of extracellular fluid volume, we consider the factors that control the amount of sodium chloride in the extracellular fluid because changes in extracellular fluid sodium chloride content usually cause parallel changes in extracellular fluid volume, provided the antidiuretic hormone (ADH)–thirst mechanisms are operative. When the ADH-thirst mechanisms are functioning normally, a change in extracellular fluid sodium chloride content is usually matched by a similar change in the amount of extracellular water, and thus maintenance of osmolality and sodium concentration is relatively constant.

Sodium Intake and Excretion Are Balanced Under Steady-State Conditions

An important consideration in overall control of sodium excretion, as well as for most electrolytes, is that excretion by the kidneys is determined mainly by intake under steady-state conditions. To maintain life, a person must, over the long term, excrete almost exactly the amount of sodium ingested. Therefore, even with disturbances that cause major changes in kidney function, balance between intake and output of sodium usually is restored within a few days.

If disturbances of kidney function are not too severe, sodium balance may be achieved mainly by intrarenal adjustments, with minimal changes in the extracellular fluid volume or other systemic adjustments. However, when perturbations to the kidneys are severe and intrarenal compensations are exhausted, systemic adjustments are often invoked, such as changes in blood pressure, circulating hormones, and sympathetic nervous system activity.

These adjustments can be costly because they cause other changes throughout the body that may, in the long run, be damaging. For example, impaired kidney function may lead to increased blood pressure that, in turn, helps maintain normal sodium excretion. Over the long term, the high blood pressure may injure the blood vessels, heart, and other organs. These compensations, however, are necessary because a sustained imbalance between fluid and electrolyte intake and excretion would quickly lead to accumulation or loss of electrolytes and fluid, causing severe cardiovascular consequences within a few days. Thus, one can view the systemic adjustments that occur in response to abnormalities of kidney function as a necessary trade-off that brings electrolyte and fluid excretion back into balance with intake.

Sodium Excretion Is Controlled By Altering Glomerular Filtration or Tubular Sodium Reabsorption Rates

The two variables that influence sodium and water excretion are the rates of glomerular filtration and tubular reabsorption:

Excretion = Glomerular filtration − Tubular reabsorption

The GFR averages about 180 L/day, tubular reabsorption is 178.5 L/day, and urine excretion is 1.5 L/day. Thus, small changes in GFR or tubular reabsorption potentially can cause large changes in renal excretion. For example, a 5% increase in GFR (to 189 L/day) would cause a 9-L/day increase in urine volume if tubular compensations did not occur; this increase would quickly cause catastrophic changes in body fluid volumes. Similarly, small changes in tubular reabsorption, in the absence of compensatory adjustments of GFR, would also lead to dramatic changes in urine volume and sodium excretion. Tubular reabsorption and the GFR usually are regulated precisely in parallel, so that excretion by the kidneys can be exactly matched to the intake of water and electrolytes.

Even with disturbances that alter GFR or tubular reabsorption, changes in urinary excretion are minimized by various intrarenal buffering mechanisms. For example, if the kidneys become greatly vasodilated, and GFR increases (as can occur with certain drugs or high fever), this condition raises sodium chloride delivery to the tubules, which in turn leads to at least two intrarenal compensations: (1) *glomerulotubular balance* mechanisms that increase tubular reabsorption of much of the extra sodium chloride filtered; and (2) *macula densa feedback*, in which increased sodium chloride delivery to the distal tubule causes afferent arteriolar constriction and return of GFR toward normal. Likewise, abnormalities of tubular reabsorption in the proximal tubule or loop of Henle are partially compensated for by these same intrarenal feedbacks, as discussed in Chapter 27.

Because neither of these two mechanisms operates perfectly to restore distal sodium chloride delivery all the way back to normal, changes in GFR or tubular reabsorption can lead to significant changes in urine sodium and water excretion. When this occurs, other feedback mechanisms may come into play, such as changes in blood pressure and various hormones; these mechanisms eventually return sodium excretion to equal sodium intake. In the next few sections, we review how these mechanisms operate together to control sodium and water balance and, in so doing, also act to control extracellular fluid volume. All of these feedback mechanisms control renal excretion of sodium and water by altering GFR or tubular reabsorption.

Importance of Pressure Natriuresis and Pressure Diuresis in Maintaining Body Sodium and Fluid Balance

One of the most basic and powerful mechanisms for maintaining sodium and fluid balance, as well as for controlling blood volume and extracellular fluid volume, is the effect of blood pressure on sodium and water excretion—the *pressure natriuresis* and *pressure diuresis* mechanisms, respectively. As discussed in Chapter 19, this feedback also plays a dominant role in long-term blood pressure regulation.

Fig. 30.13 shows the effect of arterial pressure on urinary sodium output. Note that acute increases in blood pressure of 30 to 50 mm Hg cause a 2-fold to 3-fold increase in urinary sodium output. This effect is independent of changes in activity of the sympathetic nervous system or of various hormones because pressure natriuresis can be demonstrated in an isolated kidney that has been removed from the influence of these factors. With chronic increases in blood pressure, the effectiveness of pressure natriuresis is greatly enhanced because the increased blood pressure also, after a short time delay, suppresses renin release and, therefore, decreases the formation of angiotensin II (Ang II) and aldosterone. As discussed previously, decreased levels of Ang II and aldosterone inhibit renal tubular reabsorption of sodium, thereby amplifying

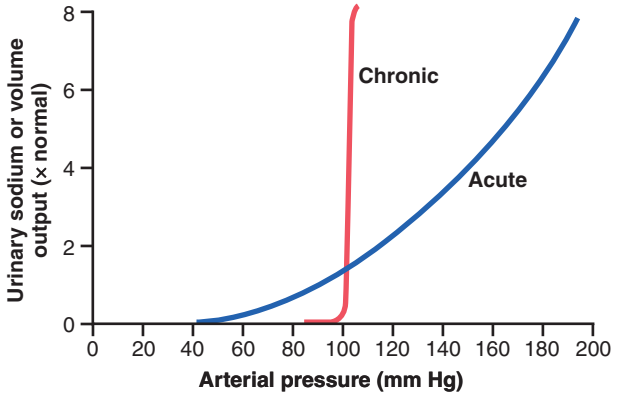

Figure 30.13 Acute and chronic effects of arterial pressure on urinary sodium output by the kidneys (pressure natriuresis). Note that chronic increases in arterial pressure cause much greater increases in sodium output than those measured during acute increases in arterial pressure.

the direct effects of increased blood pressure to increase sodium and water excretion.

Pressure Natriuresis and Diuresis: Key Components of a Renal–Body Fluid Feedback for Regulating Body Fluid Volumes and Arterial Pressure

The effect of increased blood pressure to raise urine output is part of a powerful feedback system that operates to maintain balance between fluid intake and output, as shown in **Fig. 30.14**. This mechanism is the same mechanism discussed in Chapter 19 for arterial pressure control. The extracellular fluid volume, blood volume, cardiac output, arterial pressure, and urine output are all controlled at the same time as separate parts of this basic feedback mechanism.

During changes in sodium and fluid intake, this feedback mechanism helps maintain fluid balance and minimizes changes in blood volume, extracellular fluid volume, and arterial pressure as follows:

1. An increase in fluid intake (assuming that sodium accompanies the fluid intake) above the level of urine output causes a temporary accumulation of fluid in the body.
2. As long as fluid intake exceeds urine output, fluid accumulates in the blood and interstitial spaces, causing parallel increases in blood volume and extracellular fluid volume. As discussed later, the actual increases in these variables are usually small because of the effectiveness of this feedback.
3. An increase in blood volume raises mean circulatory filling pressure.
4. An increase in mean circulatory filling pressure raises the pressure gradient for venous return.
5. An increased pressure gradient for venous return elevates cardiac output.
6. An increased cardiac output raises arterial pressure, although increases in pressure are buffered by nervous reflexes and hormonal changes, as discussed in Chapter 19.
7. An increased arterial pressure increases urine output by way of pressure diuresis. The steepness of the normal pressure natriuresis relationship indicates that only a slight increase in blood pressure is required to raise urinary excretion severalfold.
8. The increased fluid excretion balances the increased intake, and further accumulation of fluid is prevented.

Thus, the renal–body fluid feedback mechanism operates to prevent continuous accumulation of salt and water in the body during increased salt and water intake. As long as the kidneys and various nervous and hormonal mechanisms are operating effectively, large changes in salt and water intake can be accommodated with minimal changes in blood volume, extracellular fluid volume, cardiac output, and arterial pressure.

The opposite sequence of events occurs when fluid intake falls below normal. In this case, there is a tendency toward decreased blood volume and extracellular fluid volume, as well as reduced arterial pressure. Even a small decrease in blood pressure causes a large decrease in urine output, thereby allowing fluid balance to be maintained, with minimal changes in blood pressure, blood volume, or extracellular fluid volume. The effectiveness of this mechanism in preventing large changes in blood volume is demonstrated in **Fig. 30.15**, which shows that changes in blood volume are almost imperceptible, despite large variations in daily intake of water and electrolytes, except

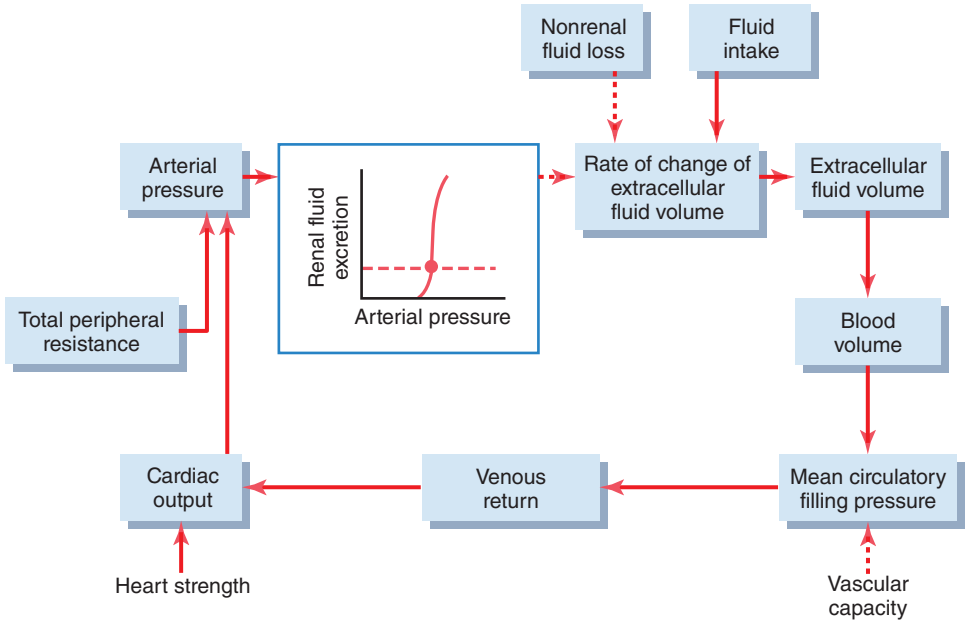

Figure 30.14 The basic renal–body fluid feedback mechanism for control of blood volume, extracellular fluid volume, and arterial pressure. *Solid lines* indicate positive effects; *dashed lines* indicate negative effects.

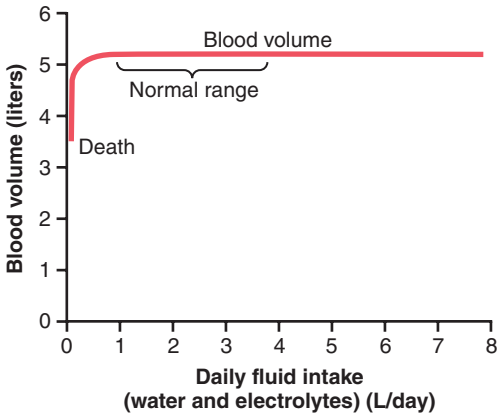

Figure 30.15 Approximate effect of changes in daily fluid intake on blood volume. Note that blood volume remains relatively constant in the normal range of daily fluid intakes.

when intake becomes so low that it is not sufficient to make up for fluid losses caused by evaporation or other inescapable losses.

As discussed later, there are nervous and hormonal systems, in addition to intrarenal mechanisms, that can raise sodium excretion to match increased sodium intake, even without measurable increases in cardiac output or arterial pressure in many persons. Other individuals, especially those who have impaired kidney function, may be more "salt-sensitive" and have significant increases in arterial pressure with even moderate increases in sodium intake. As discussed in Chapter 19 and later in this chapter, there is considerable heterogeneity of blood pressure response to changes in salt intake depending on various factors, such as age, the number of functional nephrons, and the many factors that regulate the ability of the kidneys to excrete sodium. However, with prolonged high-sodium intake, lasting over several years, high blood pressure may occur, even in persons who are not initially salt-sensitive, due to gradual kidney injury. When blood pressure does rise, pressure natriuresis provides a critical means of maintaining balance between sodium intake and urinary sodium excretion.

Effectiveness of Blood Volume and Extracellular Fluid Volume Regulation

Fig. 30.14 illustrates the basic feedback mechanisms that maintain blood volume at a relatively constant level despite extreme changes in daily fluid intake: (1) a slight change in blood volume causes a change in cardiac output; (2) a slight change in cardiac output causes a change in blood pressure; and (3) a slight change in blood pressure causes a large change in urine output. These factors work together to provide effective feedback control of blood volume.

The same control mechanisms operate whenever there is blood loss because of hemorrhage. In this case, a fall in blood pressure along with nervous and hormonal factors (discussed later) cause fluid retention by the kidneys. Other parallel processes occur to reconstitute the red blood cells and plasma proteins in the blood. If abnormalities of red blood cell volume remain, such as when there is a deficiency of erythropoietin or other factors needed to stimulate red blood cell production, the plasma volume will usually make up the difference, and the overall blood volume will return essentially to normal, despite the low red blood cell mass.

DISTRIBUTION OF EXTRACELLULAR FLUID BETWEEN INTERSTITIAL SPACES AND VASCULAR SYSTEM

From **Fig. 30.14** it is apparent that blood volume and extracellular fluid volume are usually controlled in parallel with each other. Ingested fluid initially is absorbed from the gut into the blood, but it rapidly becomes distributed between the interstitial spaces and the plasma. Therefore, blood volume and extracellular fluid volume usually are controlled simultaneously.

There are circumstances, however, in which the distribution of extracellular fluid between the interstitial spaces and blood can vary greatly. As discussed in Chapter 25, *the principal factors that can cause accumulation of fluid in the interstitial spaces include the following: (1) increased capillary hydrostatic pressure; (2) decreased plasma colloid osmotic pressure; (3) increased permeability of the capillaries; and (4) obstruction of lymphatic vessels.* In all these conditions, an unusually high proportion of the extracellular fluid becomes distributed to the interstitial spaces.

Fig. 30.16 shows the approximate relationship between extracellular fluid volume and blood volume under normal conditions and in edema states. The interstitial fluid volume is the difference between extracellular fluid volume and blood volume. When small amounts of fluid accumulate in the blood as a result of too much fluid intake or a decrease in renal output of fluid, about 20% to 30% of it stays in the blood and increases the blood

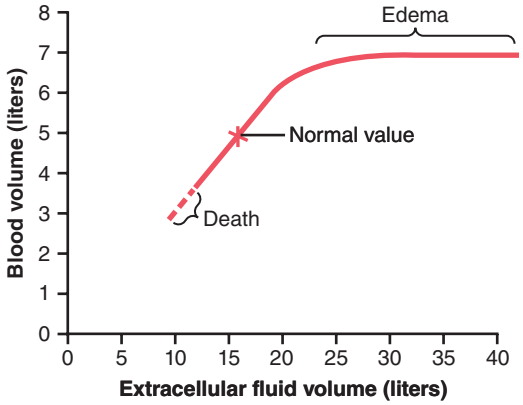

Figure 30.16 Approximate relationship between extracellular fluid volume and blood volume, showing a nearly linear relationship in the normal range and failure of blood volume to continue to increase when the extracellular fluid volume becomes excessive. When this condition occurs, the additional extracellular fluid volume resides in the interstitial spaces, and edema results.

volume. The remainder is distributed to the interstitial spaces. When the extracellular fluid volume rises more than 30% to 50% above normal, almost all the additional fluid goes into the interstitial spaces, and little remains in the blood. Once the interstitial fluid pressure rises from its normally negative value to become positive, the tissue interstitial spaces become compliant, and large amounts of fluid then pour into the tissues without the interstitial fluid pressure rising much more. In other words, the safety factor against edema, owing to a rising interstitial fluid pressure that counteracts fluid accumulation in the tissues, is lost once the tissues become highly compliant.

Thus, under normal conditions, the interstitial spaces act as an overflow reservoir for excess fluid, sometimes increasing in volume 10 to 30 liters. This situation causes edema, as explained in Chapter 25, but it also acts as an important overflow release valve for the circulation, protecting the cardiovascular system against a dangerous overload that could lead to pulmonary edema and cardiac failure.

To summarize, extracellular fluid volume and blood volume are often controlled simultaneously, but the quantitative amounts of fluid distribution between the interstitium and the blood depend on the physical properties of the circulation and the interstitial spaces, as well as on the dynamics of fluid exchange through the capillary membranes.

NERVOUS AND HORMONAL FACTORS INCREASE EFFECTIVENESS OF RENAL–BODY FLUID FEEDBACK CONTROL

In Chapters 27 and 28, we discuss the nervous and hormonal factors that influence GFR and tubular reabsorption and, therefore, renal excretion of salt and water. These nervous and hormonal mechanisms usually act together with pressure natriuresis and pressure diuresis, making them more effective in minimizing the changes in blood volume, extracellular fluid volume, and arterial pressure that occur in response to daily challenges. In many cases, nervous and hormonal mechanisms can regulate renal sodium and water excretion and maintain balance between intake and output without significant changes in blood pressure. However, abnormalities of kidney function or of the various nervous and hormonal factors that influence the kidneys can lead to serious changes in blood pressure and body fluid volumes, as discussed later.

Sympathetic Nervous System Control of Renal Excretion: Arterial Baroreceptor and Low-Pressure Stretch Receptor Reflexes

Because the kidneys receive extensive sympathetic innervation, changes in sympathetic activity can alter renal sodium and water excretion, as well as regulation of extracellular fluid volume under some conditions. For example, when blood volume is reduced by hemorrhage, pressures in the pulmonary blood vessels and other low-pressure regions of the thorax decrease, causing reflex activation of the sympathetic nervous system. This, in turn, increases renal sympathetic nerve activity, which has several effects to decrease sodium and water excretion: (1) constriction of the renal arterioles, which decreases GFR if the sympathetic activation is severe; (2) increased tubular reabsorption of salt and water; and (3) stimulation of renin release and increased formation of Ang II and aldosterone, both of which further increase tubular reabsorption. If the reduction in blood volume is great enough to lower systemic arterial pressure, further activation of the sympathetic nervous system occurs because of decreased stretch of the arterial baroreceptors located in the carotid sinus and aortic arch. All these reflexes together play an important role in the rapid restitution of blood volume that occurs in acute conditions such as hemorrhage. Also, reflex inhibition of renal sympathetic activity may contribute to the rapid elimination of excess fluid in the circulation that occurs after eating a meal that contains large amounts of salt and water.

Excessive and inappropriate activation of the sympathetic nervous system, however, can lead to a cascade of effects, including increases in renin secretion, Ang II formation, and renal sodium reabsorption that elevate blood pressure. In fact, ablation of the renal sympathetic nerves often lowers arterial pressure in hypertension, especially when associated with obesity.

Role of Angiotensin II in Controlling Renal Excretion

One of the body's most powerful controllers of sodium excretion is Ang II. Changes in sodium intake are associated with reciprocal changes in Ang II formation, and this in turn contributes greatly to the maintenance of body sodium balances. When sodium intake is elevated above normal, renin secretion and Ang II formation decrease. Because Ang II has several important effects to increase tubular reabsorption of sodium, as explained in Chapter 28, a reduced level of Ang II decreases sodium and water reabsorption, thus increasing renal excretion of sodium and water. The net result is to minimize the rise in extracellular fluid volume and arterial pressure that would otherwise occur when sodium intake increases.

Conversely, when sodium intake decreases below normal, increased levels of Ang II cause sodium and water retention and oppose reductions in arterial blood pressure that would otherwise occur. Thus, changes in activity of the renin-angiotensin system act as a powerful regulator of sodium excretion and as an amplifier of the pressure natriuresis mechanism for maintaining stable blood pressures and body fluid volumes.

Importance of Changes in Ang II in Regulating Sodium Balance and Altering Pressure Natriuresis. The importance of Ang II in regulating sodium balance and making the pressure natriuresis mechanism more effective is shown in **Fig. 19.13** and **Fig. 30.17**. Note that

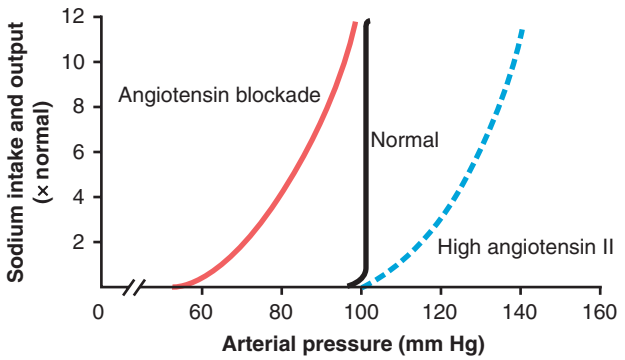

Figure 30.17 Effects of excessive angiotensin II (Ang II) formation or blocking Ang II formation on the renal-pressure natriuresis curve. Note that high levels of Ang II formation decrease the slope of pressure natriuresis, making blood pressure very sensitive to changes in sodium intake. Blockade of Ang II formation shifts pressure natriuresis to lower blood pressures but also makes blood pressure more sensitive to changes in sodium intake.

when Ang II control of natriuresis is fully functional, the pressure natriuresis curve is steep (normal curve), indicating that increases in sodium excretion can be achieved when sodium intake is raised with minimal changes in arterial pressure.

In contrast, when Ang II levels cannot be suppressed in response to increased sodium intake (high angiotensin II curve), as occurs in some individuals who have an impaired ability to decrease renin secretion and Ang II formation, the pressure natriuresis curve is not nearly as steep. Therefore, when sodium intake is raised, much greater increases in arterial pressure are necessary to increase sodium excretion and maintain sodium balance. For example, in most people, a 10-fold increase in sodium intake causes only a few mm Hg increase in arterial pressure, whereas in subjects who cannot suppress Ang II formation appropriately in response to excess sodium, the same rise in sodium intake causes greater increases in blood pressure. Thus, the inability to suppress Ang II formation when there is excess sodium reduces the slope of pressure natriuresis and makes arterial pressure very salt-sensitive, as discussed in Chapter 19.

The use of drugs to block the effects of Ang II has proved to be important clinically for improving the kidneys' ability to excrete salt and water. When Ang II formation is blocked with an angiotensin-converting enzyme (ACE) inhibitor (see **Figs. 19.13 and 30.17**) or an Ang II receptor antagonist, the renal-pressure natriuresis curve is shifted to lower pressures, which indicates an enhanced ability of the kidneys to excrete sodium because normal levels of sodium excretion can now be maintained at reduced arterial pressures. This shift of pressure natriuresis provides the basis for the chronic blood pressure–lowering effects of the ACE inhibitors and Ang II receptor antagonists in hypertensive patients. However, blood pressure also becomes much more salt sensitive after Ang II blockade, and with high levels of sodium intake the Ang II blockers are much less effective in lowering blood pressure.

Excessive Ang II Does Not Usually Cause Large Increases in Extracellular Fluid Volume Because Increased Arterial Pressure Counterbalances Ang II–Mediated Sodium Retention. Although Ang II is one of the most powerful sodium- and water-retaining hormones in the body, neither a decrease nor increase in circulating Ang II has a large effect on extracellular fluid volume or blood volume as long as heart failure or kidney failure does not occur. With large increases in Ang II levels, as occurs with a renin-secreting tumor of the kidney, the high Ang II levels initially cause sodium and water retention by the kidneys and a small increase in extracellular fluid volume. However, this also initiates a rise in arterial pressure that quickly increases kidney output of sodium and water, thereby overcoming the sodium- and water-retaining effects of the Ang II and reestablishing a balance between the intake and output of sodium at a higher blood pressure. Conversely, after blockade of Ang II formation with an ACE inhibitor or an Ang II receptor antagonist, there is initial loss of sodium and water, but the fall in blood pressure rapidly offsets this effect, and sodium excretion is once again restored to normal.

If the heart is weakened, due to underlying heart disease, cardiac pumping ability may not be able to raise arterial pressure enough to overcome the sodium-retaining effects of high levels of Ang II; in these cases, Ang II may cause large amounts of sodium and water retention that progresses to *congestive heart failure*. Blockade of Ang II formation may, in these cases, relieve some of the sodium and water retention and attenuate the large expansion of extracellular fluid volume associated with heart failure.

Role of Aldosterone in Controlling Renal Excretion

Aldosterone increases sodium reabsorption, especially in the collecting tubules and collecting ducts. The increased sodium reabsorption is also associated with increased water reabsorption and potassium secretion. Therefore, the net effect of aldosterone is to make the kidneys retain sodium and water and increase potassium excretion in the urine.

The function of aldosterone in regulating sodium balance is closely related to that described for Ang II. That is, with a reduction in sodium intake, increased Ang II levels stimulate secretion of aldosterone, which, in turn, contributes to the reduction in urinary sodium excretion and maintenance of sodium balance. Conversely, with high sodium intake, suppression of aldosterone formation decreases tubular reabsorption, allowing the kidneys to excrete larger amounts of sodium. Thus, changes in aldosterone formation also aid the pressure natriuresis mechanism in maintaining sodium balance during variations in salt intake.

During Chronic Excess Aldosterone Secretion, the Kidneys Escape From Sodium Retention as Arterial Pressure Rises. Although aldosterone has powerful effects on sodium reabsorption, when there is excessive formation of

aldosterone, as occurs in patients with tumors of the adrenal gland (Conn syndrome), the increased sodium reabsorption and decreased sodium excretion by the kidneys are transient. After a few days of sodium and water retention, the extracellular fluid volume rises by about 10% to 15%, and there is a simultaneous increase in arterial blood pressure. When the arterial pressure rises sufficiently, the kidneys "escape" from the sodium and water retention and thereafter excrete amounts of sodium equal to the daily intake, despite the continued presence of high levels of aldosterone. The primary reasons for this escape are suppression of Ang II formation and the pressure natriuresis and diuresis that occur when the arterial pressure rises (see Chapter 78, **Fig. 78.3**).

In patients with adrenal insufficiency who do not secrete enough aldosterone (Addison disease), there is increased excretion of sodium and water, reduction in extracellular fluid volume, and a tendency toward low blood pressure. In the complete absence of aldosterone, the volume depletion may be severe unless the person ingests large amounts of salt and water to balance the increased urine output of salt and water.

Role of Antidiuretic Hormone in Controlling Renal Water Excretion

As discussed in Chapter 29, ADH plays an important role in allowing the kidneys to form a small volume of concentrated urine while excreting normal amounts of salt. This effect is especially important during water deprivation, which elevates plasma levels of ADH and water reabsorption by the kidneys, helping to minimize the decreases in extracellular fluid volume and arterial pressure that would otherwise occur. Water deprivation for 24 to 48 hours normally causes only a small decrease in extracellular fluid volume and arterial pressure. However, if the effects of ADH are blocked, the same period of water deprivation causes a substantial fall in extracellular fluid volume and arterial pressure. Conversely, when there is excess extracellular volume, *decreased* ADH levels reduce water reabsorption by the kidneys, thus helping rid the body of the excess volume.

Excess Antidiuretic Hormone Secretion Usually Causes Only Small Increases in Extracellular Fluid Volume But Large Decreases in Sodium Concentration. Although ADH is important in regulating extracellular fluid volume, excessive ADH seldom causes large increases in arterial pressure or extracellular fluid volume. Infusion of large amounts of ADH into animals initially causes renal retention of water and a 10% to 15% increase in extracellular fluid volume. As the arterial pressure rises in response to this increased volume, much of the excess volume is excreted because of pressure diuresis. Also, the rise in blood pressure causes pressure natriuresis and loss of sodium from the extracellular fluid. After several days of ADH infusion, the blood volume and extracellular fluid volume are elevated by no more than 5% to 10%, and the arterial pressure is also elevated by less than 10 mm Hg. The same is true for patients with *inappropriate ADH syndrome*, in which ADH levels may be elevated severalfold.

Thus, high levels of ADH do not cause major increases of body fluid volume or arterial pressure, although *high ADH levels can cause severe reductions in extracellular sodium ion concentration*. The reason for this is that increased water reabsorption by the kidneys dilutes the extracellular sodium and, at the same time, the small increase in blood pressure that does occur causes loss of sodium from the extracellular fluid in the urine through pressure natriuresis.

In patients who are unable to secrete ADH because of destruction of the supraoptic nuclei, the urine volume may become 5 to 10 times normal. This increase in volume is almost always compensated for by ingestion of enough water to maintain fluid balance. If free access to water is prevented, the inability to secrete ADH may lead to marked reductions in blood volume and arterial pressure.

Role of Atrial Natriuretic Peptide in Controlling Renal Excretion

Thus far, we have discussed mainly the role of sodium- and water-retaining hormones in controlling extracellular fluid volume. However, several different natriuretic hormones may also contribute to volume regulation. One of the most important of these is a peptide referred to as *atrial natriuretic peptide* (ANP), released by the cardiac atrial muscle fibers. A major stimulus for release of this peptide is increased stretch of the atria, which can result from excess blood volume. Once released by the cardiac atria, ANP enters the circulation and acts on the kidneys to cause small increases in GFR, decreases in renin secretion and Ang II formation, and reductions in sodium reabsorption by the collecting ducts. These combined actions of ANP lead to increased excretion of salt and water, which helps compensate for the excess blood volume.

Changes in ANP levels help minimize changes in blood volume during various disturbances, such as increased salt and water intake. However, excessive production of ANP or even complete lack of ANP does not cause major changes in blood volume because these effects can be overcome by small changes in blood pressure, acting through pressure natriuresis. For example, infusions of large amounts of ANP initially raise urine output of salt and water and cause slight decreases in blood volume. In less than 24 hours, this effect is overcome by a slight decrease in blood pressure that returns urine output toward normal, despite continued excess of ANP.

INTEGRATED RESPONSES TO CHANGES IN SODIUM INTAKE

The integration of different control systems that regulate sodium and fluid excretion under normal conditions can be summarized by examining the homeostatic responses to progressive increases in dietary sodium intake. As noted previously, the kidneys have an amazing capability to match their excretion of salt and water to intakes, which can range from as low as one-tenth of normal to as high as 10 times normal.

High Sodium Intake Suppresses Antinatriuretic Systems and Activates Natriuretic Systems. As sodium intake is increased, sodium output initially lags slightly behind intake. The time delay results in a small increase in the cumulative sodium balance, which causes a slight increase in extracellular fluid volume. It is mainly this small increase in extracellular fluid volume that triggers multiple mechanisms in the body to increase sodium excretion. These mechanisms include the following:

1. *Activation of low-pressure receptor reflexes* that originate from the stretch receptors of the right atrium and the pulmonary blood vessels. Signals from the stretch receptors go to the brain stem and there inhibit sympathetic nerve activity to the kidneys to decrease tubular sodium reabsorption. This mechanism is most important in the first few hours—or perhaps the first day—after a large increase in salt and water intake.
2. *Suppression of Ang II and aldosterone formation*, caused by increased arterial pressure and extracellular fluid volume expansion, decreases tubular sodium reabsorption by eliminating the normal effect of Ang II and aldosterone to increase sodium reabsorption.
3. *Stimulation of natriuretic systems*, especially ANP, contributes further to increased sodium excretion. Thus, the combined activation of natriuretic systems and suppression of sodium- and water-retaining systems leads to an increase in sodium excretion when sodium intake is increased. The opposite changes take place when sodium intake is reduced below normal levels.
4. *Small increases in arterial pressure*, caused by volume expansion, may occur with large increases in sodium intake, especially in salt-sensitive individuals; this mechanism raises sodium excretion through pressure natriuresis, as well as by suppression of the renin-angiotensin-aldosterone system (RAAS). As discussed previously, if the nervous, hormonal, and intrarenal mechanisms are operating effectively, measurable increases in blood pressure may not occur, even with large increases in sodium intake over several days. However, when high sodium intake is sustained for months or years, the kidneys may become damaged and less effective in excreting sodium, necessitating increased blood pressure to maintain sodium balance through the pressure natriuresis mechanism.

CONDITIONS THAT CAUSE LARGE INCREASES IN BLOOD VOLUME AND EXTRACELLULAR FLUID VOLUME

Despite the powerful regulatory mechanisms that maintain blood volume and extracellular fluid volume at reasonably constant levels, there are multiple abnormal conditions that can cause large increases in both these variables. Almost all these conditions result from circulatory abnormalities.

Increased Blood Volume and Extracellular Fluid Volume Caused By Heart Diseases

In persons with congestive heart failure, blood volume may increase by 15% to 20%, and the extracellular fluid volume sometimes increases by 200% or more. The reason for these increases can be understood by reexamination of **Fig. 30.14**. Initially, heart failure reduces cardiac output and, consequently, decreases arterial pressure. This effect in turn activates multiple sodium-retaining systems, especially the RAAS and sympathetic nervous system. In addition, the low blood pressure itself causes the kidneys to retain salt and water. Therefore, the kidneys retain volume in an attempt to return the arterial pressure and cardiac output toward normal.

If the heart failure is not too severe, the rise in blood volume can often return cardiac output and arterial pressure all the way to normal, and sodium excretion will eventually increase back to normal, although increased extracellular fluid volume and blood volume will remain to keep the weakened heart pumping adequately. However, if the heart is greatly weakened, arterial pressure may not be able to increase enough to restore urine output to normal. When this situation occurs, the kidneys continue to retain volume until severe circulatory congestion develops, and the person may eventually die of pulmonary edema unless corrective actions are taken to relieve the fluid retention or improve cardiac function.

In myocardial failure, heart valvular disease, and congenital abnormalities of the heart, increased blood volume serves as an important circulatory compensation that helps return cardiac output and blood pressure toward normal. This compensation allows even the weakened heart to maintain a life-sustaining level of cardiac output.

Increased Blood Volume Caused By Increased Vascular Capacity

Any condition that increases vascular capacity will also cause the blood volume to increase to fill this extra capacity. An increase in vascular capacity initially reduces mean circulatory filling pressure (see **Fig. 30.14**), which leads to decreased cardiac output and decreased arterial pressure. The fall in pressure causes salt and water retention by the kidneys until blood volume increases sufficiently to fill the extra capacity.

During pregnancy, increased vascular capacity of the uterus, placenta, and other enlarged organs of the woman's body generally increases blood volume by 15% to 25%. Similarly, in patients who have large varicose veins of the legs, which in rare cases may hold up to an extra liter of blood, the blood volume increases to fill the extra vascular capacity. In these cases, salt and water are retained by the kidneys until the total vascular bed is filled enough to raise blood pressure to the level required to balance renal output of fluid with daily intake of fluid.

CONDITIONS THAT CAUSE LARGE INCREASES IN EXTRACELLULAR FLUID VOLUME WITH NORMAL OR REDUCED BLOOD VOLUME

In several conditions, extracellular fluid volume becomes markedly increased, but blood volume remains normal or even slightly reduced. These conditions are usually initiated by leakage of fluid and protein into the interstitium, which tends to decrease the blood volume. The kidneys' response to these conditions is similar to the response after hemorrhage—that is, the kidneys retain salt and water in an attempt to restore blood volume toward normal. Much of the extra fluid, however, leaks into the interstitium, causing further edema.

Nephrotic Syndrome—Loss of Plasma Proteins in Urine and Sodium Retention By the Kidneys

The general mechanisms that lead to extracellular edema are reviewed in Chapter 25. An important clinical cause of edema is *nephrotic syndrome*, in which the glomerular capillaries leak large amounts of protein into the filtrate and urine because of increased glomerular capillary permeability. Thirty to 50 grams of plasma protein may be lost in the urine each day, sometimes causing plasma protein concentration to fall to less than one-third normal and reducing plasma colloid osmotic pressure to low levels. This effect causes the capillaries all over the body to filter large amounts of fluid into the various tissues, which in turn causes edema and decreases the plasma volume.

Renal sodium retention in nephrotic syndrome occurs through multiple mechanisms activated by leakage of protein and fluid from the plasma into the interstitial fluid, including stimulation of various sodium-retaining systems, such as the RAAS and sympathetic nervous system. The kidneys continue to retain sodium and water until plasma volume is restored nearly to normal. However, because of the large amount of sodium and water retention, the plasma protein concentration becomes further diluted, causing still more fluid to leak into the tissues of the body. The net result is massive fluid retention by the kidneys until tremendous extracellular edema occurs, unless treatment is instituted to restore the plasma proteins.

Liver Cirrhosis—Decreased Synthesis of Plasma Proteins By the Liver and Sodium Retention by the Kidneys

In liver cirrhosis, a reduction in plasma protein concentration results from destruction of liver cells, thus reducing the ability of the liver to synthesize enough plasma proteins. Cirrhosis is also associated with large amounts of fibrous tissue in the liver, which greatly impedes the flow of portal blood through the liver. This impedance, in turn, raises capillary pressure throughout the portal vascular bed, which also contributes to the leakage of fluid and proteins into the peritoneal cavity, a condition called *ascites*.

Once fluid and protein are lost from the circulation, the renal responses are similar to those observed in other conditions associated with decreased plasma volume. That is, the kidneys continue to retain salt and water until plasma volume and arterial pressure are restored to normal. In some cases, plasma volume may actually increase above normal because of increased vascular capacity in cirrhosis; the high pressures in the portal circulation can greatly distend veins and therefore increase vascular capacity.

CHAPTER 31

Acid–Base Regulation

The regulation of hydrogen ion (H^+) balance is similar in some ways to the regulation of other ions in the body. For example, there must be a balance between the intake or production of H^+ and the net removal of H^+ from the body to achieve homeostasis. And, as is true for other ions, the kidneys play a key role in regulating H^+ removal from the body. However, precise control of extracellular fluid H^+ concentration involves much more than the simple elimination of H^+ by the kidneys. Multiple acid–base buffering mechanisms involving the blood, cells, and lungs also are essential in maintaining normal H^+ concentrations in extracellular and intracellular fluids.

In this chapter, we consider the mechanisms that regulate H^+ concentration, with special emphasis on renal H^+ secretion and renal reabsorption, production, and excretion of HCO_3^-, one of the key components of acid–base control systems in the body fluids.

HYDROGEN ION CONCENTRATION IS PRECISELY REGULATED

Precise H^+ regulation is essential because the activities of almost all enzyme systems in the body are influenced by H^+ concentration. Therefore, changes in H^+ concentration alter virtually all cell and body functions.

Compared with other ions, H^+ concentration of the body fluids normally is kept at a low level. For example, the concentration of sodium in extracellular fluid (142 mEq/L) is about 3.5 million times as great as the normal concentration of H^+, which averages only 0.00004 mEq/L. Equally important, the normal variation in H^+ concentration in extracellular fluid is only about one-millionth as great as the normal variation in sodium ion (Na^+) concentration. Thus, the precision with which H^+ is regulated emphasizes its importance to various cell functions.

ACIDS AND BASES—DEFINITIONS AND MEANINGS

A hydrogen ion is a single free proton released from a hydrogen atom. Molecules containing hydrogen atoms that can release hydrogen ions in a solution are called *acids*. An example is hydrochloric acid (HCl), which ionizes in water to form hydrogen ions (H^+) and chloride ions (Cl^-). Likewise, carbonic acid (H_2CO_3) ionizes in water to form H^+ and HCO_3^-.

A *base* is an ion or a molecule that can accept an H^+. For example, HCO_3^- is a base because it can combine with H^+ to form H_2CO_3. Likewise, HPO_4^{2-} is a base because it can accept an H^+ to form $H_2PO_4^-$. The proteins in the body also function as bases because some of the amino acids that make up proteins have net negative charges that readily accept H^+. The protein *hemoglobin* in the red blood cells and proteins in other cells of the body are among the most important of the body's bases.

The terms *base* and *alkali* are often used synonymously. An *alkali* is a molecule formed by the combination of one or more of the alkaline metals—such as sodium, potassium, and lithium—with a highly basic ion such as a hydroxyl ion (OH^-). The base portion of these molecules reacts quickly with H^+ to remove it from solution and are, therefore, typical bases. For similar reasons, the term *alkalosis* refers to the excess removal of H^+ from the body fluids, in contrast to the excess addition of H^+, which is referred to as *acidosis*.

Strong and Weak Acids and Bases. Strong acids, such as HCl, rapidly dissociate and release especially large amounts of H^+ in solution. Weak acids, such as H_2CO_3, are less likely to dissociate their ions and, therefore, release H^+ with less vigor. A strong base is one that reacts rapidly and strongly with H^+ and, therefore, quickly removes H^+ from a solution. A typical example is OH^-, which reacts with H^+ to form water (H_2O). A typical weak base is HCO_3^- because it binds with H^+ much more weakly than OH^-. Most acids and bases in the extracellular fluid that are involved in normal acid–base regulation are weak acids and bases. The most important ones that we discuss are carbonic acid (H_2CO_3) and HCO_3^- base.

Normal H^+ Concentration and pH of Body Fluids and Changes That Occur in Acidosis and Alkalosis. The blood H^+ concentration is usually maintained within tight limits around a normal value of about 0.00004 mEq/L (40 nEq/L). Normal variations are only about 3 to 5 nEq/L, but under extreme conditions, the H^+ concentration can vary from as low as 10 nEq/L to as high as 160 nEq/L without resulting in death.

Because H^+ concentration normally is low and because these small numbers are cumbersome, it is customary to express H^+ concentration on a logarithm scale using pH units. pH is related to the actual H^+ concentration by the following formula (H^+ concentration $[H^+]$ is expressed in *equivalents* per liter):

$$pH = \log \frac{1}{[H^+]} = -\log [H^+]$$

For example, normal $[H^+]$ is 40 nEq/L (0.00000004 Eq/L). Therefore, the normal pH is as follows:

$$pH = -\log[0.00000004]$$
$$pH = 7.4$$

From this formula, one can see that pH is inversely related to the H^+ concentration; therefore, a low pH corresponds to a high H^+ concentration, and a high pH corresponds to a low H^+ concentration.

The normal pH of arterial blood is 7.4, whereas the pH of venous blood and interstitial fluids is about 7.35 because of the extra amounts of carbon dioxide (CO_2) released from the tissues to form H_2CO_3 in these fluids (**Table 31.1**). Because the normal pH of arterial blood is 7.4, a person is considered to have *acidemia* when the pH falls significantly below this value and *alkalemia* when the pH rises above 7.4. The lower limit of pH at which a person can live more than a few hours is about 6.8, and the upper limit is about 8.0.

Intracellular pH usually is slightly lower than plasma pH because cell metabolism produces acid, especially H_2CO_3. Depending on the type of cells, the pH of intracellular fluid has been estimated to range between 6.0 and 7.4. Hypoxia of the tissues and poor blood flow to the tissues can cause acid accumulation and decreased intracellular pH. The terms *acidosis* and *alkalosis* describe the processes that lead to acidemia and alkalemia, respectively.

The pH of urine can range from 4.5 to 8.0, depending on the acid–base status of the extracellular fluid. As discussed later, the kidneys play a major role in correcting abnormalities of extracellular fluid H^+ concentration by excreting acids or bases at variable rates.

An extreme example of an acidic body fluid is the HCl secreted into the stomach by the *oxyntic (parietal)* cells of the stomach mucosa, as discussed in Chapter 65. The H^+ concentration in these cells is about 4 million times greater than the hydrogen concentration in blood, with a pH of 0.8. In the remainder of this chapter, we discuss the regulation of extracellular fluid H^+ concentration.

Table 31.1 pH and H^+ Concentration of Body Fluids

	H^+ Concentration (mEq/L)	pH
Extracellular Fluid		
• Arterial blood	4.0×10^{-5}	7.40
• Venous blood	4.5×10^{-5}	7.35
• Interstitial fluid	4.5×10^{-5}	7.35
Intracellular fluid	1×10^{-3} to 4×10^{-5}	6.0–7.4
Urine	3×10^{-2} to 1×10^{-5}	4.5–8.0
Gastric HCl	160	0.8

DEFENDING AGAINST CHANGES IN H^+ CONCENTRATION: BUFFERS, LUNGS, AND KIDNEYS

Three primary systems regulate H^+ concentration in the body fluids: (1) the *chemical acid–base buffer systems of the body fluids*, which immediately combine with an acid or a base to prevent excessive changes in H^+ concentration; (2) the *respiratory center*, which regulates the removal of CO_2 (and, therefore, H_2CO_3) from the extracellular fluid; and (3) the *kidneys*, which can excrete acidic or alkaline urine, thereby readjusting the extracellular fluid H^+ concentration toward normal during acidosis or alkalosis.

When there is a change in H^+ concentration, the *buffer systems* of the body fluids react within seconds to minimize these changes. Buffer systems do not eliminate H^+ from or add H^+ to the body but only keep them tied up until balance can be reestablished.

The second line of defense, the *respiratory system*, acts within a few minutes to eliminate CO_2 and, therefore, H_2CO_3 from the body.

These first two lines of defense keep the H^+ concentration from changing too much until the more slowly responding third line of defense, the *kidneys*, can eliminate the excess acid or base from the body. Although the kidneys are relatively slow to respond compared with the other defenses, over a period of hours to several days, they are by far the most powerful of the acid–base regulatory systems.

BUFFERING OF H^+ IN THE BODY FLUIDS

A buffer is any substance that can reversibly bind H^+. The general form of the buffering reaction is as follows:

$$\text{Buffer} + H^+ \rightleftharpoons H\ \text{Buffer}$$

In this example, a free H^+ combines with the buffer to form a weak acid (H buffer) that can either remain as an unassociated molecule or dissociate back to the buffer and H^+. When H^+ concentration increases, the reaction is forced to the right, and more H^+ binds to the buffer, as long as buffer is available. Conversely, when H^+ concentration decreases, the reaction shifts toward the left, and H^+ is released from the buffer. In this way, changes in H^+ concentration are minimized.

The importance of the body fluid buffers can be quickly realized if one considers the low concentration of H^+ in the body fluids and the relatively large amounts of acids produced by the body each day. About 80 milliequivalents of H^+ is ingested or produced each day by metabolism, whereas the H^+ concentration of the body fluids normally is only about 0.00004 mEq/L. Without buffering, the daily

production and ingestion of acids would rapidly cause lethal changes in the body fluid H^+ concentration.

The action of acid–base buffers can perhaps best be explained by considering the buffer system that is quantitatively the most important in the extracellular fluid—the bicarbonate buffer system.

BICARBONATE BUFFER SYSTEM

The bicarbonate buffer system consists of a water solution that contains two ingredients: (1) a weak acid, H_2CO_3; and (2) a bicarbonate salt, such as sodium bicarbonate ($NaHCO_3$).

H_2CO_3 is formed in the body by the reaction of CO_2 with H_2O:

$$CO_2 + H_2O \underset{}{\overset{\text{carbonic anhydrase}}{\rightleftharpoons}} H_2CO_3$$

This reaction is slow, and exceedingly small amounts of H_2CO_3 are formed unless the enzyme *carbonic anhydrase* is present. This enzyme is especially abundant in the walls of the lung alveoli, where CO_2 is released; carbonic anhydrase is also present in the epithelial cells of the renal tubules, where CO_2 reacts with H_2O to form H_2CO_3.

H_2CO_3 ionizes weakly to form small amounts of H^+ and HCO_3^-:

$$H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

The second component of the system, bicarbonate salt, occurs predominantly as $NaHCO_3$ in the extracellular fluid. $NaHCO_3$ ionizes almost completely to form HCO_3^- and Na^+, as follows:

$$NaHCO_3 \rightleftharpoons Na^+ + HCO_3^-$$

Now, putting the entire system together, we have the following:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + \underbrace{HCO_3^-}_{+\ Na^+}$$

Because of the weak dissociation of H_2CO_3, the H^+ concentration is extremely low.

When a strong acid such as HCl is added to the bicarbonate buffer solution, the increased H^+ released from the acid ($HCl \rightarrow H^+ + Cl^-$) is buffered by HCO_3^-:

$$\uparrow H^+ + HCO_3^- \rightarrow H_2CO_3 \rightarrow CO_2 + H_2O$$

As a result, more H_2CO_3 is formed, causing increased CO_2 and H_2O production. From these reactions, one can see that H^+ from the strong acid HCl reacts with HCO_3^- to form the very weak acid H_2CO_3, which in turn forms CO_2 and H_2O. The excess CO_2 greatly stimulates respiration, which eliminates CO_2 from the extracellular fluid.

The opposite reactions take place when a strong base, such as sodium hydroxide (NaOH), is added to the bicarbonate buffer solution.

$$NaOH + H_2CO_3 \rightarrow NaHCO_3 + H_2O$$

In this case, OH^- from the NaOH combines with H_2CO_3 to form additional HCO_3^-. Thus, the weak base $NaHCO_3$ replaces the strong base NaOH. At the same time, the concentration of H_2CO_3 decreases (because it reacts with NaOH), causing more CO_2 to combine with H_2O to replace H_2CO_3:

$$\begin{array}{ccccc} CO_2 + H_2O & \longrightarrow & H_2CO_3 & \longrightarrow & \uparrow HCO_3^- + H_2O \\ & & + & & + \\ & & NaOH & & Na \end{array}$$

The net result is a tendency for blood CO_2 levels to decrease, but decreased blood CO_2 inhibits respiration and decreases CO_2 expiration. The rise in blood HCO_3^- concentration that occurs is compensated for by increased renal excretion of HCO_3^-.

Quantitative Dynamics of the Bicarbonate Buffer System

All acids, including H_2CO_3, are ionized to some extent. From mass balance considerations, the concentrations of H^+ and HCO_3^- are proportional to the concentration of H_2CO_3:

$$H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

For any acid, the concentrations of its dissociated ions relative to the acid are defined by the *dissociation constant, K′*.

$$K' = \frac{H^+ \times HCO_3^-}{H_2CO_3} \quad (1)$$

This equation indicates that in an H_2CO_3 solution, the amount of free H^+ is equal to

$$H^+ = K' \times \frac{H_2CO_3}{HCO_3^-} \quad (2)$$

The concentration of undissociated H_2CO_3 cannot be measured in solution because it rapidly dissociates into CO_2 and H_2O or into H^+ and HCO_3^-. However, the CO_2 dissolved in the blood is directly proportional to the amount of undissociated H_2CO_3. Therefore, Equation 2 can be rewritten as follows:

$$H^+ = K \times \frac{CO_2}{HCO_3^-} \quad (3)$$

The dissociation constant (K) for Equation 3 is only about 1/400 of the dissociation constant (K′) of Eq. 2 because the proportionality ratio between H_2CO_3 and CO_2 is 1:400.

Equation 3 is written in terms of the total amount of CO_2 dissolved in solution. However, most clinical laboratories measure the blood CO_2 tension (P_{CO_2}) rather than the actual amount of CO_2. Fortunately, the amount of CO_2 in the blood is a linear function of P_{CO_2} multiplied by the solubility coefficient for CO_2; under physiological conditions, the solubility coefficient for CO_2 is 0.03 mmol/L per mm Hg at body temperature. This means that 0.03 mmol/L of CO_2 is present in the blood for each mm Hg P_{CO_2} measured. Therefore, Equation 3 can be rewritten as

$$H^+ = K \times \frac{(0.03 \times P_{CO_2})}{HCO_3^-} \quad (4)$$

Henderson-Hasselbalch Equation. As discussed earlier, it is customary to express the H^+ concentration in pH units rather than in actual concentrations. Recall that $pH = -\log H^+$.

The dissociation constant (pK) can be expressed in a similar manner.

$$pK = -\log K$$

Therefore, we can express the H^+ concentration in Equation 4 in pH units by taking the negative logarithm of that equation, which yields the following:

$$-\log H^+ = -\log K - \log \frac{(0.03 \times Pco_2)}{HCO_3^-} \quad (5)$$

Therefore,

$$pH = pK - \log \frac{(0.03 \times Pco_2)}{HCO_3^-} \quad (6)$$

Rather than work with a negative logarithm, we can change the sign of the logarithm and invert the numerator and denominator in the last term, using the law of logarithms, to yield the following:

$$pH = pK + \log \frac{HCO_3^-}{(0.03 \times Pco_2)} \quad (7)$$

For the bicarbonate buffer system, the pK is 6.1, and Equation 7 can be written as follows:

$$pH = 6.1 + \log \frac{HCO_3^-}{0.03 \times Pco_2} \quad (8)$$

Equation 8 is the Henderson-Hasselbalch equation that can be used to calculate the pH of a solution if the molar concentration of HCO_3^- and the Pco_2 are known.

From the Henderson-Hasselbalch equation, it is apparent that an increase in HCO_3^- concentration causes the pH to rise, shifting the acid–base balance toward alkalosis. An increase in Pco_2 causes the pH to decrease, shifting the acid–base balance toward acidosis.

The Henderson-Hasselbalch equation, in addition to defining the determinants of normal pH regulation and acid–base balance in the extracellular fluid, provides insight into the physiological control of the acid and base composition of the extracellular fluid. As discussed later, *HCO_3^- concentration is regulated mainly by the kidneys, whereas Pco_2 in extracellular fluid is controlled by the rate of respiration.* By increasing the rate of respiration, the lungs remove CO_2 from the plasma and, by decreasing respiration, the lungs elevate Pco_2. Normal physiological acid–base homeostasis results from the coordinated efforts of both the lungs and kidneys, and acid–base disorders occur when one or both of these control mechanisms are impaired, thus altering either the HCO_3^- concentration or Pco_2 of extracellular fluid.

When disturbances of acid–base balance result from a primary change in extracellular fluid HCO_3^- concentration, they are referred to as *metabolic* acid–base disorders. Therefore, acidosis caused by a primary decrease in HCO_3^- concentration is termed *metabolic acidosis*, whereas alkalosis caused by a primary increase in HCO_3^- concentration is called *metabolic alkalosis*. Acidosis caused by an increase in Pco_2 is called *respiratory acidosis*, whereas alkalosis caused by a decrease in Pco_2 is termed *respiratory alkalosis*.

Bicarbonate Buffer System Titration Curve. **Fig. 31.1** shows the changes in pH of the extracellular fluid when the ratio of HCO_3^- to CO_2 in extracellular fluid is altered.

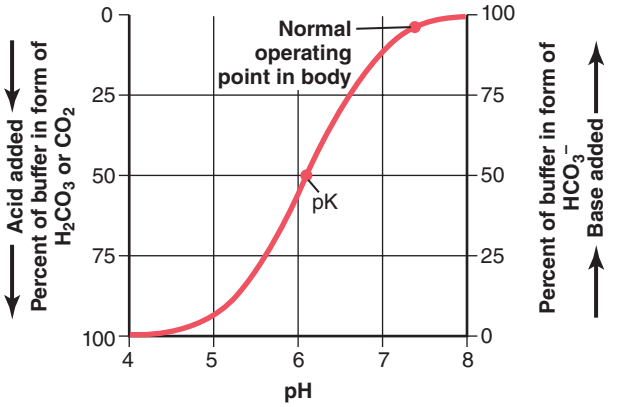

Figure 31.1 Titration curve for bicarbonate buffer system showing the pH of extracellular fluid when the percentages of buffer in the form of HCO_3^- and CO_2 (or H_2CO_3) are altered.

When the concentrations of these two components are equal, the right-hand portion of Equation 8 becomes the log of 1, which is equal to 0. Therefore, when the two components of the buffer system are equal, the pH of the solution is the same as the pK (6.1) of the bicarbonate buffer system. When base is added to the system, part of the dissolved CO_2 is converted into HCO_3^-, causing an increase in the ratio of HCO_3^- to CO_2 and increasing the pH, as is evident from the Henderson-Hasselbalch equation. When acid is added, it is buffered by HCO_3^-, which is then converted into dissolved CO_2, decreasing the ratio of HCO_3^- to CO_2 and decreasing the pH of the extracellular fluid.

Buffer Power Determined By Amount and Relative Concentrations of Buffer Components. From the titration curve in **Fig. 31.1**, several points are apparent. First, the pH of the system is the same as the pK when each of the components (HCO_3^- and CO_2) constitutes 50% of the total concentration of the buffer system. Second, the buffer system is most effective in the central part of the curve, where the pH is near the pK of the system. Thus, the change in pH for any given amount of acid or base added to the system is least when the pH is near the pK of the system. The buffer system is still reasonably effective for 1.0 pH unit on either side of the pK, which, for the bicarbonate buffer system, extends from a pH of about 5.1 to 7.1 units. Beyond these limits, the buffering power rapidly diminishes. And, when all the CO_2 has been converted into HCO_3^-, or when all the HCO_3^- has been converted into CO_2, the system has no more buffering power.

The absolute concentration of the buffers is also an important factor in determining the buffer power of a system. With low concentrations of the buffers, only a small amount of acid or base added to the solution changes the pH considerably.

Bicarbonate Buffer System Is the Most Important Extracellular Buffer. From the titration curve shown in **Fig. 31.1**, one might not expect the bicarbonate buffer system to be powerful, for two reasons. First, the pH of the extracellular fluid is about 7.4, whereas the pK of the bicarbonate buffer system is 6.1, which means that there is about 20 times as much of the bicarbonate buffer system in the form of HCO_3^- as in the form of dissolved CO_2. For this reason, this system operates on the portion of the buffering

curve where the slope is low, and the buffering power is poor. Second, the concentrations of the two elements of the bicarbonate system, CO_2 and HCO_3^-, are not high.

Despite these characteristics, the bicarbonate buffer system is the most powerful extracellular buffer in the body. This apparent paradox is due mainly to the fact that the two elements of the buffer system, HCO_3^- and CO_2, are regulated, respectively, by the kidneys and lungs, as discussed later. As a result of this regulation, the pH of the extracellular fluid can be precisely controlled by the relative rate of removal and addition of HCO_3^- by the kidneys and rate of removal of CO_2 by the lungs.

PHOSPHATE BUFFER SYSTEM

Although the phosphate buffer system is not a major extracellular fluid buffer, it plays an important role in buffering renal tubular fluid and intracellular fluids.

The main elements of the phosphate buffer system are $H_2PO_4^-$ and HPO_4^{2-}. When a strong acid such as HCl is added to a mixture of these two substances, the H^+ is accepted by the base HPO_4^{2-} and converted to $H_2PO_4^-$:

$$HCl + Na_2HPO_4 \rightarrow NaH_2PO_4 + NaCl$$

The result of this reaction is that the strong acid, HCl, is replaced by an additional amount of a weak acid, NaH_2PO_4, and the decrease in pH is minimized.

When a strong base, such as NaOH, is added to the buffer system, the OH^- is buffered by the $H_2PO_4^-$ to form additional amounts of $HPO_4^{2-} + H_2O$:

$$NaOH + NaH_2PO_4 \rightarrow Na_2HPO_4 + H_2O$$

In this case, a strong base, NaOH, is traded for a weak base, Na_2HPO_4, causing only a slight increase in pH.

The phosphate buffer system has a pK of 6.8, which is not far from the normal pH of 7.4 in the body fluids, allowing the system to operate near its maximum buffering power. However, its concentration in the extracellular fluid is low, at only about 8% of the concentration of the bicarbonate buffer. Therefore, the total buffering power of the phosphate system in the extracellular fluid is much less than that of the bicarbonate buffering system.

In contrast to its minor role as an extracellular buffer, *the phosphate buffer is especially important in the tubular fluids of the kidneys* for two reasons: (1) phosphate usually becomes greatly concentrated in the tubules, thereby increasing the buffering power of the phosphate system; and (2) the tubular fluid usually has a considerably lower pH than the extracellular fluid, bringing the operating range of the buffer closer to the pK (6.8) of the system.

The phosphate buffer system is also important in buffering intracellular fluid because the concentration of phosphate in this fluid is many times higher than in the extracellular fluid. Also, the pH of intracellular fluid is lower than that of extracellular fluid and, therefore, is usually closer to the pK of the phosphate buffer system compared with the extracellular fluid.

PROTEINS ARE IMPORTANT INTRACELLULAR BUFFERS

Proteins are among the most plentiful buffers in the body because of their high concentrations, especially in the cells. The pH of the cells, although slightly lower than in the extracellular fluid, nevertheless changes approximately in proportion to extracellular fluid pH changes. There is a slight diffusion of H^+ and HCO_3^- through the cell membrane, although these ions require several hours to reach equilibrium with the extracellular fluid, except for the rapid equilibrium that occurs in the red blood cells. CO_2, however, can rapidly diffuse through all the cell membranes.

This diffusion of the elements of the bicarbonate buffer system causes the pH in intracellular fluid to change when there are changes in extracellular pH. For this reason, the buffer systems in the cells help prevent changes in the pH of the extracellular fluid but may take several hours to become maximally effective.

In the red blood cell, hemoglobin (Hb) is an important buffer, as follows:

$$H^+ + Hb \rightleftharpoons HHb$$

Approximately 60% to 70% of the total chemical buffering of the body fluids is inside the cells, and most of this buffering results from the intracellular proteins. However, except for the red blood cells, the slow rate at which H^+ and HCO_3^- move through the cell membranes often delays the maximum ability of the intracellular proteins to buffer extracellular acid–base abnormalities for several hours.

In addition to the high concentration of proteins in the cells, another factor that contributes to their buffering power is the fact that the pKs of many of these protein systems are fairly close to intracellular pH.

Isohydric Principle: All Buffers in a Common Solution Are in Equilibrium With the Same H^+ Concentration

We have discussed buffer systems as though they operate individually in the body fluids. However, they all work together because H^+ is common to the reactions of all these systems. Therefore, whenever there is a change in H^+ concentration in the extracellular fluid, the balance of all the buffer systems changes at the same time. This phenomenon is called the *isohydric principle* and is illustrated by the following formula:

$$H^+ = K_1 \times \frac{HA_1}{A_1} = K_2 \times \frac{HA_2}{A_2} = K_3 \times \frac{HA_3}{A_3}$$

K_1, K_2, and K_3 are the dissociation constants of three respective acids—HA_1, HA_2, HA_3—and A_1, A_2, A_3 are the concentrations of the free negative ions that constitute the bases of the three buffer systems.

The implication of this principle is that any condition that changes the balance of one of the buffer systems also changes the balance of all the others because the buffer systems actually buffer one another by shifting H^+ back and forth between them.

RESPIRATORY REGULATION OF ACID–BASE BALANCE

The second line of defense against acid–base disturbances is control of extracellular fluid CO_2 concentration by the lungs. An increase in ventilation eliminates CO_2 from extracellular fluid, which, by mass action, reduces the H^+ concentration. Conversely, decreased ventilation increases CO_2 and H^+ concentrations in the extracellular fluid.

Pulmonary Expiration of CO_2 Balances Metabolic Formation of CO_2

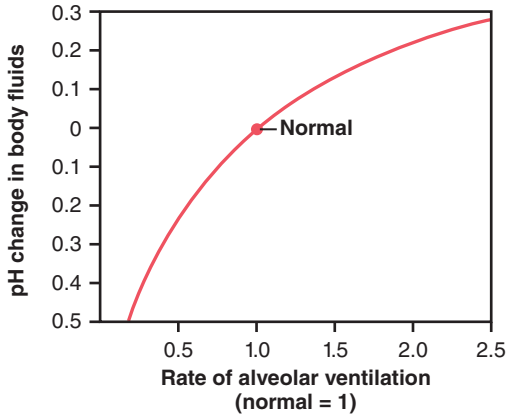
CO_2 is formed continually in the body by intracellular metabolic processes. After it is formed, it diffuses from the cells into the interstitial fluids and blood, and the flowing blood transports it to the lungs, where it diffuses into the alveoli and then is transferred to the atmosphere by pulmonary ventilation. About 1.2 mol/L of dissolved CO_2 is normally in the extracellular fluid, corresponding to a P_{CO_2} of 40 mm Hg.

If the rate of metabolic formation of CO_2 increases, the P_{CO_2} of the extracellular fluid is likewise increased. Conversely, decreased metabolic rate lowers the P_{CO_2}. If the rate of pulmonary ventilation is increased, CO_2 is blown off from the lungs and P_{CO_2} in the extracellular fluid decreases. Therefore, changes in pulmonary ventilation or the rate of CO_2 formation by the tissues can change the extracellular fluid P_{CO_2}.

Increasing Alveolar Ventilation Decreases Extracellular Fluid H^+ Concentration and Raises pH

If metabolic formation of CO_2 remains constant, the only other factor that affects P_{CO_2} in extracellular fluid is the rate of alveolar ventilation. The higher the alveolar ventilation, the lower the P_{CO_2}. When CO_2 concentration increases, the H_2CO_3 concentration and H^+ concentration also increase, thereby lowering extracellular fluid pH.

Fig. 31.2 shows the approximate changes in blood pH that are caused by increasing or decreasing alveolar ventilation rate. Note that increasing alveolar ventilation to about twice normal raises extracellular fluid pH by about 0.23. If pH of the body fluids is 7.40 with normal alveolar ventilation, doubling the ventilation rate raises the pH to about 7.63. Conversely, a decrease in alveolar ventilation to one-fourth normal reduces pH by 0.45. That is, if pH is 7.4 at a normal alveolar ventilation, reducing the ventilation to one-fourth normal reduces pH to 6.95. Because alveolar ventilation rate can change markedly, from as low as 0 to as high as 15 times normal, one can easily understand how much pH of the body fluids can be changed by the respiratory system.



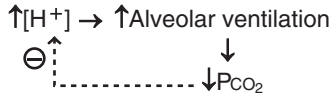


Figure 31.2 Change in extracellular fluid pH caused by an increased or decreased rate of alveolar ventilation, expressed as times normal.

Increased H^+ Concentration Stimulates Alveolar Ventilation

Not only does the alveolar ventilation rate influence H^+ concentration by changing P_{CO_2} of the body fluids, but H^+ concentration affects the rate of alveolar ventilation. Thus, **Fig. 31.3** shows that alveolar ventilation rate increases four to five times normal as pH decreases from the normal value of 7.4 to the strongly acidic value of 7.0. Conversely, a rise in plasma pH above 7.4 causes a decrease in ventilation rate. The change in ventilation rate per unit pH change is much greater at reduced levels of pH (corresponding to elevated H^+ concentration) compared with increased levels of pH. The reason for this is that as the alveolar ventilation rate decreases as a result of increased pH (decreased H^+ concentration), the amount of oxygen added to the blood decreases, and the partial pressure of oxygen (P_{O_2}) in the blood also decreases, which stimulates the ventilation rate. Therefore, the respiratory compensation for an increase in pH is not nearly as effective as the response to a marked reduction in pH.

Feedback Control of H^+ Concentration By the Respiratory System. Because increased H^+ concentration stimulates respiration and because increased alveolar ventilation decreases H^+ concentration, the respiratory system acts as a typical negative feedback controller of H^+ concentration:

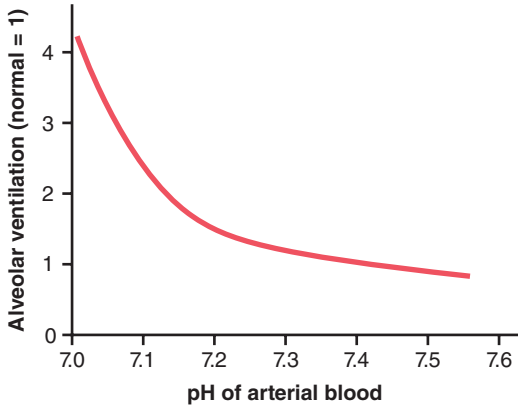

Figure 31.3 Effect of blood pH on the alveolar ventilation rate.

That is, whenever H^+ concentration increases above normal, the respiratory system is stimulated and alveolar ventilation increases. This mechanism decreases P_{CO_2} in extracellular fluid and reduces H^+ concentration back toward normal. Conversely, if H^+ concentration falls below normal, the respiratory center becomes depressed, alveolar ventilation decreases, and H^+ concentration increases back toward normal. Although alkalosis tends to depress the respiratory centers, the response is generally less robust and less predictable than the response to metabolic acidosis; the hypoxemia associated with reduced alveolar ventilation eventually activates oxygen-sensitive chemoreceptors that tend to stimulate ventilation and limit the respiratory compensation for metabolic alkalosis.

Efficiency of Respiratory Control of H^+ Concentration. Respiratory control cannot return H^+ concentration all the way back to normal when a disturbance outside the respiratory system has altered the pH. Ordinarily, the respiratory mechanism for controlling H^+ concentration is approximately 50% to 75% effective, corresponding to a *feedback gain* of 1 to 3 for metabolic acidosis. That is, if the pH is suddenly decreased by adding acid to the extracellular fluid, and the pH falls from 7.4 to 7.0, the respiratory system can return the pH to a value of about 7.2 to 7.3. This response occurs within 3 to 12 minutes. As discussed previously, the respiratory responses to metabolic alkalosis are rapid but limited by hypoxemia associated with reduced alveolar ventilation.

Buffering Power of the Respiratory System. *Respiratory regulation of acid–base balance is a physiological type of buffer system* because it acts rapidly and keeps the H^+ concentration from changing too much until the slowly responding kidneys can eliminate the imbalance. In general, the overall buffering power of the respiratory system is one to two times as great as the buffering power of all other chemical buffers in the extracellular fluid combined. That is, one to two times as much acid or base can normally be buffered by this mechanism as by the chemical buffers.

Impairment of Lung Function Can Cause Respiratory Acidosis. We have discussed thus far the role of the *normal* respiratory mechanism as a means of buffering changes in H^+ concentration. However, *abnormalities of respiration* can also cause changes in H^+ concentration. For example, an impairment of lung function, such as severe emphysema, decreases the ability of the lungs to eliminate CO_2, which causes a buildup of CO_2 in the extracellular fluid and a tendency toward *respiratory acidosis*. Also, the ability to respond to metabolic acidosis is impaired because the compensatory reductions in P_{CO_2} that would normally occur by means of increased ventilation are blunted. In these circumstances, the kidneys represent the sole remaining physiological mechanism for returning pH toward normal after the initial chemical buffering in the extracellular fluid has occurred.

RENAL CONTROL OF ACID–BASE BALANCE

The kidneys control acid–base balance by excreting acidic or basic urine. Excreting acidic urine reduces the amount of acid in extracellular fluid, whereas excreting basic urine removes base from the extracellular fluid.

The overall mechanism whereby the kidneys excrete acidic or basic urine is as follows. Large amounts of HCO_3^- are filtered continuously into the tubules and, if excreted into the urine, remove base from the blood. Large numbers of H^+ are also secreted into the tubular lumen by the tubular epithelial cells, thus removing acid from the blood. If more H^+ is secreted than HCO_3^- is filtered, there will be a net loss of acid from the extracellular fluid. Conversely, if more HCO_3^- is filtered than H^+ is secreted, there will be a net loss of base.

Each day, the body produces about 80 mEq of nonvolatile strong acids (e.g., sulfuric, phosphoric, hydrochloric), mainly from metabolism of proteins. These acids are called *nonvolatile* because they are not H_2CO_3 and, therefore, cannot be excreted by the lungs. The primary mechanism for removal of these acids from the body is renal excretion. These acids release H^+ that reacts mainly with HCO_3^- to form H_2CO_3, which dissociates to form H_2O and CO_2. This reaction buffers the strong acids but also decreases extracellular fluid HCO_3^-. However, the HCO_3^- is replenished when the renal tubules generate new HCO_3^- when H^+ is excreted in combination with renal tubular buffers (mainly NH_4^+ and $H_2PO_4^-$), as discussed later.

The kidneys must also prevent the loss of HCO_3^- in the urine, a task that is quantitatively more important than the excretion of nonvolatile acids. Each day, the kidneys filter about 4320 mEq of HCO_3^- (180 L/day × 24 mEq/L); under normal conditions, almost all of this is reabsorbed from the tubules, thereby conserving the primary buffer system of the extracellular fluid.

Both the reabsorption of HCO_3^- and excretion of H^+ are accomplished through H^+ secretion by the tubules. Because HCO_3^- must react with a secreted H^+ to form H_2CO_3 before it can be reabsorbed, 4320 mEq of H^+ must be secreted each day just to reabsorb the filtered HCO_3^-. Then, an additional 80 mEq of H^+ must be secreted to rid the body of the nonvolatile acids produced each day for a total of 4400 mEq of H^+ secreted into the tubular fluid each day.

When there is a reduction in extracellular fluid H^+ concentration (alkalosis), the kidneys usually secrete less H^+ and fail to reabsorb all the filtered HCO_3^-, thereby increasing excretion of HCO_3^-. Because HCO_3^- normally buffers H^+ in the extracellular fluid, this loss of HCO_3^- has the same effect as adding a H^+ to the extracellular fluid. Therefore, in alkalosis, removal of HCO_3^- raises extracellular fluid H^+ concentration back toward normal.

In acidosis, the kidneys secrete additional H^+ and do not excrete HCO_3^- into the urine but reabsorb all the

filtered HCO_3^- and produce new HCO_3^-, which is added back to the extracellular fluid. This action reduces extracellular fluid H^+ concentration back toward normal.

Thus, the kidneys regulate extracellular fluid H^+ concentration through three fundamental mechanisms: (1) secretion of H^+; (2) reabsorption of filtered HCO_3^-; and (3) production of new HCO_3^-. All these processes are accomplished through the same basic mechanisms, as discussed in the next few sections.

SECRETION OF H^+ AND REABSORPTION OF HCO_3^- BY THE RENAL TUBULES

Hydrogen ion secretion and HCO_3^- reabsorption occur in virtually all parts of the tubules except the descending and ascending thin limbs of the loop of Henle. **Fig. 31.4** summarizes HCO_3^- reabsorption along the tubule. Keep in mind that for *each HCO_3^- reabsorbed, a H^+ must be secreted.*

About 80% to 90% of the HCO_3^- reabsorption (and H^+ secretion) occurs in the proximal tubule, so only a small amount of HCO_3^- flows into the distal tubules and collecting ducts. In the thick ascending loop of Henle, another 10% of the filtered HCO_3^- is reabsorbed, and the remainder of the reabsorption takes place in the distal tubules and collecting ducts. As discussed previously, the mechanism whereby HCO_3^- is reabsorbed also involves tubular secretion of H^+, but different tubular segments accomplish this task differently.

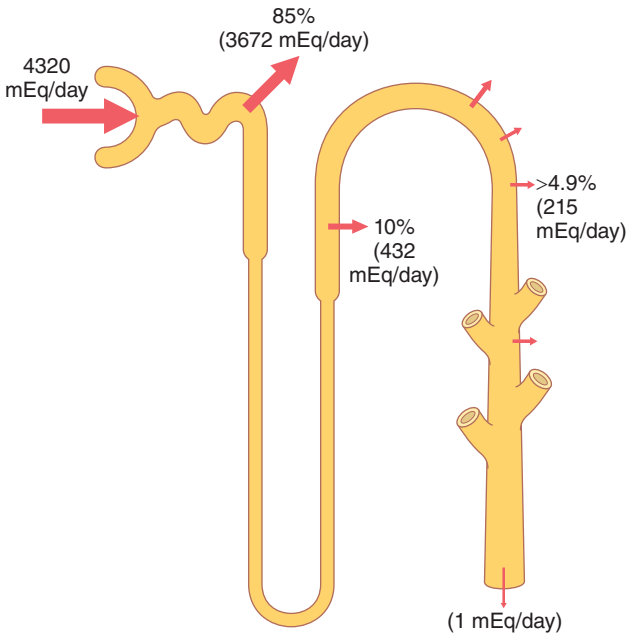

Figure 31.4 Reabsorption of HCO_3^- in different segments of the renal tubule. The percentages of the filtered load of HCO_3^- absorbed by the various tubular segments are shown, as well as the number of milliequivalents reabsorbed per day under normal conditions.

H^+ Is Secreted Mainly By Secondary Active Transport in Early Tubular Segments

The epithelial cells of the proximal tubule, the thick segment of the ascending loop of Henle, and the early distal tubule all secrete H^+ into the tubular fluid by Na^+-H^+ counter-transport, as shown in **Fig. 31.5**. This secondary active secretion of H^+ is coupled with transport of Na^+ into the cell at the luminal membrane by the *sodium-hydrogen exchanger protein*, and the energy for H^+ secretion against a concentration gradient is derived from the sodium gradient, favoring Na^+ movement into the cell. This gradient is established by the sodium-potassium adenosine triphosphatase (Na^+-K^+ ATPase) pump in the basolateral membrane. About 95% of the HCO_3^- is reabsorbed in this manner, requiring about 4000 mEq of H^+ to be secreted each day by the tubules. This mechanism, however, can establish a minimum pH of only about 6.7; the tubular fluid becomes very acidic only in the collecting tubules and collecting ducts, which can establish a urine pH as low as about 4.5.

The proximal tubule epithelial cells also secrete a smaller amount of H^+ by a *hydrogen-transporting ATPase* (*H^+-ATPase*) located on the luminal membrane. However, this H^+ pump accounts for only a small percentage of the H^+ secretion in the proximal tubules.

Fig. 31.5 shows how the process of H^+ secretion achieves HCO_3^- reabsorption. The secretory process begins when CO_2 either diffuses into the tubular cells or is formed by metabolism in the tubular epithelial cells. Under the influence of the enzyme *carbonic anhydrase*, CO_2 combines with H_2O to form H_2CO_3, which dissociates into HCO_3^- and H^+. The H^+ is secreted from the cell into the tubular lumen by Na^+-H^+ counter-transport and the H^+-ATPase pump. The HCO_3^- generated in the cell (when H^+ dissociates from H_2CO_3) is transported across the basolateral membrane, into the renal interstitial fluid

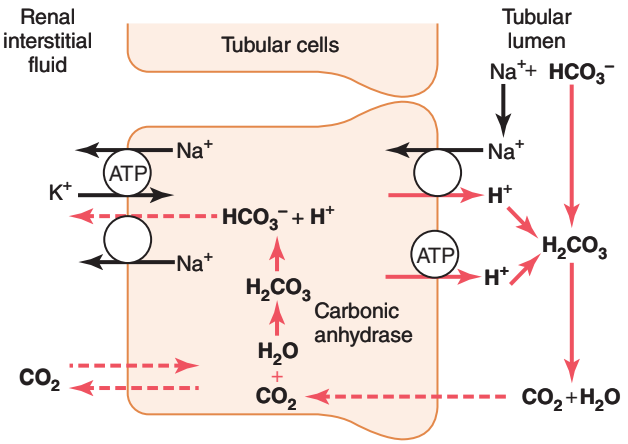

Figure 31.5 Shown are the cellular mechanisms for the following: (1) active secretion of H^+ into the renal tubule; (2) tubular reabsorption of HCO_3^- by combination with H^+ to form H_2CO_3, which dissociates to form CO_2 and H_2O; and (3) Na^+ reabsorption in exchange for H^+ secreted. This pattern of H^+ secretion occurs in the proximal tubule, thick ascending segment of the loop of Henle, and early distal tubule.

and peritubular capillary blood. The net result is that for every H^+ secreted into the tubular lumen, a HCO_3^- enters the blood.

Filtered HCO_3^- Is Reabsorbed By Interaction with H^+ in the Tubules

Bicarbonate ions do not readily permeate the luminal membranes of the renal tubular cells; therefore, HCO_3^- that is filtered by the glomerulus cannot be directly reabsorbed. Instead, HCO_3^- is reabsorbed by a special process in which it first combines with H^+ to form H_2CO_3, which eventually becomes CO_2 and H_2O, as shown in **Fig. 31.5**.

This reabsorption of HCO_3^- is initiated by a reaction in the tubules between HCO_3^- filtered at the glomerulus and H^+ secreted by the tubular cells. The H_2CO_3 formed then dissociates into CO_2 and H_2O. The CO_2 can move easily across the tubular membrane; therefore, it instantly diffuses into the tubular cell, where it recombines with H_2O, under the influence of carbonic anhydrase, to generate a new H_2CO_3 molecule. This H_2CO_3 dissociates to form HCO_3^- and H^+; the HCO_3^- is then transported through the basolateral membrane into the interstitial fluid and is taken up into the peritubular capillary blood. The transport of HCO_3^- across the basolateral membrane is facilitated by two mechanisms: (1) Na^+-HCO_3^- co-transport in the proximal tubules; and (2) Cl^--HCO_3^- exchange in the late segments of the proximal tubule, thick ascending loop of Henle, and collecting tubules and ducts.

Thus, each time a H^+ is formed in the tubular epithelial cells, a HCO_3^- is also formed and released back into the blood. The net effect of these reactions is "reabsorption" of HCO_3^- from the tubules, although the HCO_3^- that actually enters the extracellular fluid is not the same as that filtered into the tubules. The reabsorption of filtered HCO_3^- does not result in net secretion of H^+ because the secreted H^+ combines with the filtered HCO_3^- and is therefore not excreted.

HCO_3^- Is Titrated Against H^+ in the Tubules. Under normal conditions, the rate of tubular H^+ secretion is about 4400 mEq/day, and the rate of filtration by HCO_3^- is about 4320 mEq/day. Thus, the quantities of these two ions entering the tubules are almost equal, and they combine with each other to form CO_2 and H_2O. Therefore, HCO_3^- and H^+ normally "titrate" each other in the tubules.

The titration process is not quite exact because there is usually a slight excess of H^+ in the tubules to be excreted in the urine. This excess H^+ (~80 mEq/day) rids the body of nonvolatile acids produced by metabolism. As discussed later, most of this H^+ is not excreted as free H^+ but is in combination with other urinary buffers, especially phosphate and ammonia.

When there is an excess of HCO_3^- over H^+ in the urine, as occurs in metabolic alkalosis, the excess HCO_3^- cannot be reabsorbed. Therefore, the excess HCO_3^- remains in the tubules to be excreted into the urine, which helps correct the metabolic alkalosis.

In acidosis, there is excess H^+ relative to HCO_3^- in the tubules, causing complete reabsorption of the HCO_3^-; the excess H^+ passes into the urine in combination with urinary buffers, especially phosphate and ammonia, and eventually is excreted as salts. Thus, the basic mechanism whereby the kidneys correct acidosis or alkalosis is incomplete titration of H^+ against HCO_3^-, leaving one or the other to pass into the urine and be removed from the extracellular fluid.

Primary Active Secretion of H^+ in the Intercalated Cells of Late Distal and Collecting Tubules

Beginning in the late distal tubules and continuing through the remainder of the tubular system, the tubular epithelium secretes H^+ by *primary active transport*. The mechanism for primary active H^+ secretion was discussed in Chapter 28 and is shown in **Fig. 31.6**. It occurs at the luminal membrane of the tubular cell, where H^+ is transported directly by specific proteins, a *H^+-ATPase* and a *hydrogen-potassium-ATPase* (*H^+-K^+-ATPase*) *transporter*. The energy required for pumping the H^+ is derived from the breakdown of ATP to adenosine diphosphate.

Primary active secretion of H^+ occurs in special types of cells called the *type A intercalated cells* of the late distal tubules and collecting tubules. Hydrogen ion secretion in these cells is accomplished in two steps: (1) the dissolved CO_2 in this cell combines with H_2O to form H_2CO_3; (2) the H_2CO_3 then dissociates into HCO_3^-, which is reabsorbed into the blood, plus H^+, which is secreted into the tubule by means of the H^+-ATPase and the H^+-K^+-ATPase transporters. For each H^+ secreted, a HCO_3^- is reabsorbed, similar to the process in the proximal tubules. The main difference is that H^+ moves across the luminal

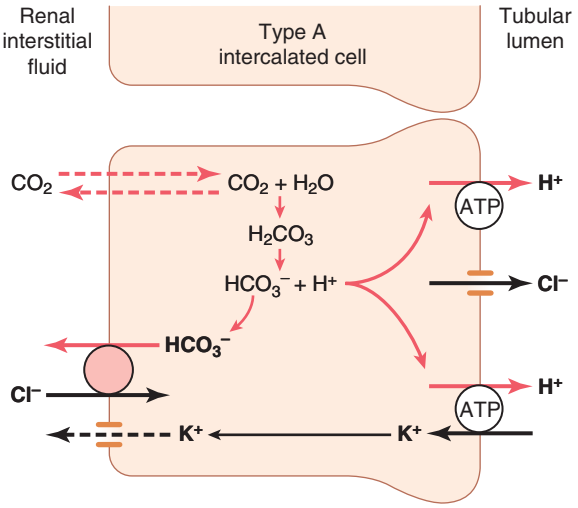

Figure 31.6 Active secretion of H^+ through the luminal membrane of the type A intercalated epithelial cells of the late distal and collecting tubules. Type A cells contain hydrogen–adenosine triphosphatase (ATPase) and hydrogen-potassium-ATPase in the luminal membrane and secrete H^+ while reabsorbing HCO_3^- and K^+ in acidosis. Note that one HCO_3^- is reabsorbed for each H^+ secreted, and one Cl^- is passively secreted along with H^+.

membrane by an active H^+ pump instead of mainly by counter-transport, as occurs in the early parts of the nephron.

Although secretion of H^+ in the late distal tubules and collecting tubules accounts for only about 5% of the total H^+ secreted, this mechanism is important in forming maximally acidic urine. Although large *amounts* of H^+ are secreted in the proximal tubules, H^+ concentration can be increased only about 3-fold to 4-fold and the tubular fluid pH can be reduced to only about 6.7 by this nephron segment. However, H^+ concentration can be increased as much as 900-fold in the collecting tubules. This mechanism decreases the pH of the tubular fluid to about 4.5, which is the lower limit of pH that can be achieved in normal kidneys.

COMBINATION OF EXCESS H^+ WITH PHOSPHATE AND AMMONIA BUFFERS IN THE TUBULE GENERATES "NEW" HCO_3^-

When H^+ is secreted in excess of the HCO_3^- filtered into the tubular fluid, only a small part of the excess H^+ can be excreted in the ionic form in the urine. This is because the minimal urine pH is about 4.5, corresponding to an H^+ concentration of $10^{-4.5}$ mEq/L, or 0.03 mEq/L. Thus, for each liter of urine formed, a maximum of only about 0.03 mEq of free H^+ can be excreted. To excrete the 80 mEq of nonvolatile acid formed by metabolism each day, about 2667 liters of urine would have to be excreted if the H^+ remained free in solution.

The excretion of large amounts of H^+ (on occasion as much as 500 mEq/day) in the urine is accomplished primarily by combining H^+ with buffers in the tubular fluid. The most important buffers are phosphate buffer and ammonia buffer. Other weak buffer systems, such as urate and citrate, are much less important.

When H^+ is titrated in the tubular fluid with HCO_3^-, this leads to reabsorption of one HCO_3^- for each H^+ secreted, as discussed earlier. However, when there is excess H^+ in the tubular fluid, it combines with buffers other than HCO_3^-, and this leads to generation of new HCO_3^- that can also enter the blood. Thus, when there is excess H^+ in the extracellular fluid, the kidneys not only reabsorb all the filtered HCO_3^- but also generate new HCO_3^-, thereby helping replenish the HCO_3^- lost from the extracellular fluid in acidosis. In the next two sections, we discuss the mechanisms whereby phosphate and ammonia buffers contribute to generation of new HCO_3^-.

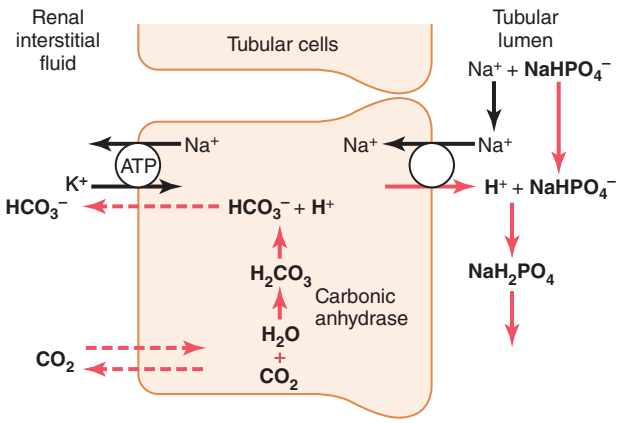

Figure 31.7 Buffering of secreted H^+ by filtered phosphate ($NaHPO_4^-$). Note that a new HCO_3^- is returned to the blood for each $NaHPO_4^-$ that reacts with a secreted H^+.

Phosphate Buffer System Carries Excess H^+ Into the Urine and Generates New HCO_3^-

The phosphate buffer system is composed of HPO_4^{2-} as the proton acceptor (base) and $H_2PO_4^-$ as the proton donor (acid). Both become concentrated in the tubular fluid because water is normally reabsorbed to a greater extent than phosphate by the renal tubules. Therefore, although phosphate is not an important extracellular fluid buffer, it is much more effective as a buffer in the tubular fluid.

Another factor that makes phosphate important as a tubular buffer is the fact that the pK of this system is about 6.8. Under normal conditions, the urine is slightly acidic, and the urine pH is near the pK of the phosphate buffer system. Therefore, in the tubules, the phosphate buffer system normally functions near its most effective pH range.

Fig. 31.7 shows the sequence of events whereby H^+ is excreted in combination with phosphate buffer and the mechanism whereby new HCO_3^- is added to the blood. The process of H^+ secretion into the tubules is the same as described earlier. As long as there is excess HCO_3^- in the tubular fluid, most of the secreted H^+ combines with HCO_3^-. However, once all the HCO_3^- has been reabsorbed and is no longer available to combine with H^+, any excess H^+ can combine with HPO_4^{2-} and other tubular buffers. After the H^+ combines with HPO_4^{2-} to form $H_2PO_4^-$, it can be excreted as a sodium salt (NaH_2PO_4), carrying with it the excess H^+.

There is one important difference in this sequence of H^+ excretion from that discussed previously. In this case, the HCO_3^- that is generated in the tubular cell and enters the peritubular blood represents a net gain of HCO_3^- by the blood, rather than merely a replacement of filtered HCO_3^-. *Therefore, whenever a H^+ secreted into the tubular lumen combines with a buffer other than HCO_3^-, the net effect is the addition of a new HCO_3^- to the blood.* This process demonstrates one of the mechanisms whereby the kidneys can replenish the extracellular fluid stores of HCO_3^-.

Under normal conditions, much of the filtered phosphate is reabsorbed, and only 30 to 40 mEq/day are available for buffering H^+. Therefore, much of the buffering of excess H^+ in the tubular fluid in acidosis occurs through the ammonia buffer system.

Excretion of Excess H^+ and Generation of New HCO_3^- By Ammonia Buffer System

A second buffer system in the tubular fluid that is even more important quantitatively than the phosphate buffer system is composed of ammonia (NH_3) and the ammonium ion (NH_4^+). Ammonium ion is synthesized from glutamine, which comes mainly from metabolism of amino acids in the liver. The glutamine delivered to the kidneys is transported into epithelial cells of the proximal tubules, thick ascending limb of the loop of Henle, and distal tubules (**Fig. 31.8**). Once inside the cell, each molecule of glutamine is metabolized in a series of reactions to ultimately form two NH_4^+ and two HCO_3^-. The NH_4^+ is secreted into the tubular lumen by a counter-transport mechanism in exchange for sodium, which is reabsorbed. The HCO_3^- is transported across the basolateral membrane, along with the reabsorbed Na^+, into the interstitial fluid and is taken up by the peritubular capillaries. Thus, for each molecule of glutamine metabolized in the proximal tubules, two NH_4^+ are secreted into the urine and two HCO_3^- are reabsorbed into the blood. *The HCO_3^- generated by this process constitutes new HCO_3^-.*

In the collecting tubules, the addition of NH_4^+ to the tubular fluid occurs through a different mechanism (**Fig. 31.9**). Here, H^+ is actively secreted by the tubular membrane into the lumen, where it combines with NH_3 to form NH_4^+, which is then excreted. The collecting ducts are permeable to NH_3, which can easily diffuse into the tubular lumen. However, the luminal membrane of this part of the tubules is much less permeable to NH_4^+; therefore, once the H^+ has reacted with NH_3 to form NH_4^+, the NH_4^+ is trapped in the tubular lumen and eliminated in the urine. *For each NH_4^+ excreted, a new HCO_3^- is generated and added to the blood.*

Chronic Acidosis Increases NH_4^+ Excretion. One of the most important features of the renal ammonium-ammonia buffer system is that it is subject to physiological control. An increase in extracellular fluid H^+ concentration stimulates renal glutamine metabolism and, therefore, increases formation of NH_4^+ and new HCO_3^- to be used in H^+ buffering; a decrease in H^+ concentration has the opposite effect.

Under *normal conditions*, the amount of H^+ eliminated by the ammonia buffer system accounts for 30% to 50% of the acid excreted and 30% to 50% of the new HCO_3^- generated by the kidneys. However, with *chronic acidosis the dominant mechanism for acid elimination is excretion of NH_4^+* (**Fig. 31.10**), which can increase to as

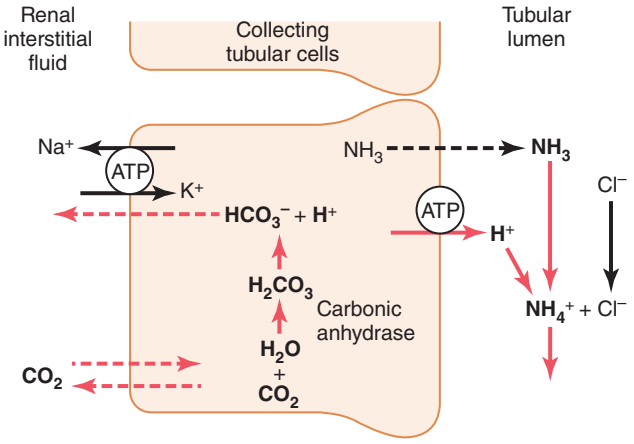

Figure 31.9 Buffering of H^+ secretion by ammonia (NH_3) in the collecting tubules. NH_3 diffuses into the tubular lumen, where it reacts with secreted H^+ to form NH_4^+, which is then excreted. For each NH_4^+ excreted, a new HCO_3^- is formed in the tubular cells and returned to the blood.

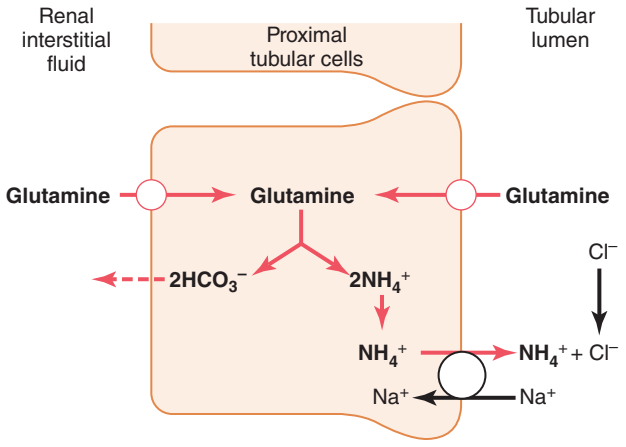

Figure 31.8 Production and secretion of ammonium ion (NH_4^+) by proximal tubular cells. Glutamine is metabolized in the cell, yielding NH_4^+ and HCO_3^-. The NH_4^+ is secreted into the lumen by a Na^+-NH_4^+ exchanger. For each glutamine molecule metabolized, two NH_4^+ are produced and secreted, and two HCO_3^- are returned to the blood.

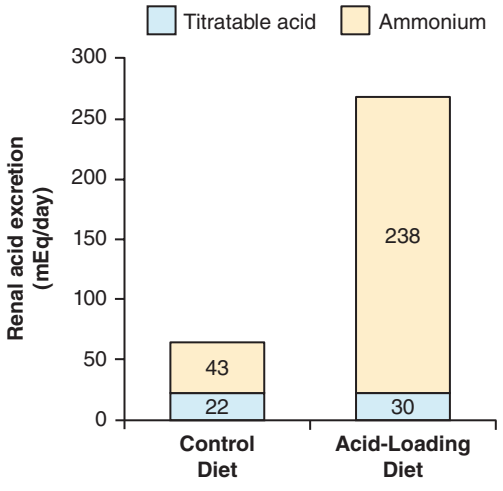

Figure 31.10 Relative importance of renal urinary titratable acid and ammonium excretion in net acid excretion; healthy adults were placed on a normal control diet or an acid-loading diet for at least 12 days. *(Data from Lemann Jr. J, Bushinsky DA, Hamm LL. Bone buffering of acid and base in humans.* Am J Physiol Renal Physiol. *2003;285:F811-F832.)*

high as 500 mEq/day. This process also provides the most important mechanism for generating new HCO_3^- during chronic acidosis.

QUANTIFYING RENAL ACID–BASE EXCRETION

Based on the principles discussed earlier, we can quantify the kidneys' net excretion of acid or net addition or elimination of HCO_3^- from the blood as follows.

Bicarbonate excretion is calculated as urine flow rate multiplied by the urinary HCO_3^- concentration and indicates how rapidly the kidneys are removing HCO_3^- from the blood, which is the same as adding an H^+ to the blood. In alkalosis, the increased excretion of HCO_3^- helps return the plasma pH toward normal.

The amount of new HCO_3^- contributed to the blood at any given time is equal to the amount of H^+ secreted that ends up in the tubular lumen with nonbicarbonate urinary buffers. As discussed previously, the primary sources of nonbicarbonate urinary buffers are NH_4^+ and phosphate. Therefore, part of the HCO_3^- added to the blood (and H^+ excreted by NH_4^+) is calculated by measuring NH_4^+ excretion (urine flow rate multiplied by urinary NH_4^+ concentration).

The rest of the nonbicarbonate, non-NH_4^+ buffer excreted in the urine is measured by determining a value known as *titratable acid*. The amount of titratable acid in the urine is measured by titrating the urine with a strong base, such as NaOH, to a pH of 7.4, the pH of normal plasma and the pH of the glomerular filtrate. This titration reverses the events that occurred in the tubular lumen when the tubular fluid was titrated by secreted H^+. Therefore, the number of milliequivalents of NaOH required to return the urinary pH to 7.4 equals the number of milliequivalents of H^+ added to the tubular fluid that combined with phosphate and other organic buffers. The titratable acid measurement does not include H^+ in association with NH_4^+ because the pK of the ammonia-ammonium reaction is 9.2, and titration with NaOH to a pH of 7.4 does not remove the H^+ from NH_4^+.

Thus, the *net acid excretion* by the kidneys can be assessed as follows:

$$\text{Net acid excretion} = NH_4^+ \text{ excretion} + \text{Urinary titratable acid} - HCO_3^- \text{ excretion}$$

The reason we subtract HCO_3^- excretion is that the loss of HCO_3^- is the same as the addition of H^+ to the blood. To maintain acid–base balance, the net acid excretion must equal the nonvolatile acid production in the body.

In acidosis, the net acid excretion increases markedly, especially because of increased NH_4^+ excretion, thereby removing acid from the blood. The net acid excretion also equals the rate of net HCO_3^- addition to the blood. *Therefore, in acidosis, the kidneys compensate with a net addition of HCO_3^- back to the blood as more NH_4^+ and urinary titratable acid are excreted.*

In alkalosis, titratable acid and NH_4^+ excretion drop to 0, whereas HCO_3^- excretion increases. *Therefore, in alkalosis, there is a negative net acid secretion*, which means that there is a net loss of HCO_3^- from the blood, which is the same as adding H^+ to the blood, and that no new HCO_3^- is generated by the kidneys.

REGULATION OF RENAL TUBULAR H^+ SECRETION

As discussed earlier, H^+ secretion by the tubular epithelium is necessary for HCO_3^- reabsorption and generation of new HCO_3^- associated with titratable acid formation and NH_4^+ excretion. Therefore, the rate of H^+ secretion must be carefully regulated if the kidneys are to perform their functions in acid–base homeostasis effectively. Under normal conditions, the kidney tubules must secrete at least enough H^+ to reabsorb almost all the HCO_3^- that is filtered, and there must be enough H^+ left over to be excreted as titratable acid or NH_4^+ to rid the body of the nonvolatile acids produced each day from metabolism.

In alkalosis, the tubular secretion of H^+ is reduced to a level that is too low to achieve complete HCO_3^- reabsorption, enabling the kidneys to increase HCO_3^- excretion. Titratable acid and ammonia are not excreted in alkalosis because there is no excess H^+ available to combine with nonbicarbonate buffers; therefore, no new HCO_3^- is added to the blood in alkalosis.

During acidosis, the tubular H^+ secretion is increased sufficiently to reabsorb all the filtered HCO_3^-, with enough H^+ left over to excrete large amounts of NH_4^+ and titratable acid, thereby contributing large amounts of new HCO_3^- to the total body extracellular fluid. *The most important stimuli for increasing H^+ secretion by the tubules in acidosis are as follows: (1) an increase in P_{CO_2} of the extracellular fluid in respiratory acidosis; (2) an increase in H^+ concentration of the extracellular fluid (decreased pH) in respiratory or metabolic acidosis.*

The tubular cells respond directly to an increase in P_{CO_2} of the blood, as in respiratory acidosis, with an increase in the rate of H^+ secretion. The increased P_{CO_2} raises the P_{CO_2} of the tubular cells, causing increased formation of H^+ in the tubular cells, which in turn stimulates secretion of H^+. The second factor that stimulates H^+ secretion is an increase in extracellular fluid H^+ concentration (decreased pH).

Another factor that can increase H^+ secretion under some pathophysiological conditions is excessive aldosterone secretion. Aldosterone stimulates secretion of H^+ by type A intercalated cells of the collecting tubules and ducts. Therefore, excessive secretion of aldosterone,

as occurs in persons with Conn syndrome, increases secretion of H^+ into the tubular fluid and, consequently, increases the amount of HCO_3^- added back to the blood. This action usually causes alkalosis in patients with excessive aldosterone secretion.

The tubular cells usually respond to a decrease in H^+ concentration (alkalosis) by reducing H^+ secretion. The decreased H^+ secretion results from decreased extracellular P_{CO_2}, as in respiratory alkalosis, or from a decrease in H^+ concentration, as in both respiratory and metabolic alkalosis.

Table 31.2 summarizes the major factors that influence H^+ secretion and HCO_3^- reabsorption. Some of these factors are not directly related to the regulation of acid–base balance. For example, H^+ secretion is coupled to Na^+ reabsorption by the Na^+-H^+ exchanger in the proximal tubule and the thick ascending loop of Henle. Therefore, factors that stimulate Na^+ reabsorption, such as decreased extracellular fluid volume and increased angiotensin II (Ang II), may also secondarily increase H^+ secretion and HCO_3^- reabsorption.

Extracellular fluid volume depletion stimulates sodium reabsorption by the renal tubules and increases H^+ secretion and HCO_3^- reabsorption through multiple mechanisms, including the following: (1) increased Ang II, which directly stimulates activity of the Na^+-H^+ exchanger in the renal tubules; (2) increased aldosterone, which stimulates H^+ secretion by the intercalated cells of the cortical collecting tubules. Therefore, extracellular fluid volume depletion tends to cause alkalosis due to excess H^+ secretion and HCO_3^- reabsorption.

Changes in plasma potassium concentration can also influence H^+ secretion, with hypokalemia stimulating and hyperkalemia inhibiting H^+ secretion in the proximal tubule. Decreased plasma potassium concentration tends to increase H^+ concentration in the renal tubular cells. This, in turn, stimulates H^+ secretion and HCO_3^- reabsorption and leads to alkalosis. Hyperkalemia decreases H^+ secretion and HCO_3^- reabsorption and tends to cause acidosis.

Table 31.2 Plasma or Extracellular Fluid Factors That Increase or Decrease H^+ Secretion and HCO_3^- Reabsorption by the Renal Tubules

Increase H^+ Secretion and HCO_3^- Reabsorption	Decrease H^+ Secretion and HCO_3^- Reabsorption
↑P_{CO_2}	↓P_{CO_2}
↑H^+, ↓HCO_3^-	↓H^+, ↑HCO_3^-
↓Extracellular fluid volume	↑Extracellular fluid volume
↑Angiotensin II	↓Angiotensin II
↑Aldosterone	↓Aldosterone
Hypokalemia	Hyperkalemia

RENAL CORRECTION OF ACIDOSIS—INCREASED EXCRETION OF H^+ AND ADDITION OF HCO_3^- TO THE EXTRACELLULAR FLUID

Referring to Eq. 8, the Henderson-Hasselbalch equation, we can see that acidosis occurs when the ratio of HCO_3^- to CO_2 in the extracellular fluid decreases, thereby decreasing the pH. If this ratio decreases because of a fall in HCO_3^-, the acidosis is referred to as *metabolic acidosis*. If the pH falls because of an increase in P_{CO_2}, the acidosis is referred to as *respiratory acidosis*.

Acidosis Decreases HCO_3^-/H^+ Ratio in Renal Tubular Fluid

Respiratory and metabolic acidosis both cause a decrease in the ratio of HCO_3^-/H^+ in the renal tubular fluid. As a result, there is excess H^+ in the renal tubules, causing complete reabsorption of HCO_3^- and still leaving additional H^+ available to combine with the urinary buffers NH_4^+ and HPO_4^{2-}. Thus, in acidosis, the kidneys reabsorb all the filtered HCO_3^- and contribute new HCO_3^- through formation of NH_4^+ and titratable acid.

In metabolic acidosis, an excess of H^+ over HCO_3^- occurs in the tubular fluid, primarily because of decreased extracellular fluid concentration of HCO_3^- and therefore decreased glomerular filtration of HCO_3^-.

In respiratory acidosis, the excess H^+ in the tubular fluid is due mainly to the rise in extracellular fluid P_{CO_2}, which stimulates H^+ secretion.

With chronic acidosis, regardless of whether it is respiratory or metabolic, there is increased production of NH_4^+, which further contributes to excretion of H^+ and addition of new HCO_3^- to the extracellular fluid. With severe chronic acidosis, as much as 500 mEq/day of H^+ can be excreted in the urine, mainly in the form of NH_4^+; this excretion, in turn, contributes up to 500 mEq/day of new HCO_3^- that is added to the blood.

Thus, with chronic acidosis, increased secretion of H^+ by the tubules helps eliminate excess H^+ from the body and increases the quantity of HCO_3^- in the extracellular fluid. This process increases the HCO_3^- part of the bicarbonate buffer system, which, in accordance with the Henderson-Hasselbalch equation, helps raise the extracellular pH and corrects the acidosis. If the acidosis is metabolically mediated, additional compensation by the lungs causes a reduction in P_{CO_2}, also helping correct the acidosis.

Table 31.3 summarizes the extracellular fluid characteristics associated with respiratory and metabolic acidosis, as well as respiratory and metabolic alkalosis, discussed in the next section. Note that in *respiratory acidosis*, there is a reduction in pH, an increase in extracellular fluid H^+ concentration, and an increase in P_{CO_2}, which is the initial cause of the acidosis. *The compensatory response is increased plasma* HCO_3^-,

Table 31.3 Extracellular Fluid Characteristics of Primary Acid–Base Disturbances[a]

	pH	H^+	P_{CO_2}	HCO_3^-
Normal	7.4	40 nEq/L	40 mm Hg	24 mEq/L
Respiratory acidosis	↓	↑	↑↑	↑
Respiratory alkalosis	↑	↓	↓↓	↓
Metabolic acidosis	↓	↑	↓	↓↓
Metabolic alkalosis	↑	↓	↑	↑↑

[a]The primary event is indicated by the double arrows (↑↑ or ↓↓). Note that respiratory acid–base disorders are initiated by an increase or decrease in P_{CO_2}, whereas metabolic disorders are initiated by an increase or decrease in HCO_3^-.

caused by addition of new HCO_3^- to the extracellular fluid by the kidneys. The rise in HCO_3^- helps offset increased P_{CO_2}, thereby returning the plasma pH toward normal.

In *metabolic acidosis*, there is also a decrease in pH and a rise in the extracellular fluid H^+ concentration. In this case, the primary abnormality is a decrease in plasma HCO_3^-. *The primary compensations include increased ventilation rate, which reduces P_{CO_2}, and renal compensation, which, by adding new HCO_3^- to the extracellular fluid, helps attenuate the initial fall in extracellular HCO_3^- concentration.*

RENAL CORRECTION OF ALKALOSIS—DECREASED TUBULAR SECRETION OF H^+ AND INCREASED EXCRETION OF HCO_3^-

The compensatory responses to alkalosis are basically opposite to those that occur in acidosis. In alkalosis, the ratio of HCO_3^- to CO_2 in the extracellular fluid increases, causing a rise in pH (a decrease in H^+ concentration), as evident from the Henderson-Hasselbalch equation.

Alkalosis Increases HCO_3^-/H^+ Ratio in Renal Tubular Fluid

Regardless of whether alkalosis is caused by metabolic or respiratory abnormalities, there is still an increase in the ratio of HCO_3^-/H^+ in the renal tubular fluid. The net effect of this is an excess of HCO_3^- that cannot be reabsorbed from the tubules and is excreted in the urine. Thus, in alkalosis, HCO_3^- is removed from the extracellular fluid by renal excretion, which has the same effect as adding an H^+ to the extracellular fluid. This process helps return the H^+ concentration and pH toward normal.

Table 31.3 shows the overall extracellular fluid characteristics of respiratory and metabolic alkalosis. In *respiratory alkalosis*, there is an increase in extracellular fluid pH and a decrease in H^+ concentration. *The cause of the alkalosis is decreased plasma P_{CO_2}, caused by hyperventilation*. Reduction in P_{CO_2} then leads to decreased renal tubular H^+ secretion. Consequently, there is not enough H^+ in the renal tubular fluid to react with all the HCO_3^- that is filtered. Therefore, the HCO_3^- that cannot react with H^+ is not reabsorbed and is excreted in the urine. This results in a decreased plasma HCO_3^- concentration and correction of the alkalosis. *Therefore, the compensatory response to a primary reduction in P_{CO_2} in respiratory alkalosis is a reduction in plasma HCO_3^- concentration caused by increased renal excretion of HCO_3^-.*

In *metabolic alkalosis*, there is also decreased plasma H^+ concentration and increased pH. *The cause of metabolic alkalosis, however, is a rise in the extracellular fluid HCO_3^- concentration*. This rise is partly compensated for by a reduction in the respiration rate, which increases P_{CO_2} and helps return the extracellular fluid pH toward normal. More importantly, increased HCO_3^- concentration in the extracellular fluid increases the filtered load of HCO_3^-, which, in turn, causes excess HCO_3^- over H^+ secreted in the renal tubular fluid. The excess HCO_3^- in the tubular fluid fails to be reabsorbed because there is no H^+ with which it can react, and it is excreted in the urine. *In metabolic alkalosis, the primary compensation is increased renal HCO_3^- excretion, which helps compensate for the initial rise in extracellular fluid HCO_3^- concentration. A reduction in ventilation rate may also contribute, albeit weakly, to the compensatory response by increasing P_{CO_2}.*

Clinical Causes of Acid–Base Disorders

Respiratory Acidosis Results From Decreased Ventilation and Increased P_{CO_2}

From the previous discussion, it is obvious that any factor that decreases the rate of pulmonary ventilation also increases P_{CO_2} of extracellular fluid. This causes an increase in H_2CO_3 and H^+ concentrations, resulting in acidosis. Because the acidosis is caused by an abnormality in respiration, it is called *respiratory acidosis*.

Respiratory acidosis can occur from pathological conditions that damage the respiratory centers or that decrease the ability of the lungs to eliminate CO_2. For example, damage to the respiratory center in the medulla oblongata can lead to respiratory acidosis. Also, obstruction of the passageways of the respiratory tract, pneumonia, emphysema, or decreased pulmonary membrane surface area, as well as any factor that interferes with exchange of gases between the blood and alveolar air, can cause respiratory acidosis.

In respiratory acidosis, the compensatory responses available are as follows: (1) the buffers of the body fluids; (2) the kidneys, which require several days to compensate for the disorder.

Respiratory Alkalosis Results From Increased Ventilation and Decreased P_{CO_2}

Respiratory alkalosis is caused by excessive ventilation by the lungs. Rarely does this occur because of physical pathological conditions. However, a psychoneurosis can occasionally increase breathing to the extent that a person becomes alkalotic.

A physiological type of respiratory alkalosis occurs when a person ascends to a high altitude. The low oxygen content of the air stimulates respiration, which causes loss of CO_2 and development of mild respiratory alkalosis. Again, the major means for compensation are the chemical buffers of the body fluids and ability of the kidneys to increase HCO_3^- excretion.

Metabolic Acidosis Results From Decreased Extracellular Fluid HCO_3^- Concentration

The term *metabolic acidosis* refers to all other types of acidosis besides those caused by excess CO_2 in the body fluids. Metabolic acidosis can result from several general causes: (1) failure of the kidneys to reabsorb HCO_3^- and excrete metabolic acids normally formed in the body; (2) formation of excess quantities of metabolic acids in the body; (3) addition of metabolic acids to the body by ingestion or infusion of acids; and (4) loss of base (e.g., HCO_3^-) from the body fluids, which has the same effect as adding an acid to the body fluids. Some specific conditions that cause metabolic acidosis are described in the following sections.

Renal Tubular Acidosis. Renal tubular acidosis results from a defect in renal secretion of H^+, reabsorption of HCO_3^-, or both. These disorders are generally of two types: (1) impairment of renal tubular HCO_3^- reabsorption, causing loss of HCO_3^- in the urine; or (2) inability of the renal tubular H^+ secretory mechanism to establish normal acidic urine, causing the excretion of alkaline urine. In these cases, inadequate amounts of titratable acid and NH_4^+ are excreted, so there is net accumulation of acid in the body fluids. Some causes of renal tubular acidosis include *chronic renal failure*, *insufficient aldosterone secretion (Addison disease)*, and several hereditary and acquired disorders that impair tubular function, such as *Fanconi syndrome* (see Chapter 32).

Diarrhea. Severe diarrhea is probably the most frequent cause of metabolic acidosis. *The cause of this acidosis is the loss of large amounts of sodium bicarbonate into the feces.* The gastrointestinal secretions normally contain large amounts of HCO_3^-, and diarrhea results in the loss of HCO_3^- from the body, which has the same effect as losing large amounts of HCO_3^- in the urine. This form of metabolic acidosis can be serious and can cause death, especially in young children.

Vomiting of Intestinal Contents. Vomiting of gastric contents alone would cause a loss of acid and a tendency toward alkalosis because the stomach secretions are highly acidic. However, vomiting large amounts from deeper in the gastrointestinal tract causes loss of HCO_3^- and results in metabolic acidosis in the same way that diarrhea causes acidosis.

Diabetes Mellitus. Diabetes mellitus is caused by lack of insulin secretion by the pancreas (type 1 diabetes) or by insufficient insulin secretion to compensate for decreased sensitivity to the effects of insulin (type 2 diabetes). In the absence of sufficient insulin action, the normal metabolism of glucose is prevented. Instead, some of the fats are split into acetoacetic acid, and this acid is metabolized by the tissues for energy in place of glucose. With severe diabetes mellitus, blood acetoacetic acid levels can rise very high, causing severe metabolic acidosis. In an attempt to compensate for this acidosis, large amounts of acid are excreted in the urine—sometimes as much as 500 mmol/day.

Ingestion of Acids. Rarely are large amounts of acids ingested in normal foods. However, severe metabolic acidosis occasionally results from the ingestion of certain acidic poisons. Some of these substances include some acetylsalicylic compounds (e.g., aspirin) and methyl alcohol, which forms formic acid when it is metabolized.

Chronic Renal Failure. When kidney function declines markedly, there is a buildup in the body fluids of the anions of weak acids that are not being excreted by the kidneys. In addition, the decreased glomerular filtration rate reduces excretion of phosphates and NH_4^+, which reduces the amount of HCO_3^- added back to the body fluids. Thus, chronic renal failure can be associated with severe metabolic acidosis.

Metabolic Alkalosis Results From Increased Extracellular Fluid HCO_3^- Concentration

Excess retention of HCO_3^- or loss of H^+ from the body causes metabolic alkalosis. Metabolic alkalosis is not nearly as common as metabolic acidosis, but some of the causes of metabolic alkalosis are described in the following sections.

Administration of Diuretics (Except Carbonic Anhydrase Inhibitors). All diuretics cause increased flow of fluid along the tubules, usually increasing flow in the distal and collecting tubules. This effect leads to increased reabsorption of Na^+ from these parts of the nephrons. Because the sodium reabsorption here is coupled with H^+ secretion, the enhanced sodium reabsorption also leads to an increase in H^+ secretion and increase in HCO_3^- reabsorption. Reductions in extracellular fluid volume associated with the use of diuretics are also generally associated with increased formation of Ang II and aldosterone, which both stimulate H^+ secretion and HCO_3^- reabsorption. These changes lead to the development of alkalosis, characterized by increased extracellular fluid HCO_3^- concentration.

Excess Aldosterone. When excess amounts of aldosterone are secreted by the adrenal glands, a mild metabolic alkalosis develops. As discussed previously, aldosterone promotes extensive reabsorption of Na^+ from the distal and collecting tubules and, at the same time, stimulates secretion of H^+ and HCO_3^- reabsorption by the intercalated cells of the collecting tubules. This increased H^+ secretion and HCO_3^- reabsorption leads to metabolic alkalosis.

Vomiting of Gastric Contents. Vomiting of the gastric contents alone, without vomiting of the lower gastrointestinal contents, causes loss of the HCl secreted by the stomach mucosa. The net result is loss of acid from the extracellular fluid and development of metabolic alkalosis. This type of alkalosis occurs especially in neonates who have pyloric stenosis caused by hypertrophied pyloric sphincter muscles.

Ingestion of Alkaline Drugs. A common cause of metabolic alkalosis is ingestion of alkaline drugs, such as sodium bicarbonate, for the treatment of gastritis or peptic ulcer.

Treatment of Acidosis or Alkalosis

The best treatment for acidosis or alkalosis is to correct the condition that caused the abnormality. This is often difficult, especially in chronic diseases that cause impaired lung function or kidney failure. In these circumstances, various agents can be used to neutralize the excess acid or base in the extracellular fluid.

To neutralize excess acid, large amounts of *sodium bicarbonate* can be ingested by mouth. The sodium bicarbonate is absorbed from the gastrointestinal tract into the blood and increases the HCO_3^- portion of the bicarbonate buffer system, thereby increasing pH toward normal. Sodium bicarbonate can also be infused intravenously, but because of the potentially dangerous physiological effects of such treatment, other substances are often used instead, such as *sodium lactate* and *sodium gluconate*. The lactate and gluconate portions of the molecules are metabolized in the body, leaving the sodium in the extracellular fluid in the form of sodium bicarbonate and thereby increasing pH of the fluid toward normal.

For the treatment of alkalosis, *ammonium chloride* can be administered by mouth. When ammonium chloride is absorbed into the blood, the ammonia portion is converted by the liver into urea. This reaction liberates HCl, which immediately reacts with the buffers of the body fluids to shift the H^+ concentration in the acidic direction. Ammonium chloride occasionally is infused intravenously, but NH_4^+ is highly toxic, and this procedure can be dangerous. The most appropriate treatment is to reverse the underlying cause of the alkalosis. For example, if metabolic alkalosis is associated with extracellular fluid volume depletion, but not heart failure, appropriate repletion of volume by infusion of isotonic saline solution is often beneficial in correcting the alkalosis.

Clinical Measurements and Analysis of Acid–Base Disorders

Choosing the appropriate therapy for acid–base disorders requires a proper diagnosis. The simple acid–base disorders described previously can be diagnosed by analyzing three measurements from an arterial blood sample: pH, plasma HCO_3^- concentration, and P_{CO_2}.

The diagnosis of simple acid–base disorders involves several steps, as shown in **Fig. 31.11**. By examining the pH, one can determine whether the disorder is acidosis or alkalosis. A pH less than 7.4 indicates acidosis, whereas a pH greater than 7.4 indicates alkalosis.

The second step is to examine the plasma P_{CO_2} and HCO_3^- concentrations. The normal value for P_{CO_2} is about 40 mm Hg and for HCO_3^- it is 24 mEq/L. If the disorder has been diagnosed as acidosis and plasma P_{CO_2} is increased, there must be a respiratory component to the acidosis. After renal compensation, the plasma HCO_3^- concentration in respiratory acidosis would tend to increase above normal. *Therefore, the expected values for a simple respiratory acidosis would be reduced plasma pH, increased P_{CO_2}, and increased plasma HCO_3^- concentration after partial renal compensation.*

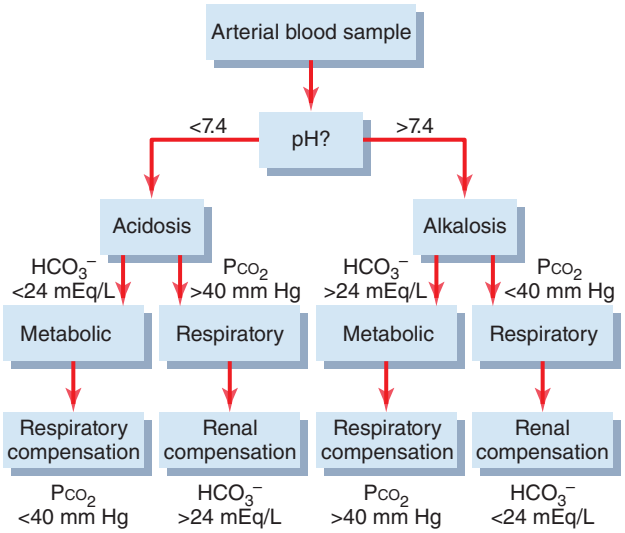

Figure 31.11 Analysis of simple acid–base disorders. If the compensatory responses are markedly different from those shown at the bottom of the figure, one should suspect a mixed acid–base disorder.

For metabolic acidosis, there would also be a decrease in plasma pH. However, with metabolic acidosis, the primary abnormality is a decrease in plasma HCO_3^- concentration. Therefore, if a low pH is associated with a low HCO_3^- concentration, there must be a metabolic component to the acidosis. In simple metabolic acidosis, the P_{CO_2} is reduced because of partial respiratory compensation, in contrast to respiratory acidosis, in which P_{CO_2} is increased. *Therefore, in simple metabolic acidosis, one would expect to find a low pH, a low plasma HCO_3^- concentration, and a reduction in P_{CO_2} after partial respiratory compensation.*

The procedures for categorizing the types of alkalosis involve the same basic steps. First, alkalosis implies that there is an increase in plasma pH. If the increase in pH is associated with decreased P_{CO_2}, there must be a respiratory component to the alkalosis. If the rise in pH is associated with increased HCO_3^-, there must be a metabolic component to the alkalosis. *Therefore, in simple respiratory alkalosis, one would expect to find increased pH, decreased P_{CO_2}, and decreased HCO_3^- concentration in the plasma. In simple metabolic alkalosis, one would expect to find increased pH, increased plasma HCO_3^-, and increased P_{CO_2}.*

Complex Acid–Base Disorders and Use of Acid–Base Nomogram for Diagnosis

In some cases, acid–base disorders are not accompanied by appropriate compensatory responses. When this situation occurs, the abnormality is referred to as a *mixed acid–base disorder*, which means that there are two or more underlying causes for the acid–base disturbance. For example, a patient with a low pH would be categorized as acidotic. If the disorder was metabolically mediated, this would also be accompanied by a low plasma HCO_3^- concentration and, after appropriate respiratory compensation, a low P_{CO_2}. However, if the low plasma pH and low HCO_3^- concentration are associated with an elevated P_{CO_2}, there must be a respiratory component to the acidosis, as well as a metabolic component. Therefore, this disorder would be categorized as a mixed acidosis.

This disorder could occur, for example, in a patient with acute HCO_3^- loss from the gastrointestinal tract because of diarrhea (metabolic acidosis) and emphysema (respiratory acidosis).

A convenient way to diagnose acid–base disorders is to use an acid–base nomogram, as shown in **Fig. 31.12**. This diagram can be used to assess the type of acidosis or alkalosis, as well as its severity. In this acid–base diagram, pH, HCO_3^- concentration, and P_{CO_2} values intersect according to the Henderson-Hasselbalch equation. The central open circle shows normal values and the deviations that can still be considered within the normal range. The shaded areas of the diagram show the 95% confidence limits for the normal compensations to simple metabolic and respiratory disorders.

When using this diagram, one must assume that sufficient time has elapsed for a full compensatory response, which is 6 to 12 hours for the ventilatory compensations in primary metabolic disorders and 3 to 5 days for the metabolic compensations in primary respiratory disorders. If a value is within the shaded area, this suggests that there is a simple acid–base disturbance. Conversely, if the values for pH, HCO_3^-, or P_{CO_2} lie outside the shaded area, this suggests that the patient may have a mixed acid–base disorder.

It is important to recognize that an acid–base value within the shaded area does not *always* mean that a simple acid–base disorder is present. With this reservation in mind, the acid–base diagrams can be used as a quick means of determining the specific type and severity of an acid–base disorder.

For example, assume that the arterial plasma from a patient yields the following values: pH, 7.30; plasma HCO_3^- concentration, 12.0 mEq/L; and plasma P_{CO_2}, 25 mm Hg. With these values, one can look at the diagram and find that this represents a simple metabolic acidosis, with appropriate respiratory compensation that reduces the P_{CO_2} from its normal value of 40 mm Hg to 25 mm Hg.

A second example would be a patient with the following values: pH, 7.15; plasma HCO_3^- concentration, 17 mEq/L; and plasma P_{CO_2}, 50 mm Hg. In this example, the patient is acidotic, and there appears to be a metabolic component because the plasma HCO_3^- concentration is lower than the normal value of 24 mEq/L. However, the respiratory compensation that would normally reduce P_{CO_2} is absent and P_{CO_2} is slightly increased above the normal value of 40 mm Hg. This finding is consistent with a mixed acid–base disturbance consisting of metabolic acidosis, as well as a respiratory component.

The acid–base nomogram serves as a quick way to assess the type and severity of disorders that may be contributing to abnormal pH, P_{CO_2}, and plasma HCO_3^- concentrations. In a clinical setting, the patient's history and other physical findings also provide important clues concerning the causes and treatment of the acid–base disorders.

Use of Anion Gap to Diagnose Acid–Base Disorders

The concentrations of anions and cations in plasma must be equal to maintain electrical neutrality. Therefore, there is no real anion gap in the plasma. However, only certain cations and anions are routinely measured in the clinical laboratory. The cation normally measured is Na^+, and the anions are usually Cl^- and HCO_3^-. The anion gap—which is only a diagnostic concept— is the difference between unmeasured anions and unmeasured cations and is estimated as follows:

$$\text{Plasma anion gap} = [Na^+] - [HCO_3^-] - [Cl^-]$$
$$= 144 - 24 - 108 = 12 \text{ mEq/L}$$

The anion gap will increase if unmeasured anions rise or if unmeasured cations fall. The most important unmeasured cations include calcium, magnesium, and potassium, and the major unmeasured anions are albumin, phosphate, sulfate, and other organic anions. Usually, the unmeasured

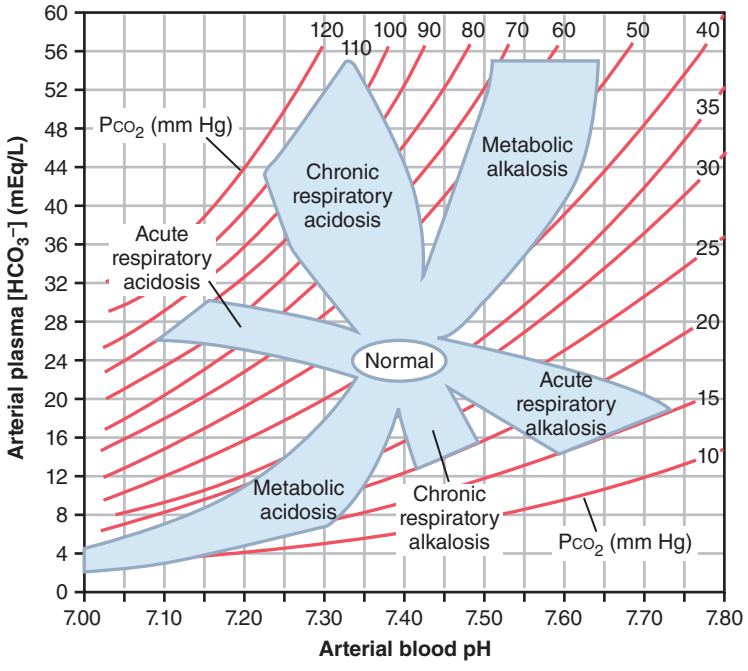

Figure 31.12 Acid–base nomogram showing arterial blood pH, arterial plasma HCO_3^-, and P_{CO_2} values. The central open circle shows the approximate limits for acid–base status in normal people. The shaded areas in the nomogram show the approximate limits for the normal compensations caused by simple metabolic and respiratory disorders. For values lying outside the shaded areas, one should suspect a mixed acid–base disorder. *(Modified from Cogan MG, Rector Jr. FC.* Acid-Base Disorders in the Kidney, *3rd ed. Philadelphia: WB Saunders; 1986.)*

Table 31.4 Metabolic Acidosis Associated With Normal or Increased Plasma Anion Gap

Increased Anion Gap (Normochloremia)	Normal Anion Gap (Hyperchloremia)
Diabetes mellitus (ketoacidosis)	Diarrhea
Lactic acidosis	Renal tubular acidosis
Chronic renal failure	Carbonic anhydrase inhibitors
Aspirin (acetylsalicylic acid) poisoning	Addison disease
Methanol poisoning	
Ethylene glycol poisoning	
Starvation	

anions exceed the unmeasured cations, and the anion gap ranges between 8 and 16 mEq/L.

The plasma anion gap is used mainly in diagnosing different causes of metabolic acidosis. In metabolic acidosis, plasma HCO_3^- concentration is reduced. If plasma sodium concentration is unchanged, the concentration of anions (Cl^- or an unmeasured anion) increases to maintain electroneutrality. If plasma Cl^- increases in proportion to the fall in plasma HCO_3^-, the anion gap will remain normal. This is often referred to as *hyperchloremic metabolic acidosis*.

If the decrease in plasma HCO_3^- is not accompanied by increased Cl^-, there must be increased levels of unmeasured anions and therefore an increase in the calculated anion gap. Metabolic acidosis caused by excess nonvolatile acids (besides HCl), such as lactic acid or ketoacids, is associated with an increased plasma anion gap because the fall in HCO_3^- is not matched by an equal increase in Cl^-. Some examples of metabolic acidosis associated with a normal or increased anion gap are shown in **Table 31.4**. By calculating the anion gap, one can narrow some of the potential causes of metabolic acidosis.

CHAPTER 32

Diuretics and Kidney Diseases

DIURETICS AND THEIR MECHANISMS OF ACTION

Diuretics increase the rate of urine volume output, as the name implies. Most diuretics also increase urinary excretion of solutes, especially sodium and chloride. In fact, most diuretics that are used clinically act by decreasing renal tubular sodium reabsorption, which causes natriuresis (increased sodium output) and diuresis (increased water output). In most cases, increased water excretion occurs secondary to inhibition of tubular sodium reabsorption because sodium remaining in the tubules acts osmotically to decrease water reabsorption. Because renal tubular reabsorption of many solutes, such as potassium, chloride, magnesium, and calcium, is also influenced secondarily by sodium reabsorption, many diuretics increase the renal excretion of these solutes as well.

The most common clinical use of diuretics is to reduce extracellular fluid volume, especially in diseases associated with edema and in hypertension. As discussed in Chapter 25, loss of sodium from the body mainly decreases extracellular fluid volume; therefore, diuretics are usually administered in clinical conditions associated with extracellular fluid volume expansion.

Some diuretics can increase urine output more than 20-fold within a few minutes after they are administered. However, the effect of most diuretics on daily renal output of salt and water subsides within a few days due to activation of compensatory mechanisms initiated by decreased extracellular fluid volume (**Fig. 32.1**). For example, a decrease in extracellular fluid volume may reduce arterial pressure and glomerular filtration rate (GFR) and increase renin secretion and angiotensin II (Ang II) formation; all these responses together eventually override the chronic effects of the diuretic on urine output. Thus, in the steady state, urine output becomes equal to intake, but only after reductions in arterial pressure and extracellular fluid volume have occurred, relieving the hypertension or edema that prompted the use of diuretics in the first place.

The many diuretics available for clinical use have different mechanisms of action and, therefore, inhibit tubular reabsorption at different sites along the renal nephron. The general classes of diuretics, their mechanisms of action, and their tubular sites of action are shown in **Table 32.1**.

Osmotic Diuretics Decrease Water Reabsorption By Increasing Osmotic Pressure of Tubular Fluid

Injection into the blood of substances that are filtered by the glomerular capillaries but are not easily reabsorbed by the renal tubules, such as urea, mannitol, and sucrose, causes a marked increase in the concentration of osmotically active molecules in the tubules. The osmotic pressure of these solutes then reduces water reabsorption, flushing large amounts of tubular fluid into the urine.

Large volumes of urine are also formed in certain diseases associated with excess solutes that fail to be reabsorbed from the tubular fluid. For example, when blood glucose concentration rises to high levels in diabetes mellitus, the increased filtered load of glucose into the tubules exceeds their capacity to reabsorb glucose (i.e., exceeds their *transport maximum* for glucose). Above a plasma glucose concentration of about 250 mg/dL, little of the extra glucose is reabsorbed by the tubules; instead, the excess glucose remains in the tubules, acts as an osmotic diuretic, and increases urine flow rate. Therefore, one of the hallmarks of uncontrolled diabetes mellitus is *polyuria* (frequent urination), which is balanced by a high level of fluid intake *(polydipsia)* secondary to dehydration, increased extracellular fluid osmolarity, and activation of the thirst mechanism.

Loop Diuretics Decrease Sodium-Chloride-Potassium Reabsorption in the Thick Ascending Loop of Henle

Furosemide, ethacrynic acid, and *bumetanide* are powerful diuretics that decrease reabsorption in the thick ascending limb of the loop of Henle by blocking the 1-sodium, 2-chloride, 1-potassium co-transporter located in the luminal membrane of the epithelial cells (see **Fig. 28.9**). These loop diuretics are among the most powerful of the clinically used diuretics.

By blocking sodium-chloride-potassium co-transport in the luminal membrane of the loop of Henle, the loop diuretics increase urine output of sodium, chloride, potassium, and other electrolytes, as well as water, for two reasons: (1) they greatly increase the quantities of solutes delivered to the distal parts of the nephrons, and these solutes act as osmotic agents to prevent water reabsorption;

and (2) they disrupt the countercurrent multiplier system by decreasing absorption of ions from the loop of Henle into the medullary interstitium, thereby decreasing the osmolarity of the medullary interstitial fluid. Therefore, loop diuretics impair the ability of the kidneys to concentrate or dilute the urine.

Urinary dilution is impaired with loop diuretics because the inhibition of sodium and chloride reabsorption in the loop of Henle causes more of these ions to be excreted, along with increased water excretion. Urine concentrating ability is impaired because the renal medullary interstitial fluid concentration of these ions, and therefore renal medullary osmolarity, is reduced. Consequently, reabsorption of fluid from the collecting ducts is decreased, so the maximal concentrating ability of the kidneys is also greatly reduced. In addition, decreased renal medullary interstitial fluid osmolarity reduces reabsorption of water from the descending loop of Henle. Because of these multiple effects, 20% to 25% of the glomerular filtrate may be delivered into the urine, causing urine output, under acute conditions, to be as great as 25 times normal for at least a few minutes.

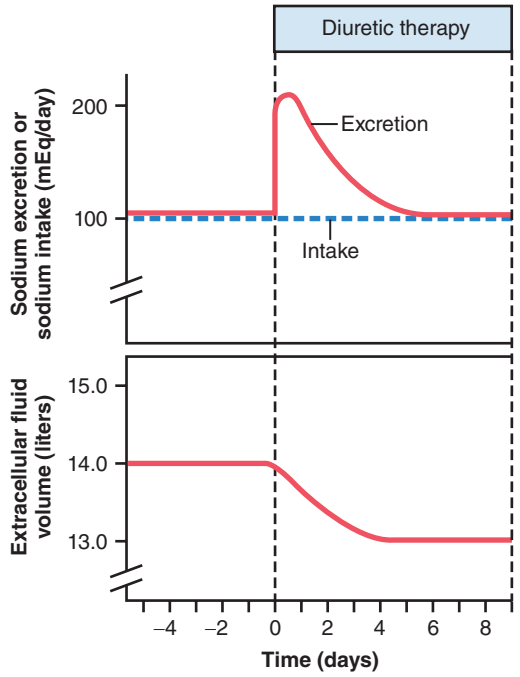

Figure 32.1 Sodium excretion and extracellular fluid volume during diuretic administration. The immediate increase in sodium excretion is accompanied by a decrease in extracellular fluid volume. If sodium intake is constant, compensatory mechanisms will eventually return sodium excretion to equal sodium intake, thus reestablishing sodium balance.

Loop diuretics also increase renal calcium excretion. As discussed in Chapter 30, calcium reabsorption in the thick ascending loop of Henle is primarily passive through the paracellular pathway, driven by the electrochemical gradient due to active sodium chloride transport. Therefore, inhibition of sodium chloride reabsorption causes a parallel reduction in calcium reabsorption and increased calcium excretion.

Because they inhibit sodium-chloride-potassium co-transport and increase distal and collecting tubule volume delivery, loop diuretics also increase renal potassium excretion and may be associated with significant *hypokalemia*.

Thiazide Diuretics Inhibit Sodium-Chloride Reabsorption in the Distal Convoluted Tubule

The thiazide derivatives, such as chlorothiazide, act mainly on the distal convoluted tubules to block the sodium-chloride co-transporter in the luminal membrane of the tubular cells (see **Fig. 28.10**). Under favorable conditions, these agents may cause a maximum of 5% of the glomerular filtrate to pass into the urine.

Thiazide diuretics, especially when administered at high doses, may also increase potassium excretion and cause *hypokalemia*, partly related to increased delivery of sodium chloride to the collecting tubules. Thiazide diuretics are

Table 32.1 Classes of Diuretics, Their Mechanisms of Action, and Tubular Sites of Action

Class of Diuretic (Examples)	Mechanism of Action	Tubular Site of Action
Osmotic diuretics (mannitol)	Inhibit water and solute reabsorption by increasing osmolarity of tubular fluid	Mainly proximal tubules
Loop diuretics (furosemide, bumetanide)	Inhibit Na^+-K^+-Cl^- co-transport in luminal membrane	Thick ascending loop of Henle
Thiazide diuretics (hydrochlorothiazide, chlorthalidone)	Inhibit Na^+-Cl^- co-transport in luminal membrane	Early distal tubules
Carbonic anhydrase inhibitors (acetazolamide)	Inhibit H^+ secretion and HCO_3^- reabsorption, which reduces Na^+ reabsorption	Mainly proximal tubules
Mineralocorticoid receptor antagonists (spironolactone, eplerenone, finerenone)	Inhibit action of mineralocorticoids (e.g., aldosterone) on tubular receptor, decrease Na^+ reabsorption, decrease K^+ secretion	Collecting tubules
Epithelial sodium channel blockers (triamterene, amiloride)	Block entry of Na^+ into Na^+ channels of luminal membrane, decrease Na^+ reabsorption, decrease K^+ secretion	Collecting tubules

also associated with activation of the renin-angiotensin-aldosterone system (RAAS) due to the loss of sodium and volume. Both of these effects—increased sodium delivery to the collecting tubules and increased aldosterone—stimulate potassium secretion, as discussed in Chapter 30.

Thiazide diuretics are among the most widely used drugs for treatment of hypertension and other cardiovascular disorders such as heart failure. Low doses of thiazide diuretics have been demonstrated in multiple randomized controlled trials to not only lower blood pressure in patients with primary hypertension, but also to reduce mortality and adverse cardiovascular events.

Carbonic Anhydrase Inhibitors Block Sodium Bicarbonate Reabsorption

Acetazolamide inhibits the enzyme *carbonic anhydrase*, which is critical for reabsorption of bicarbonate (HCO_3^-) in the renal tubules, as discussed in Chapter 31. Carbonic anhydrase is especially abundant in the proximal tubule, the primary site of action of carbonic anhydrase inhibitors. Some carbonic anhydrase is also present in other tubular cells, such as in the intercalated cells of the collecting tubule.

Because H^+ secretion and HCO_3^- reabsorption in the proximal tubules are coupled to sodium reabsorption through the Na^+-H^+ counter-transport mechanism in the luminal membrane, decreasing HCO_3^- reabsorption also reduces sodium reabsorption. The blockage of sodium and HCO_3^- reabsorption from the tubular fluid causes these ions to remain in the tubules and act as an osmotic diuretic. Predictably, a disadvantage of the carbonic anhydrase inhibitors is that they cause some degree of acidosis because of the excessive loss of HCO_3^- in the urine.

Mineralocorticoid Receptor Antagonists Decrease Sodium Reabsorption and Potassium Secretion in the Collecting Tubules

Spironolactone, eplerenone, and finerenone are mineralocorticoid receptor antagonists that compete with aldosterone for receptor-binding sites in the collecting tubule and collecting duct epithelial cells and, therefore, can decrease sodium reabsorption and potassium secretion in these tubular segments (see **Fig. 28.12**). As a consequence, sodium remains in the tubules and acts as an osmotic diuretic, causing increased excretion of water, as well as sodium. Because these drugs also block the effect of aldosterone to promote potassium secretion in the tubules, they also decrease excretion of potassium.

Mineralocorticoid receptor antagonists also cause movement of potassium from the cells to the extracellular fluid. In some cases, this movement causes excessive increases in extracellular fluid potassium concentration (*hyperkalemia*). For this reason, mineralocorticoid receptor antagonists are often referred to as *potassium-sparing diuretics*. Many of the other diuretics cause loss of potassium in the urine, in contrast to the mineralocorticoid receptor antagonists, which spare the loss of potassium.

Mineralocorticoid antagonists are especially useful for treating patients with *primary aldosteronism* (excessive aldosterone secretion), as well as hypertension and heart failure. Although mineralocorticoid receptor antagonists may tend to cause hyperkalemia, especially in patients who have impaired potassium excretion due to chronic kidney disease (CKD), this effect is dose-dependent and appears to be attenuated with nonsteroid mineralocorticoid receptor antagonists (e.g., finerenone) compared to antagonists that are steroids (e.g., spironolactone).

Epithelial Sodium Channel Blockers Decrease Sodium Reabsorption in the Collecting Tubules

Amiloride and *triamterene* are members of a subclass of sodium channel blockers that inhibit epithelial cell sodium reabsorption and potassium secretion in the collecting tubules, similar to the effects of spironolactone. However, at the cellular level, these drugs act directly to block the entry of sodium into the sodium channels of the luminal membrane of the collecting tubule epithelial cells (see **Fig. 28.12**). Because of this decreased sodium entry into the epithelial cells, there is also decreased sodium transport across the cells' basolateral membranes and, therefore, decreased activity of the Na^+-K^+ ATPase pump. This decreased activity reduces the transport of potassium into the cells and ultimately decreases the potassium secretion into the tubular fluid. For this reason, the sodium channel blockers are also potassium-sparing diuretics and decrease the urinary excretion rate of potassium.

Epithelial sodium channel blockers are used as potassium-sparing diuretics for the treatment of edema and hypertension. These diuretics are often used in combination with other antihypertensive drugs, especially for patients with treatment-resistant hypertension that requires three or more drugs to control blood pressure.

KIDNEY DISEASES

Diseases of the kidneys are among the most common causes of death and disability in many countries throughout the world. For example, in 2023, more than 14% of adults in the United States, or more than 35.5 million people, were estimated to have chronic kidney disease (CKD), and many more millions have acute renal injury or less severe forms of kidney dysfunction.

Severe kidney diseases can be divided into two main categories:

1. *Acute kidney injury* (AKI), in which there is an abrupt loss of kidney function within a few days. The term *acute renal failure* is usually reserved for severe acute kidney injury, in which the kidneys may abruptly stop working entirely or almost entirely, necessitating renal replacement therapy such as dialysis, as discussed later in this chapter. In some cases, patients with AKI may eventually recover nearly normal kidney function.

2. *Chronic kidney disease* (CKD), in which there is progressive loss of function of more and more nephrons that gradually decreases overall kidney function.

Within these two general categories, there are many specific kidney diseases that can affect the kidney blood vessels, glomeruli, tubules, renal interstitium, and parts of the urinary tract outside the kidney, including the ureters and bladder. In this chapter, we discuss specific physiological abnormalities that occur in a few of the more prevalent types of kidney diseases.

ACUTE KIDNEY INJURY

The causes of AKI are often divided into three main categories:

1. *Prerenal AKI*, resulting from decreased blood supply to the kidneys due to an abnormality originating outside the kidneys. For example, prerenal AKI can be a consequence of heart failure with reduced cardiac output and low blood pressure or conditions associated with diminished blood volume and low blood pressure, such as severe hemorrhage.
2. *Intrarenal AKI*, resulting from abnormalities within the kidney itself, including those that adversely affect the blood vessels, glomeruli, or tubules.
3. *Postrenal AKI*, resulting from obstruction of the urinary collecting system anywhere from the calyces to the outflow from the bladder. The most common causes of obstruction of the urinary tract outside the kidney are kidney stones, caused by precipitation of calcium, urate, or cystine.

In some major causes of AKI, such as sepsis, prerenal (e.g., reduced blood pressure) and intrarenal (endothelial and tubular injury) abnormalities may occur simultaneously.

PRERENAL ACUTE KIDNEY INJURY CAUSED BY DECREASED BLOOD FLOW TO THE KIDNEY

The kidneys normally receive an abundant blood supply of about 1100 mL/min, or about 20% to 25% of the cardiac output. The main purpose of this high blood flow to the kidneys is to provide enough plasma for the high rates of glomerular filtration needed for effective regulation of body fluid volumes and solute concentrations. Therefore, decreased renal blood flow is usually accompanied by decreased GFR and decreased urine output of water and solutes. Consequently, conditions that acutely diminish blood flow to the kidneys often cause *oliguria*, which refers to diminished urine output below the level of intake of water and solutes. This condition causes accumulation of water and solutes in the body fluids. If renal blood flow is markedly reduced, total cessation of urine output can occur, a condition referred to as *anuria*.

As long as renal blood flow does not fall below about 20% to 25% of normal, AKI can usually be reversed if the cause of the ischemia is corrected before damage to the renal cells has occurred. Unlike some tissues, the kidney can endure a relatively large reduction in blood flow before there is major damage to the renal cells. The reason for this phenomenon is that as renal blood flow is reduced, GFR and amount of sodium chloride filtered by the glomeruli (as well as the filtration rate of water and other electrolytes) are reduced. This decreases the amount of sodium chloride that must be reabsorbed by the tubules, which use most of the energy and oxygen consumed by the normal kidney. Therefore, as renal blood flow and GFR fall, renal oxygen consumption is also reduced. As the GFR approaches zero, oxygen consumption of the kidney approaches the rate that is required to keep the renal tubular cells alive when they are not reabsorbing sodium. When blood flow is reduced below this basal requirement, which is usually less than 20% to 25% of the normal renal blood flow, the renal cells become hypoxic, and further decreases in renal blood flow, if prolonged, will cause damage or even death of the renal cells, especially the tubular epithelial cells.

If the cause of prerenal AKI is not corrected, and ischemia of the kidney persists longer than a few hours, this type of renal failure can evolve into intrarenal AKI, as discussed later. Acute reduction of renal blood flow is a common cause of AKI in hospitalized patients, especially those who have sustained severe injuries. **Table 32.2** shows some of the common causes of decreased renal blood flow and prerenal AKI.

INTRARENAL AKI CAUSED BY ABNORMALITIES IN THE KIDNEY

Abnormalities that originate in the kidney and that abruptly diminish urine output fall into the general category of *intrarenal AKI*. This category of AKI can be further divided into the following: (1) conditions that injure the glomerular capillaries or other small renal vessels; (2) conditions that damage the renal tubular epithelium; and (3) conditions that cause damage to the renal interstitium. This type of classification refers to the primary site of injury, but because the renal vasculature and tubular system are functionally interdependent, damage to the renal blood vessels can lead to tubular damage, and primary tubular damage can lead to damage of the renal blood vessels. Some causes of intrarenal acute kidney injury are listed in **Table 32.3**.

AKI Caused By Glomerulonephritis

Acute glomerulonephritis is a type of *intrarenal AKI* usually caused by an abnormal immune reaction that damages the glomeruli. In about 95% of patients with this disease, damage to the glomeruli occurs 1 to 3 weeks after an infection elsewhere in the body, often caused by

certain types of group A beta streptococci. The infection may have been a streptococcal sore throat, streptococcal tonsillitis, or even streptococcal infection of the skin. It is not the infection itself that damages the kidneys. Instead, over a few weeks, as antibodies develop against the streptococcal antigen, the antibodies and antigen react with each other to form an insoluble immune complex that becomes entrapped in the glomeruli, especially in the basement membrane portion of the glomeruli.

Once the immune complex has been deposited in the glomeruli, many of the glomerular cells begin to proliferate, but mainly the mesangial cells that lie between the endothelium and epithelium. In addition, large numbers of white blood cells become entrapped in the glomeruli. Many of the glomeruli become blocked by this inflammatory reaction, and those that are not blocked usually become excessively permeable, allowing protein and red blood cells to leak from the blood of the glomerular capillaries into the glomerular filtrate. In severe cases, total or almost complete renal shutdown occurs.

The acute inflammation of the glomeruli usually subsides in about 2 weeks and, in most patients, the kidneys return to almost normal function within the next few weeks to few months. Sometimes, however, many of the glomeruli are destroyed beyond repair and, in a small percentage of patients, progressive renal deterioration continues indefinitely, leading to CKD, as described in a subsequent section of this chapter.

Tubular Necrosis as a Cause of AKI

Another cause of intrarenal acute renal failure is *tubular necrosis*, which means destruction of epithelial cells in the tubules. Some common causes of tubular necrosis are as follows: (1) severe ischemia and inadequate supply of oxygen and nutrients to the tubular epithelial cells; and (2) poisons, toxins, or medications that destroy the tubular epithelial cells.

Acute Tubular Necrosis Caused By Severe Renal Ischemia. Severe ischemia of the kidney can result from circulatory shock or other disturbances that severely impair the blood supply to the kidneys. If the ischemia is severe enough to seriously impair the delivery of nutrients and oxygen to the renal tubular epithelial cells, and if the insult is prolonged, damage or eventual destruction of the epithelial cells can occur. When this damage is severe, tubular cells may slough off and plug many of the nephrons so that there is no urine output from the blocked nephrons; the affected nephrons often fail to excrete urine, even when renal blood flow is restored to normal, as long as the tubules remain plugged. The most common causes of ischemic damage to the tubular epithelium are the prerenal causes of AKI associated with circulatory shock, as discussed earlier in this chapter.

Acute Tubular Necrosis Caused By Toxins or Medications. There is a long list of renal poisons and medications that can damage the tubular epithelium and cause AKI. Some of these substances are *carbon tetrachloride, heavy metals* (e.g., mercury and lead), *ethylene glycol* (a major component in antifreeze), various *insecticides*, some *medications* (e.g., tetracyclines) used as antibiotics, and *cis-platinum*, used in treating certain cancers. Each of these substances has a specific toxic action on the renal tubular epithelial cells, causing death of many of them. As a result, the epithelial cells slough away from the basement membrane and plug the tubules. In some cases, the basement membrane also is destroyed. If the basement membrane remains intact, new tubular epithelial cells can grow along the surface of the membrane, so the tubule may repair itself within 10 to 20 days.

POSTRENAL AKI CAUSED BY ABNORMALITIES OF THE LOWER URINARY TRACT

Multiple abnormalities in the lower urinary tract can block or partially block urine flow and therefore lead to AKI, even when the kidneys' blood supply and other functions are initially normal. If urine output of only one kidney is diminished, no major change in body fluid composition will occur because the contralateral kidney can increase its urine output sufficiently to maintain relatively normal levels of extracellular electrolytes and solutes, as well as normal extracellular fluid volume.

With this type of renal injury, normal kidney function can be restored if the basic cause of the problem is corrected within a few hours. However, chronic obstruction of the urinary tract that lasts for several days or weeks can lead to irreversible kidney damage. Some of the causes of postrenal AKI include the following: (1) bilateral obstruction of the ureters or renal pelvises caused by large stones or blood clots; (2) bladder obstruction caused by cancer; and (3) obstruction of the urethra caused by scar tissue, prostate hypertrophy, or cancer.

PHYSIOLOGICAL EFFECTS OF AKI

A major physiological effect of AKI is the retention of water, waste products of metabolism, and electrolytes in the blood and extracellular fluid. This can lead to water and salt overload, which, in turn, can lead to edema and hypertension. Excessive retention of potassium, however, is often a more serious threat to patients with AKI because increases in the plasma potassium concentration (hyperkalemia) above 8 mEq/L (only twice normal) can be fatal. Because the kidneys are also unable to excrete sufficient hydrogen ions, patients with AKI may experience metabolic acidosis, which can be lethal or aggravate the hyperkalemia.

In the most severe cases of AKI, complete anuria occurs. The patient will die in 8 to 14 days unless kidney function is restored or unless an artificial kidney is used to rid the body of the excessive retained water, electrolytes, and waste products of metabolism. Other effects of diminished urine output, as well as treatment with an artificial kidney, are discussed in the next section in relation to CKD.

CKD IS OFTEN ASSOCIATED WITH IRREVERSIBLE LOSS OF FUNCTIONAL NEPHRONS

CKD is usually defined as the presence of kidney damage or decreased kidney function that persists for at least 3 months. CKD is often associated with progressive and irreversible loss of large numbers of functioning nephrons. Serious clinical symptoms usually do not occur until the number of functional nephrons falls to at least 70% to 75% below normal. In fact, relatively normal blood concentrations of most electrolytes and normal body fluid volumes can still be maintained until the number of functioning nephrons decreases below 20% to 25% of normal.

Table 32.4 lists some of the most important causes of CKD. In general, CKD, like AKI, can occur because of disorders of the blood vessels, glomeruli, tubules, renal interstitium, and lower urinary tract. Despite the wide variety of disorders that can lead to CKD, the end result is essentially the same—a decrease in the number of functional nephrons.

VICIOUS CYCLE OF CKD LEADING TO END-STAGE RENAL DISEASE

In some cases, an initial insult to the kidney leads to progressive deterioration of kidney function and further loss of nephrons to the point where the person must undergo dialysis treatment or transplantation with a functional kidney to survive. This condition is referred to as *end-stage renal disease (ESRD)*.

Experimental studies have shown that surgical removal of large portions of the kidney initially causes adaptive changes in the remaining nephrons, which lead to increases in blood flow, GFR, and urine output in the

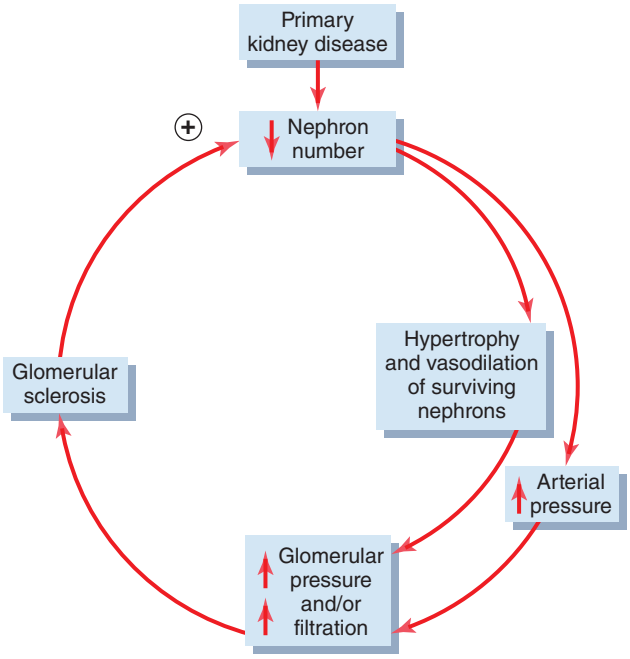

Figure 32.2 The vicious cycle that can occur with primary kidney disease. Loss of nephrons because of disease may increase pressure and flow in the surviving glomerular capillaries, which may eventually cause injury, progressive sclerosis, and further loss of nephrons.

surviving nephrons. The exact mechanisms responsible for these changes are not fully understood but involve hypertrophy (growth of various structures of surviving nephrons), as well as functional changes that decrease vascular resistance and tubular reabsorption in the surviving nephrons. These adaptive changes permit a person to excrete normal amounts of water and solutes, even when kidney mass is reduced to 20% to 25% of normal. Over a period of several years, however, these renal adaptive changes may lead to further nephron injury, particularly to the glomeruli of these nephrons.

This progressive injury may be partly related to increased pressure or stretch of the remaining glomeruli, which occurs as a result of functional vasodilation of afferent arterioles or increased blood pressure. The chronic increases in pressure and stretch of the small arterioles and glomeruli are believed to cause injury and sclerosis of these vessels (replacement of normal tissue with connective tissue). These sclerotic lesions may eventually obliterate the glomerulus, leading to further reduction in kidney function, further adaptive changes in the remaining nephrons, and a slowly progressing vicious cycle that eventually terminates in ESRD (**Fig. 32.2**). An effective method of slowing down this progressive loss of kidney function is to lower arterial pressure and glomerular hydrostatic pressure, especially by using drugs such as angiotensin-converting enzyme (ACE) inhibitors or Ang II receptor antagonists.

Table 32.5 lists the most common causes of ESRD. In the early 1980s, *glomerulonephritis* in all its various forms was believed to be the most common initiating cause of ESRD. More recently, *diabetes mellitus* and *hypertension* have become recognized as the leading causes of ESRD, together accounting for more than 75% of all ESRD.

Table 32.5 Most Common Causes of End-Stage Renal Disease (ESRD)

Cause	Approximate Percentage of Patients With ESRD[a]
Diabetes mellitus	47
Hypertension	29
Glomerulonephritis	8
Polycystic kidney disease	2
Other, unknown	14

[a]The percentages listed above are approximate since hypertension and diabetes mellitus often occur together.

Excessive weight gain (obesity) appears to be the most important risk factor for the two main causes of ESRD—diabetes and hypertension—which often occur together and interact synergistically to cause kidney damage. As discussed in Chapter 79, type 2 diabetes is closely linked to obesity and accounts for 90% to 95% of all cases of diabetes mellitus. Excess weight gain is also a major cause of essential hypertension, accounting for 65% to 75% of the risk for developing hypertension in adults. In addition to causing renal injury through diabetes and hypertension, obesity may have additive or synergistic effects to worsen renal function in patients with preexisting kidney disease.

RENAL VASCULAR INJURY AS A CAUSE OF CKD

Many types of vascular lesions can lead to renal ischemia and death of kidney tissue. The most common of these lesions are the following: (1) *atherosclerosis* of the larger renal arteries, with progressive sclerotic constriction of the vessels; (2) *fibromuscular hyperplasia* of one or more of the large arteries, which also causes occlusion of the vessels; and (3) *nephrosclerosis*, caused by sclerotic lesions of the smaller arteries, arterioles, and glomeruli.

Atherosclerotic or hyperplastic lesions of the large arteries frequently affect one kidney more than the other and therefore cause unilaterally diminished kidney function. As discussed in Chapter 19, hypertension often occurs when the artery of one kidney is constricted while the artery of the other kidney is still normal, a condition analogous to so-called two-kidney Goldblatt hypertension.

Benign nephrosclerosis, the most common form of kidney disease, is observed in about 70% of postmortem examinations in people who die after the age of 60 years. This type of vascular lesion occurs in smaller interlobular arteries and afferent arterioles of the kidney. It is believed to begin with leakage of plasma through the intimal membrane of these vessels. This leakage causes fibrinoid deposits to develop in the medial layers of these vessels, followed by progressive thickening of the vessel wall that eventually constricts the vessels and, in some cases,

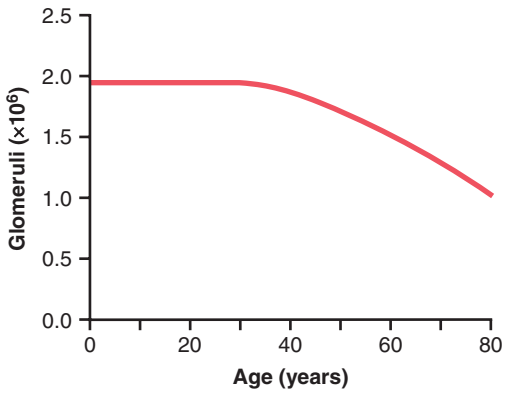

Figure 32.3 Effect of aging on the number of functional glomeruli.

occludes them. Because there is essentially no collateral circulation among the smaller renal arteries, occlusion of one or more of them causes destruction of a comparable number of nephrons. Therefore, the affected kidney tissue becomes replaced by small amounts of fibrous tissue. When sclerosis occurs in the glomeruli, the injury is referred to as *glomerulosclerosis*.

Nephrosclerosis and glomerulosclerosis occur to some extent in most people after the fourth decade of life, causing about a 10% decrease in the number of functional nephrons for every 10 years after the age of 40 years (**Fig. 32.3**). This loss of glomeruli and overall nephron function is reflected by a progressive decrease in renal blood flow and GFR. Even in healthy people without underlying hypertension or diabetes, renal plasma flow and GFR may decrease by 40% to 50% by the age of 80 years. Fortunately, the adaptive changes discussed previously permit maintenance of relatively normal blood concentrations of most electrolytes and body fluid volumes until the number of functioning nephrons decreases by 75% or more.

The frequency and severity of nephrosclerosis and glomerulosclerosis are greatly increased by concurrent *hypertension* or *diabetes mellitus*. Thus, benign nephrosclerosis in association with severe hypertension can lead to a rapidly progressing *malignant nephrosclerosis*. The characteristic histological features of malignant nephrosclerosis include large amounts of fibrinoid deposits in the arterioles and progressive thickening of the blood vessels, with severe ischemia occurring in the affected nephrons.

GLOMERULAR INJURY AS A CAUSE OF CKD—GLOMERULONEPHRITIS

Chronic glomerulonephritis can be caused by several diseases that cause inflammation and damage to the glomerular capillary loops of the kidneys. In contrast to the acute form of this disease, chronic glomerulonephritis is a slowly progressive disease that often leads to irreversible renal failure. It may be a primary kidney disease, following acute glomerulonephritis, or it may be secondary to a systemic disease, such as *systemic lupus erythematosus*, an autoimmune disease in which the immune system attacks its own tissues, causing inflammation and damage to several organs, including the kidneys.

In most cases, chronic glomerulonephritis begins with accumulation of precipitated antigen-antibody complexes in the glomerular membrane. In contrast to acute glomerulonephritis, streptococcal infections account for only a small percentage of patients with chronic glomerulonephritis. Accumulation of antigen-antibody complex in the glomerular membranes causes inflammation, progressive thickening of the membranes, and eventual invasion of glomeruli by fibrous tissue. In later stages of the disease, the glomerular capillary filtration coefficient becomes greatly reduced because of decreased numbers of filtering capillaries in the glomerular tufts and because of thickened glomerular membranes. In the final stages of the disease, many glomeruli are replaced by fibrous tissue and are unable to filter fluid.

RENAL INTERSTITIUM INJURY AS A CAUSE OF CKD—INTERSTITIAL NEPHRITIS

Primary or secondary disease of the renal interstitium is referred to as *interstitial nephritis*. In general, this condition can result from vascular, glomerular, or tubular damage that destroys individual nephrons, or it can involve primary damage to the renal interstitium by poisons, drugs, and bacterial infections.

Renal interstitial injury caused by bacterial infection is called *pyelonephritis*. The infection can result from different types of bacteria but especially from *Escherichia coli*, which originates from fecal contamination of the urinary tract. These bacteria reach the kidneys either by way of the bloodstream or, more commonly, by ascension from the lower urinary tract via the ureters to the kidneys.

Although the normal bladder is able to clear bacteria readily, there are two general clinical conditions that may interfere with the normal flushing of bacteria from the bladder: (1) the inability of the bladder to empty completely, leaving residual urine in the bladder; and (2) obstruction of urine outflow. With impaired ability to flush bacteria from the bladder, the bacteria multiply, and the bladder becomes inflamed, a condition termed *cystitis*. Once cystitis occurs, it may remain localized without ascending to the kidney or, in some people, bacteria may reach the renal pelvis because of a pathological condition in which urine is propelled up one or both of the ureters during micturition. This condition is called *vesicoureteral reflux* and is due to failure of the bladder wall to occlude the ureter during micturition; as a result, some of the urine is propelled upward toward the kidney, carrying with it bacteria that can reach the renal pelvis and renal medulla, where they can initiate infection and inflammation associated with pyelonephritis.

Pyelonephritis begins in the renal medulla and therefore usually affects the function of the medulla more than it affects the cortex, at least in the initial stages. Because one of the primary functions of the medulla is to provide

the countercurrent mechanism for concentrating urine, patients with pyelonephritis frequently have markedly impaired ability to concentrate the urine.

With long-standing pyelonephritis, invasion of the kidneys by bacteria not only causes damage to the renal medulla interstitium but also progressive damage of renal tubules, glomeruli, and other structures throughout the kidney. Consequently, large parts of functional renal tissue are lost, and CKD can develop.

NEPHROTIC SYNDROME—EXCRETION OF PROTEIN IN THE URINE

Nephrotic syndrome, characterized by the loss of large quantities of plasma proteins into the urine, develops in many patients with kidney disease. In some cases, this syndrome occurs without evidence of other major abnormalities of kidney function, but it is usually associated with some degree of CKD.

The cause of the protein loss in the urine is usually increased permeability of the glomerular membrane. Therefore, diseases that increase glomerular permeability can cause the nephrotic syndrome. Such diseases include the following: (1) *chronic glomerulonephritis*, which affects primarily the glomeruli and often causes greatly increased glomerular permeability; (2) *amyloidosis*, which results from deposition of an abnormal proteinoid substance in the walls of the blood vessels and seriously damages the basement membrane of the glomeruli; and (3) *minimal-change nephrotic syndrome*, which has been associated with an abnormal immune response and increased T-cell secretion of cytokines that cause podocyte injury and increased glomerular permeability to lower molecular weight proteins, such as albumin.

Minimal-change nephropathy can occur in adults, but more frequently it occurs in children between the ages of 2 and 6 years. Increased permeability of the glomerular capillary membrane occasionally allows as much as 40 grams of plasma protein loss into the urine each day, which is an extreme amount for a young child. Therefore, the child's plasma protein concentration often falls below 2 g/dL, and the colloid osmotic pressure falls from a normal value of 28 mm Hg to less than 10 mm Hg. As a consequence of this low colloid osmotic pressure in the plasma, large amounts of fluid leak from the capillaries all over the body into most of the tissues, causing severe edema, as discussed in Chapter 25.

NEPHRON FUNCTION IN CKD

Loss of Functional Nephrons Requires Surviving Nephrons to Excrete More Water and Solutes. It would be reasonable to suspect that decreasing the number of functional nephrons, which reduces the GFR, would also cause major decreases in renal excretion of water and solutes. Yet, patients who have lost up to 75% to 80% of their nephrons are able to excrete normal amounts of water and electrolytes without serious accumulation of fluid or most electrolytes in the body fluids. Further reduction in the number of nephrons, however, leads to electrolyte and fluid retention, and death usually ensues when the number of nephrons falls below 5% to 10% of normal.

In contrast to the electrolytes, waste products of metabolism, such as urea and creatinine, accumulate almost in proportion to the number of nephrons that have been destroyed. The reason for this is that substances such as creatinine and urea depend largely on glomerular filtration for their excretion, and they are not reabsorbed as avidly as electrolytes. Creatinine, for example, is not reabsorbed at all, and the excretion rate is approximately equal to the rate at which it is filtered (neglecting the small amount that is secreted):

$$\text{Creatinine filtration rate} = \text{GFR} \times \text{Plasma creatinine concentration} = \text{Creatinine excretion rate}$$

Therefore, if GFR decreases, creatinine excretion rate also transiently decreases, causing creatinine accumulation in the body fluids and raising plasma concentration until creatinine excretion rate returns to normal—the same rate at which creatinine is produced in the body (**Fig. 32.4**). Thus, under steady-state conditions, creatinine excretion

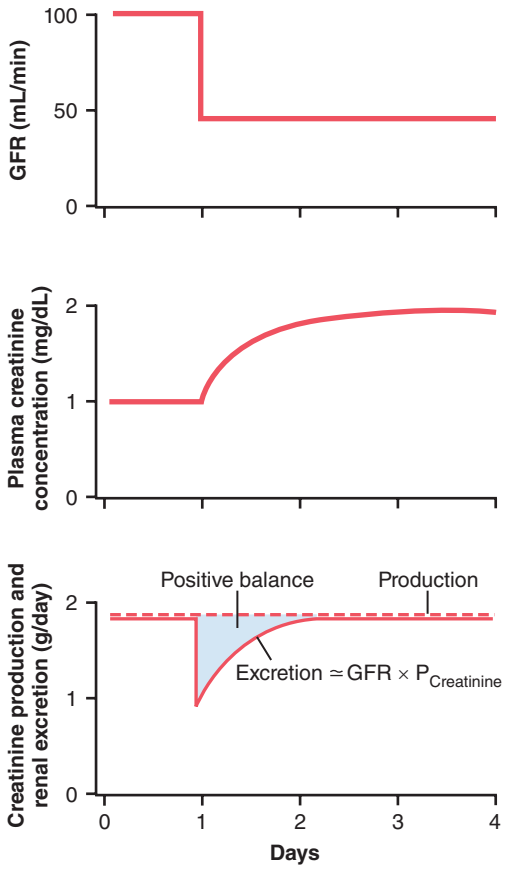

Figure 32.4 Effect of reducing the glomerular filtration rate (GFR) by 50% on serum creatinine concentration and creatinine excretion rate if the production rate of creatinine remains constant.

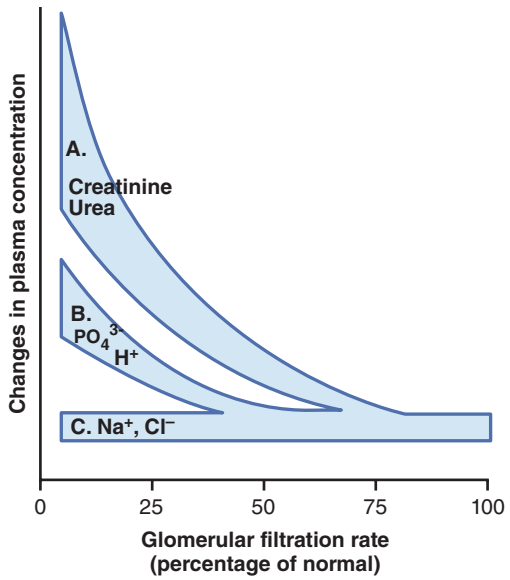

Figure 32.5 Representative patterns of adaptation for different types of solutes in chronic renal failure. *Curve A* shows the approximate changes in the plasma concentrations of solutes such as creatinine and urea that are filtered and poorly reabsorbed. *Curve B* shows the approximate concentrations for solutes such as phosphate, urate, and hydrogen ion. *Curve C* shows the approximate concentrations for solutes such as sodium and chloride.

Table 32.6 Total Kidney Excretion and Excretion per Nephron in Kidney Disease

	Normal	75% Loss of Nephrons
Number of nephrons	2,000,000	500,000
Total glomerular filtration rate (GFR; mL/min)	125	40
Single-nephron GFR (nL/min)	62.5	80
Volume excreted for all nephrons (mL/min)	1.5	1.5
