Volume excreted per nephron (nL/min)	0.75	3.0

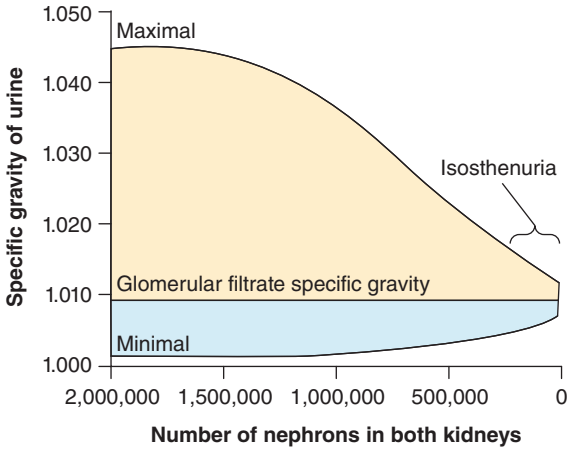

Figure 32.6 Development of isosthenuria in a patient with decreased numbers of functional nephrons.

rate equals the rate of creatinine production, despite reductions in GFR; however, this normal rate of creatinine excretion occurs at the expense of an elevated plasma creatinine concentration, as shown in **Fig. 32.4** and in curve A of **Fig. 32.5**.

Some solutes, such as phosphate, urate, and hydrogen ions, are often maintained near the normal range until GFR falls below 20% to 30% of normal. Thereafter, the plasma concentrations of these substances rise, but not in proportion to the fall in GFR, as shown in curve B of **Fig. 32.5**. Maintenance of relatively constant plasma concentrations of these solutes as GFR declines is accomplished by excreting progressively larger fractions of the amounts of these solutes that are filtered at the glomerular capillaries; this occurs by decreasing the rate of tubular reabsorption or, in some cases, by increasing tubular secretion rates.

In the case of sodium and chloride ions, their plasma concentrations are maintained virtually constant, even with severe decreases in GFR (see curve C of **Fig. 32.5**). This maintenance is accomplished by greatly decreasing tubular reabsorption of these electrolytes.

For example, with a 75% loss of functional nephrons, each surviving nephron must excrete four times as much sodium and four times as much volume as under normal conditions (**Table 32.6**). Part of this adaptation occurs because of increased blood flow and increased GFR in each of the surviving nephrons due to hypertrophy of the blood vessels and glomeruli, as well as functional changes that cause the blood vessels to dilate. Even with large decreases in the total GFR, normal rates of renal excretion can still be maintained by decreasing the rate at which the tubules reabsorb water and solutes.

Isosthenuria—Inability of the Kidney to Concentrate or Dilute the Urine. One important effect of the rapid rate of tubular flow that occurs in the remaining nephrons of diseased kidneys is that the renal tubules lose their ability to concentrate or dilute the urine fully. The concentrating ability of the kidney is impaired mainly because of the following: (1) the rapid flow of tubular fluid through the collecting ducts reduces the percentage of the tubular flow that is reabsorbed; and (2) the rapid flow through both the loop of Henle and collecting ducts prevents the countercurrent mechanism from operating effectively to concentrate the medullary interstitial fluid solutes. Therefore, as progressively more nephrons are destroyed, the maximum concentrating ability of the kidney declines, and urine osmolarity and specific gravity approach the osmolarity and specific gravity of the glomerular filtrate, as shown in **Fig. 32.6**.

The diluting mechanism in the kidney is also impaired when the number of nephrons decreases markedly

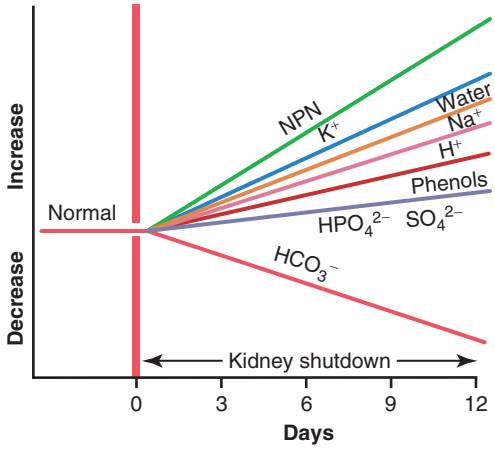

Figure 32.7 Effect of kidney failure on extracellular fluid constituents. *NPN*, Nonprotein nitrogens.

because the rapid flushing of fluid through the loops of Henle and high load of solutes such as urea cause a relatively high solute concentration in the tubular fluid of this part of the nephron. As a consequence, the diluting capacity of the kidney is impaired, and the minimal urine osmolality and specific gravity approach those of the glomerular filtrate. Because the concentrating mechanism becomes impaired to a greater extent than the diluting mechanism in CKD, a useful clinical test of renal function is to determine how well the kidneys can concentrate urine when a person's water intake is restricted for 12 or more hours.

Effects of Renal Failure on the Body Fluids—Uremia

The effect of CKD on the body fluids depends on water and food intake, as well as the degree of impairment of renal function. Assuming that a person with complete renal failure continues to ingest the same amounts of water and food, the concentrations of different substances in the extracellular fluid would change, as shown in **Fig. 32.7**. Important effects include: (1) *generalized edema* resulting from water and salt retention; (2) *acidosis* resulting from failure of the kidneys to rid the body of normal acidic products; (3) *high concentration of the nonprotein nitrogens*—especially urea, creatinine, and uric acid—resulting from failure of the body to excrete the metabolic end products of proteins; and (4) *high concentrations of other substances* excreted by the kidney, including *phenols, sulfates, phosphates, potassium*, and *guanidine bases*. This total condition is called *uremia* because of the high concentration of urea in the body fluids.

Water Retention and Development of Edema in CKD. If water intake is restricted immediately after kidney injury begins, the total body fluid content may become only slightly increased. If fluid intake is not limited, and the patient drinks in response to the normal thirst mechanisms, the body fluids begin to increase rapidly.

As long as salt and fluid intake are not excessive, accumulation of fluid in CKD may not be severe until kidney function falls to 25% of normal or lower. The reason for this, as discussed previously, is that the surviving nephrons excrete larger amounts of salt and water. Even the small fluid retention that does occur, along with increased secretion of renin and Ang II formation that usually occurs in ischemic kidney disease, often causes severe hypertension.

When kidney function is reduced to the extent that dialysis is required to preserve life, hypertension almost invariably develops. In many of these patients, severe reduction of salt intake or removal of extracellular fluid by dialysis can control the hypertension. Some patients continue to have hypertension, even after excess sodium has been removed by dialysis. In this group, removal of the ischemic kidneys usually corrects the hypertension (as long as fluid retention is prevented by dialysis) because it removes the source of excessive renin secretion and subsequent increased Ang II formation.

Increase in Urea and Other Nonprotein Nitrogens (Azotemia). The nonprotein nitrogens include urea, uric acid, creatinine, and a few other compounds. These nonprotein nitrogens, in general, are the end products of protein metabolism and must be removed from the body to ensure continued normal protein metabolism in the cells. The concentrations of these nonprotein nitrogens, particularly of urea, can rise to as high as 10 times normal during 1 to 2 weeks of total renal failure. With CKD, the concentrations rise approximately in proportion to the degree of GFR reduction. For this reason, measuring the concentrations of these substances, especially of urea and creatinine, provides an important means for assessing the severity of CKD.

Acidosis in CKD. Each day, the body normally produces about 50 to 80 millimoles more metabolic acid than metabolic alkali. Therefore, when the kidneys fail to function, acid accumulates in the body fluids. The buffers of the body fluids normally can buffer 500 to 1000 millimoles of acid without lethal increases in extracellular fluid H^+ concentration, and the phosphate compounds in the bones can buffer an additional few thousand millimoles of H^+. However, when this buffering power is exhausted, the blood pH falls drastically, and the patient will become comatose and die if the pH falls below about 6.8.

Anemia in CKD Caused By Decreased Erythropoietin Secretion. Anemia almost always develops in patients with severe CKD. The most important cause of this anemia is decreased renal secretion of *erythropoietin*, which stimulates the bone marrow to produce red blood cells. If the kidneys are seriously damaged, they are unable to form adequate quantities of erythropoietin, which leads to diminished red blood cell production and consequent anemia.

The availability since 1989 of recombinant erythropoietin, however, has provided a means of treating anemia in patients with chronic renal failure.

Osteomalacia in CKD Caused By Decreased Production of Active Vitamin D and By Phosphate Retention By the Kidneys. Prolonged CKD also causes *osteomalacia*, a condition in which the bones are partially absorbed and, therefore, become greatly weakened. An important cause of osteomalacia is that vitamin D must be converted by a two-stage process, first in the liver and then in the kidneys,

into 1,25-dihydroxycholecalciferol before it is able to promote calcium absorption from the intestine. Therefore, serious damage to the kidney greatly reduces the blood concentration of *active* vitamin D, which, in turn, decreases intestinal absorption of calcium and availability of calcium to the bones.

Another important cause of demineralization of the skeleton in CKD is the rise in serum phosphate concentration that occurs as a result of decreased GFR. This rise in serum phosphate level increases binding of phosphate with calcium in the plasma, thus decreasing plasma serum *ionized* calcium concentration, which, in turn, stimulates *parathyroid hormone* secretion. This *secondary hyperparathyroidism* then stimulates the release of calcium from bones, causing further bone demineralization.

Hypertension and Kidney Disease

As discussed earlier in this chapter, hypertension exacerbates injury to the glomeruli and blood vessels of the kidneys and is a major cause of ESRD. Abnormalities of kidney function can also cause hypertension, as discussed in Chapter 19. Thus, the relationship between hypertension and kidney disease can, in some cases, propagate a vicious cycle—primary kidney damage leads to increased blood pressure, which causes further damage to the kidneys and further increases in blood pressure, until ESRD develops.

Not all types of kidney disease cause hypertension because damage to certain portions of the kidney causes uremia without hypertension. Nevertheless, some types of renal damage are particularly prone to cause hypertension. A classification of kidney disease relative to hypertensive or nonhypertensive effects is provided in the following sections.

Renal Lesions That Reduce the Ability of the Kidneys to Excrete Sodium and Water Promote Hypertension. Renal lesions that decrease the kidneys' ability to excrete sodium and water almost invariably cause hypertension. Therefore, lesions that *decrease GFR* or *increase tubular reabsorption* usually lead to hypertension of varying degrees. Some specific types of renal abnormalities that can cause hypertension are as follows:

1. *Increased renal vascular resistance*, which reduces renal blood flow and GFR. An example is hypertension caused by renal artery stenosis.
2. *Decreased glomerular capillary filtration coefficient, which reduces GFR.* An example is chronic glomerulonephritis, which causes inflammation and thickening of the glomerular capillary membranes, thereby reducing the glomerular capillary filtration coefficient.
3. *Excessive tubular sodium reabsorption.* An example is hypertension caused by excessive aldosterone secretion, which increases sodium reabsorption mainly in the cortical collecting tubules.

Once hypertension has developed, renal excretion of sodium and water returns to normal because the high arterial pressure causes pressure natriuresis and pressure diuresis, so intake and output of sodium and water become balanced once again. Even when there are large increases in renal vascular resistance or decreases in the glomerular capillary coefficient, GFR may still return to nearly normal levels after the arterial blood pressure rises. Likewise, when tubular reabsorption is increased, as occurs with excessive aldosterone secretion, urinary excretion rate is initially reduced but then returns to normal as arterial pressure rises. Thus, after hypertension develops, there may be no obvious sign of impaired excretion of sodium and water other than the hypertension. As explained in Chapter 19, normal excretion of sodium and water at an elevated arterial pressure means that pressure natriuresis and pressure diuresis have been reset to a higher arterial pressure.

Hypertension Caused By Patchy Renal Damage and Increased Renal Secretion of Renin. If the kidney is ischemic, such as when one renal artery is severely constricted, the ischemic renal tissue secretes large quantities of renin. This secretion leads to increased formation of Ang II, which can cause hypertension. The most likely sequence of events in causing this hypertension, as discussed in Chapter 19, is as follows: (1) the ischemic kidney excretes less than normal amounts of water and salt; (2) the renin secreted by the ischemic kidney, as well as the subsequent increased Ang II formation, affects the nonischemic kidney, causing it also to retain salt and water; and (3) excess salt and water cause hypertension in the usual manner.

A similar type of hypertension can result when patchy areas of one or both kidneys become ischemic as a result of arteriosclerosis or vascular injury in specific portions of the kidneys. When this occurs, the ischemic nephrons excrete less salt and water but secrete greater amounts of renin, which causes increased Ang II formation. The high levels of Ang II then impair the ability of the surrounding, otherwise normal nephrons to excrete sodium and water. As a result, hypertension develops, which restores the overall excretion of sodium and water by the kidneys, so balance between intake and output of salt and water is maintained, but at the expense of high blood pressure.

Kidney Diseases That Cause Loss of Entire Nephrons Lead to CKD but May Not Cause Hypertension

Loss of large numbers of whole nephrons, such as occurs with the loss of one kidney and part of another kidney, almost always leads to many abnormalities associated with CKD if the loss of kidney tissue is great enough. However, if the remaining nephrons are normal and salt intake is not excessive, this condition might not cause clinically significant hypertension. This is because even a small rise in blood pressure, when combined with other compensations such as decreased formation of Ang II and aldosterone, may increase sodium and water excretion in surviving nephrons enough to maintain balance. However, a patient with this type of CKD may become hypertensive if additional stresses are imposed, such as excessive salt intake. In this case, the kidneys cannot clear adequate quantities of salt at a normal blood pressure with the small number of functioning nephrons that remain. Increased blood pressure helps restore excretion of salt and water to match intake of salt and water under steady-state conditions.

Effective treatment of hypertension requires enhancing the kidneys' capability to excrete salt and water by

increasing GFR or decreasing tubular reabsorption, so that balance between intake and renal excretion of salt and water excretion can be maintained at a lower blood pressure. This effect can be achieved by drugs that block the effects of nervous and hormonal signals that cause the kidneys to retain salt and water (e.g., with β-adrenergic blockers, Ang II receptor antagonists, ACE inhibitors, mineralocorticoid receptor antagonists), with drugs that vasodilate the kidneys and increase GFR (e.g., calcium channel blockers), or with diuretic drugs that directly inhibit renal tubular reabsorption of salt and water.

Specific Tubular Disorders

In Chapter 28, we discussed several mechanisms responsible for transporting different individual substances across the tubular epithelial membranes. In Chapter 3, we also pointed out that each cellular enzyme and each carrier protein is formed in response to a respective gene in the nucleus. If expression of any of these genes is deficient (due to a mutation, for example), the tubules may be deficient in one of the appropriate carrier proteins or one of the enzymes needed for solute transport by the renal tubular epithelial cells. In other cases, too much of the enzyme or carrier protein may be produced. Thus, there are many hereditary tubular disorders associated with abnormal transport of individual substances or groups of substances through the tubular membrane. In addition, renal tubular disorders may be acquired due to damage to the tubular epithelial membrane by toxins, inflammation, or ischemia.

Nondiabetic Renal Glycosuria—Failure of the Kidneys to Reabsorb Glucose. In *nondiabetic renal glycosuria*, the blood glucose concentration may be normal, but the transport mechanism for tubular reabsorption of glucose is greatly limited or absent. Consequently, despite a normal blood glucose level, large amounts of glucose are excreted in the urine. Because diabetes mellitus is also associated with the presence of glucose in the urine, nondiabetic renal glycosuria must be ruled out before making the diagnosis of diabetes mellitus.

Nondiabetic glycosuria can be hereditary, due to mutations of the sodium-glucose transporter 2 (SGLT2). Glycosuria can also be acquired as a result of disorders that produce a generalized reduction in proximal tubule function (e.g., Fanconi syndrome or tubulointerstitial nephritis) or as a result of medications that specifically reduce proximal tubular glucose reabsorption (e.g., SGLT2 inhibitors). Glycosuria leads to increased urine volume, via osmotic diuresis, and compensatory increases in thirst, as well as increased susceptibility to genital and urinary tract infections.

Aminoaciduria—Failure of the Kidneys to Reabsorb Amino Acids. Some amino acids share mutual transport systems for reabsorption, whereas other amino acids have their own distinct transport systems. Rarely, a condition called *generalized aminoaciduria* results from deficient reabsorption of all amino acids. More frequently, deficiencies of specific carrier systems may result in the following: (1) *essential cystinuria*, in which large amounts of cystine fail to be reabsorbed and often crystallize in the urine to form renal stones; (2) *simple glycinuria*, in which glycine fails to be reabsorbed; or (3) *beta-aminoisobutyricaciduria*, which occurs in about 5% of the population but apparently has no major clinical significance.

Renal Hypophosphatemia—Failure of the Kidneys to Reabsorb Phosphate. In renal hypophosphatemia, the renal tubules fail to reabsorb enough phosphate ions when the phosphate concentration of the body fluids falls very low. There are several rare syndromes characterized by primary renal phosphate wasting. Mutations of the sodium-phosphate co-transporter gene, for example, are associated with increased phosphate excretion and hypophosphatemia. Gain of function mutations in genes that encode for *fibroblast growth factor-23 (FGF-23)*, a bone-derived hormone that suppresses phosphate reabsorption in the kidney, can also lead to hypophosphatemia.

Renal hypophosphatemia usually does not cause serious immediate abnormalities because the phosphate concentration of the extracellular fluid can vary widely without causing major cellular dysfunction. Over a long period, however, a low phosphate level causes diminished calcification of the bones, causing *rickets* to develop. This type of rickets is refractory to vitamin D therapy, in contrast to the rapid response of the usual type of rickets, as discussed in Chapter 80.

Renal Tubular Acidosis—Reduced Tubular Secretion of Hydrogen Ions. In renal tubular acidosis, the renal tubules are unable to secrete adequate amounts of hydrogen ions. As a result, large amounts of sodium bicarbonate are continually lost in the urine. This loss causes a continued state of metabolic acidosis, as discussed in Chapter 31. This type of renal abnormality can be caused by hereditary disorders or can occur as a result of widespread injury to the renal tubules.

Nephrogenic Diabetes Insipidus—Failure of the Kidneys to Respond to Antidiuretic Hormone. Occasionally, the renal tubules do not respond to antidiuretic hormone (ADH), causing large quantities of dilute urine to be excreted. As long as the person is supplied with plenty of water, this condition seldom causes severe difficulty. However, when adequate quantities of water are not available, the person rapidly becomes dehydrated.

Fanconi Syndrome—Generalized Reabsorptive Defect of the Renal Tubules. Fanconi syndrome is usually associated with increased urinary excretion of virtually all amino acids, glucose, and phosphate. In severe cases, other manifestations are also observed, such as (1) failure to reabsorb sodium bicarbonate, which results in metabolic acidosis; (2) increased excretion of potassium and sometimes calcium; and (3) nephrogenic diabetes insipidus.

There are multiple causes of Fanconi syndrome, which results from a generalized inability of the renal tubular cells to transport various substances. Some of these include the following: (1) hereditary defects in cell transport mechanisms; (2) toxins or drugs that injure the renal tubular epithelial cells; and (3) injury to the renal tubular cells as a result of ischemia or inflammatory disorders. The proximal tubular cells are especially affected in Fanconi syndrome caused by tubular injury because these cells reabsorb and secrete many of the drugs and toxins that can cause damage.

Bartter Syndrome—Decreased Sodium, Chloride, and Potassium Reabsorption in the Loops of Henle. *Bartter syndrome* is a rare group of kidney disorders caused by mutations that impair function of the 1-sodium, 2-chloride, 1-potassium co-transporter or by defects in potassium channels in the luminal membrane or chloride channels in the basolateral membrane of the thick ascending loop of Henle. At least five mutations, usually inherited in an autosomal-recessive manner, have been found to cause Bartter syndrome. These disorders result in increased excretion of water, sodium, chloride, potassium, and calcium by the kidneys. The salt and water loss leads to mild volume depletion, resulting in activation of the RAAS. The increased aldosterone and high distal tubular flow, due to impaired loop of Henle reabsorption, stimulate potassium and hydrogen secretion in the collecting tubules, leading to hypokalemia and metabolic alkalosis.

Gitelman Syndrome—Decreased Sodium Chloride Reabsorption in the Distal Tubules. *Gitelman syndrome* is an autosomal-recessive disorder of the thiazide-sensitive sodium-chloride co-transporter in the distal tubules. Patients with Gitelman syndrome have some of the same characteristics as patients with Bartter syndrome—salt and water loss, mild water volume depletion, and activation of the RAAS—although these abnormalities are usually less severe in persons with Gitelman syndrome.

Because the tubular defects in Bartter or Gitelman syndrome cannot currently be corrected, treatment is usually focused on replacing the losses of sodium chloride and potassium. Some studies have suggested that blockade of prostaglandin synthesis with nonsteroidal antiinflammatory drugs (NSAIDs) and administration of aldosterone antagonists, such as spironolactone, may be useful in correcting the hypokalemia.

Liddle Syndrome—Increased Sodium Reabsorption. *Liddle syndrome* is a rare autosomal-dominant disorder resulting from various mutations in the amiloride-sensitive epithelial sodium channel (ENaC) in the distal and collecting tubules. These mutations cause excessive activity of ENaC, resulting in increased reabsorption of sodium and water, hypertension, and metabolic alkalosis similar to the changes that occur with oversecretion of aldosterone (primary aldosteronism).

Patients with Liddle syndrome, however, have sodium retention associated with decreased renin secretion and Ang II levels, which, in turn, decrease adrenal secretion of aldosterone. Fortunately, Liddle syndrome can be treated with the diuretic amiloride, which blocks the excessive ENaC activity.

Treatment of Renal Failure By Transplantation or Dialysis With an Artificial Kidney.

Severe loss of kidney function, acutely or chronically, is life-threatening and requires removal of toxic waste products and restoration of body fluid volume and composition toward normal. This can be accomplished by kidney transplantation or by dialysis with an artificial kidney. Over 800,000 patients in the United States are currently receiving some form of ESRD therapy.

Successful transplantation of a single donor kidney to a patient with ESRD can restore kidney function to a level sufficient to maintain essentially normal homeostasis of body fluids and electrolytes. Although approximately 25,000 kidney transplantations are performed each year in the United States, this number represents only a small percentage of patients who are waiting to receive donor kidneys.

Patients who receive kidney transplants typically live longer and have fewer health problems than those who are maintained with dialysis. Maintenance of immunosuppressive therapy is required for almost all patients to help prevent acute rejection and loss of the transplanted kidney. The side effects of drugs that suppress the immune system include increased risk for infections and some cancers, although the amount of immunosuppressive therapy can usually be reduced over time to reduce these risks greatly.

The vast majority of people who develop chronic kidney failure are treated by dialysis with artificial kidneys due in large part to the shortage of donor kidneys. Dialysis is also used in certain types of AKI to tide the patient over until the kidneys resume their function. If the loss of kidney function is irreversible, it is necessary to perform dialysis chronically to maintain life. Because dialysis cannot maintain completely normal body fluid composition and cannot replace all the multiple functions performed by the kidneys, the health of patients maintained with the use of artificial kidneys usually remains significantly impaired.

Basic Principles of Dialysis. The basic principle of the artificial kidney is to pass blood through minute blood channels bounded by a thin membrane. On the other side of the membrane is a *dialyzing fluid* into which unwanted substances in the blood pass by diffusion.

Fig. 32.8 shows the components of one type of artificial kidney in which blood flows continually between two thin membranes of cellophane; outside the membrane is a dialyzing fluid. The cellophane is porous enough to allow the constituents of the plasma, except the plasma proteins, to diffuse in both directions—from plasma into the dialyzing fluid or from the dialyzing fluid back into the plasma. If the concentration of a substance is higher in the plasma than in the dialyzing fluid, there will be a *net* transfer of the substance from the plasma into the dialyzing fluid.

The rate of movement of solute across the dialyzing membrane depends on the following: (1) the concentration gradient of the solute between the two solutions; (2) the permeability of the membrane to the solute; (3) the surface area of the membrane; and (4) the length of time that the blood and fluid remain in contact with the membrane.

Thus, the maximum rate of solute transfer occurs initially when the concentration gradient is greatest (when dialysis is begun) and slows down as the concentration gradient is dissipated. In a flowing system, as is the case with hemodialysis, in which blood and dialysate fluid flow through the artificial kidney, the dissipation of the concentration gradient can be reduced, and diffusion of solute across the membrane can be optimized, by increasing the flow rate of the blood, dialyzing fluid, or both.

In normal operation of the artificial kidney, blood flows continually or intermittently back into the vein. The total amount of blood in the artificial kidney at any one time is usually less than 500 milliliters, the rate of flow may be

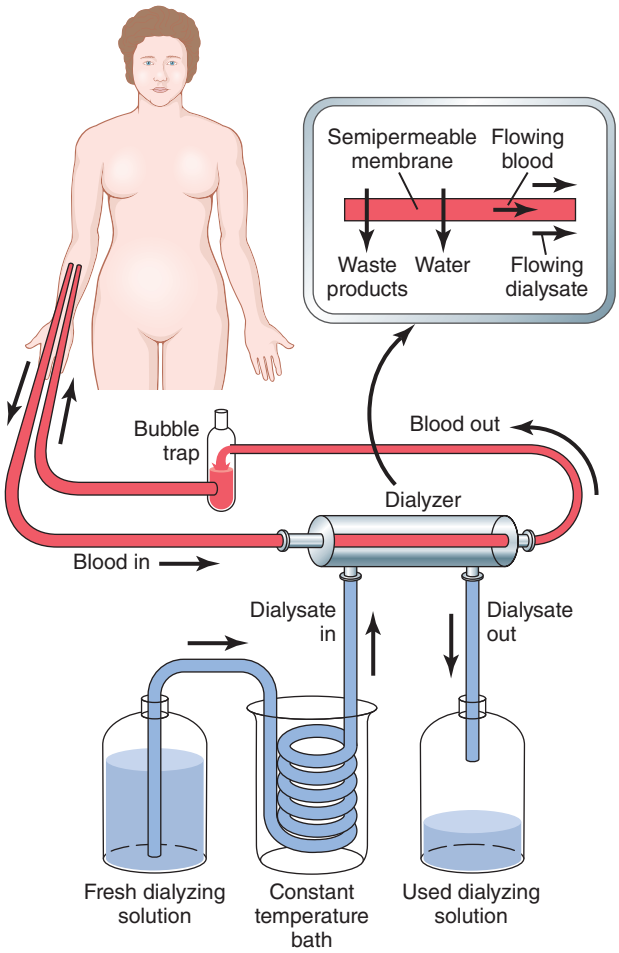

Figure 32.8 Principles of dialysis with an artificial kidney.

several hundred milliliters per minute, and the total diffusion surface area is between 0.6 and 2.5 m^2. To prevent coagulation of the blood in the artificial kidney, a small amount of heparin is infused into the blood as it enters the artificial kidney. In addition to the diffusion of solutes, mass transfer of solutes and water can be produced by applying a hydrostatic pressure to force the fluid and solutes across the membranes of the dialyzer; this type of filtration is called *bulk flow* or *hemofiltration.*

Dialyzing Fluid. Table 32.7 compares the constituents in a typical dialyzing fluid with those in normal plasma and uremic plasma. Note that the concentrations of ions and other substances in dialyzing fluid are not the same as the concentrations in normal plasma or in uremic plasma. Instead, they are adjusted to levels needed to cause the appropriate movement of water and solutes through the membrane during dialysis.

Also note that there is no phosphate, urea, urate, sulfate, or creatinine in the dialyzing fluid; however, these substances are present in high concentrations in the uremic blood. Therefore, when a uremic patient undergoes dialysis, these substances are lost in large quantities into the dialyzing fluid.

The effectiveness of the artificial kidney can be expressed in terms of the amount of plasma that is cleared of different substances each minute, which, as discussed in Chapter 28, is the primary means for expressing the functional effectiveness of the kidneys themselves to rid the body of unwanted substances. Most artificial kidneys can clear urea from the plasma at a rate of 100 to 225 mL/min, which is about twice as rapidly as two normal kidneys together, whose urea clearance is only 70 mL/min. Yet, the artificial kidney is used only for 4 to 6 hours/day, three times a week. Therefore, the overall plasma clearance is still considerably limited when the artificial kidney replaces the normal kidneys. Also, it is important to keep in mind that the artificial kidney cannot replace some of the other functions of the kidneys, such as secretion of erythropoietin, which is necessary for red blood cell production.

Table 32.7 Comparison of Dialyzing Fluid With Normal and Uremic Plasma

Constituent	Normal Plasma	Dialyzing Fluid	Uremic Plasma
Electrolytes (mEq/L)			
Na^+	142	133	142
K^+	4.2	1.0	7
Ca^{2+}	3	3	2
Mg^{2+}	1.5	1.5	1.5
Cl^-	106	105	107
HCO_3^-	24	35.7	14
$Lactate^-$	1.2	1.2	1.2
HPO_4^{2-}	3	0	9
$Urate^-$	0.3	0	2
$Sulfate^{2-}$	0.5	0	3
Nonelectrolytes (mg/dL)			
Glucose	100	125	100
Urea	14	0	200
Creatinine	1	0	6

CHAPTER 33

Red Blood Cells, Anemia, and Polycythemia

In this chapter, we discuss the *blood cells* and cells of the *macrophage system* and *lymphatic system*. We first present the functions of red blood cells (RBCs), which are the most abundant cells of the blood and are necessary for the delivery of oxygen to the tissues.

RED BLOOD CELLS (ERYTHROCYTES)

A major function of RBCs, also known as *erythrocytes*, is to transport *hemoglobin*, which, in turn, carries oxygen from the lungs to the tissues. In some animals, including many invertebrates, hemoglobin circulates as free protein in the circulatory fluids and is not enclosed in RBCs. When it is free in human plasma, about 3% of it leaks through the capillary membrane into the tissue spaces or through the glomerular membrane of the kidney into the glomerular filtrate each time the blood passes through the capillaries. Therefore, hemoglobin must remain inside RBCs to effectively perform its functions in humans.

The RBCs have other functions besides transport of hemoglobin. For example, they contain a large quantity of *carbonic anhydrase*, an enzyme that catalyzes the reversible reaction between carbon dioxide (CO_2) and water to form carbonic acid (H_2CO_3), increasing the rate of this reaction several 1000-fold. The rapidity of this reaction makes it possible for the water of the blood to transport enormous quantities of CO_2 in the form of bicarbonate ion (HCO_3^-) from the tissues to the lungs, where it is reconverted to CO_2 and expelled into the atmosphere as a waste product. The hemoglobin in the cells is an excellent *acid-base buffer* (as is true of most proteins), so the RBCs are responsible for most of the acid-base buffering power of whole blood.

Shape and Size of Red Blood Cells. Normal RBCs, shown in **Fig. 33.3** in a later section, are biconcave discs having a mean diameter of about 7.8 micrometers and a thickness of 2.5 micrometers at the thickest point and 1 micrometer or less in the center. The average volume of the RBC is 90 to 95 cubic micrometers.

The shapes of RBCs can change remarkably as the cells squeeze through capillaries. Actually, the RBC resembles a bag that can be deformed into almost any shape. Furthermore, because the normal cell has a great excess of cell membrane for the quantity of material inside, deformation does not stretch the membrane greatly and, consequently, does not rupture the cell, as would be the case with many other cells.

Concentration of Red Blood Cells in the Blood. In healthy men, the average number of RBCs per cubic millimeter is 5.2 million (±300,000); in healthy women, it is 4.7 million (±300,000). Persons living at high altitudes have greater numbers of RBCs, as discussed later.

Quantity of Hemoglobin in the Cells. RBCs can concentrate hemoglobin in the cell fluid up to about 34 g/100 mL of cells. The concentration does not rise above this value because this is the metabolic limit of the cell's hemoglobin-forming mechanism. Furthermore, in most healthy people, the percentage of hemoglobin is almost always near the maximum in each cell. However, when hemoglobin formation is deficient, the percentage of hemoglobin in the cells may fall considerably below this value, and the volume of the RBC may decrease because of diminished hemoglobin to fill the cell.

When the hematocrit (the percentage of blood that is comprised of cells—normally, 40% to 45%) and the quantity of hemoglobin in each respective cell are normal, the whole blood of men contains an average of 15 g hemoglobin/100 mL; for women, it contains an average of 14 g hemoglobin/100 mL.

As discussed in connection with blood transport of oxygen in Chapter 41, each gram of hemoglobin can combine with 1.34 mL of oxygen if the hemoglobin is 100% saturated. Therefore, in the average man, a maximum of about 20 mL of oxygen can be carried in combination with hemoglobin in each 100 mL of blood, and in women 19 mL of oxygen can be carried.

PRODUCTION OF RED BLOOD CELLS

Areas of the Body That Produce Red Blood Cells. In the early weeks of embryonic life, primitive nucleated RBCs are produced in the *yolk sac*. During the middle trimester of gestation, the *liver* is the main organ for RBC production, but reasonable numbers are also produced in

the *spleen* and *lymph nodes*. Then, during the last month or so of gestation and after birth, RBCs are produced exclusively in the *bone marrow*.

As illustrated in **Fig. 33.1**, the marrow of essentially all bones produces RBCs until a person is about 5 years old. The marrow of the long bones, except for the proximal portions of the humeri and tibiae, becomes fatty and produces no more RBCs after about the age of 20 years. Beyond this age, most RBCs continue to be produced in the marrow of the membranous bones, such as the vertebrae, sternum, ribs, and ilia. Even in these bones, the marrow becomes less productive as age increases.

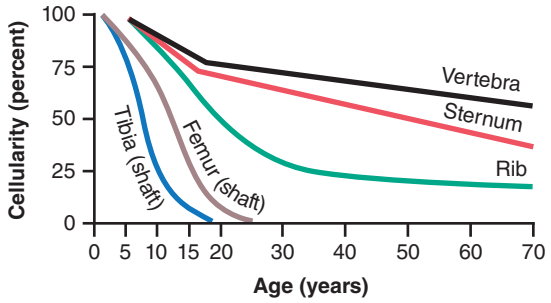

Figure 33.1 Relative rates of red blood cell production in the bone marrow of different bones at different ages.

Genesis of Blood Cells

Multipotent Hematopoietic Stem Cells, Growth Inducers, and Differentiation Inducers. The blood cells begin their lives in the bone marrow from a single type of cell called the *multipotent hematopoietic stem cell*, from which all the cells of the circulating blood are eventually derived. **Fig. 33.2** shows the successive divisions of the multipotent cells to form the different circulating blood cells. As these cells reproduce, a small portion of them remains exactly like the original multipotent cells and is retained in the bone marrow to maintain their supply, although their numbers diminish with age. Most of the reproduced cells, however, differentiate to form the other cell types, shown at the right in **Fig. 33.2**. The intermediate-stage cells are called *committed progenitor cells*.

The different hematopoietic progenitor cells, when grown in culture, will produce colonies of specific types of blood cells. A committed progenitor cell that produces erythrocytes is called a *colony-forming unit–erythrocyte*, and the abbreviation CFU-E is used to designate this type of stem cell. Likewise, colony-forming units that form granulocytes and monocytes have the designation CFU-GM, and so forth.

Growth and reproduction of the different stem cells are controlled by multiple proteins called *growth inducers*. At least four major growth inducers have been described,

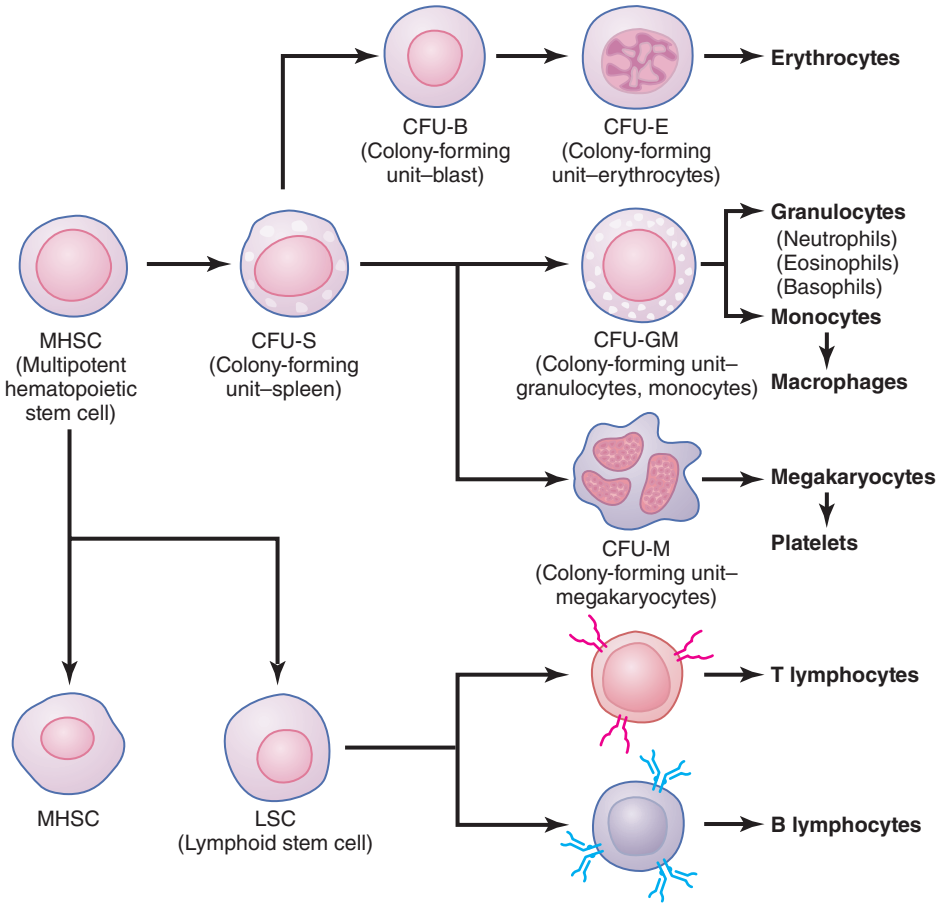

Figure 33.2 Formation of the multiple different blood cells from the original multipotent hematopoietic stem cell in the bone marrow.

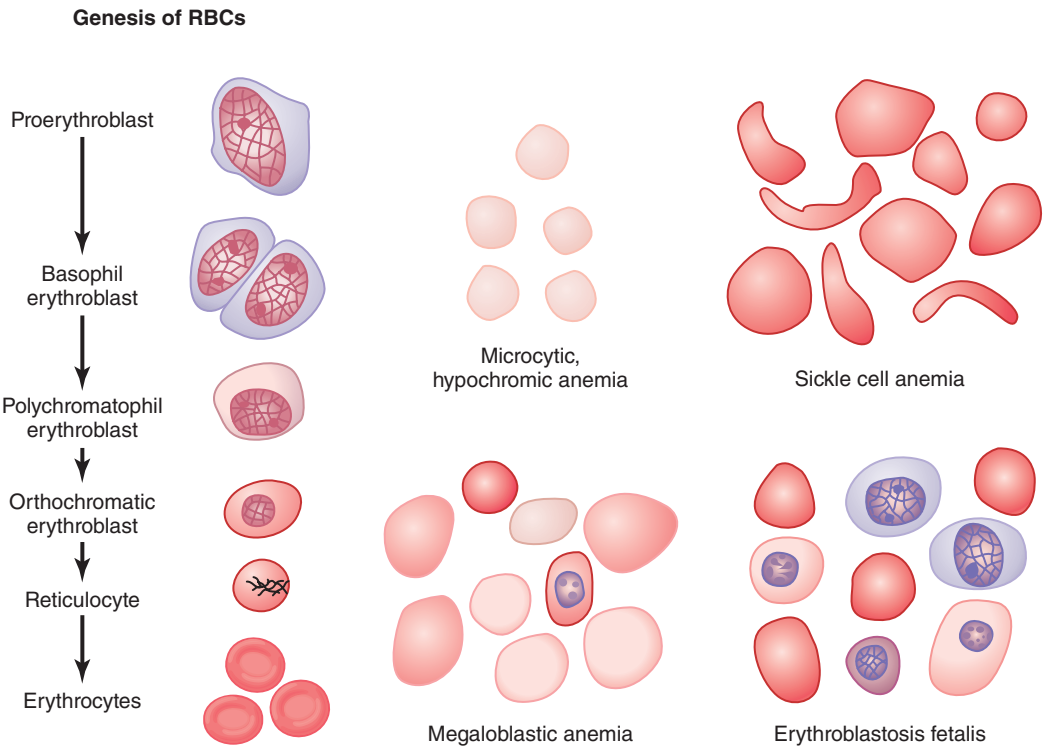

Figure 33.3 Genesis of normal red blood cells (RBCs) and characteristics of RBCs in different types of anemias.

each having different characteristics. One of these, *interleukin-3*, promotes growth and reproduction of virtually all the different types of committed stem cells, whereas the others induce growth of only specific types of cells.

The growth inducers promote growth but not differentiation of the cells, which is the function of another set of proteins called *differentiation inducers*. Each of these differentiation inducers causes one type of committed stem cell to differentiate one or more steps toward a final adult blood cell.

Formation of the growth inducers and differentiation inducers is controlled by factors outside the bone marrow. For example, in the case of RBCs, exposure of the blood to a low oxygen level for a long time causes growth induction, differentiation, and production of greatly increased numbers of RBCs, as discussed later in this chapter. In the case of some of the white blood cells, infectious diseases cause growth, differentiation, and eventual formation of specific types of white blood cells that are needed to combat each infection.

Stages of Differentiation of Red Blood Cells

The first cell that can be identified as belonging to the RBC series is the *proerythroblast*, shown at the starting point in **Fig. 33.3**. Under appropriate stimulation, large numbers of these cells are formed from the CFU-E stem cells.

Once the proerythroblast has been formed, it divides multiple times, eventually forming many mature RBCs. The first-generation cells are called *basophil erythroblasts* because they stain with basic dyes. Hemoglobin first appears in *polychromatophil erythroblasts*. In the succeeding generations, shown in **Fig. 33.3**, the cells become filled with hemoglobin to a concentration of about 34%, the nucleus condenses to a small size, and its final remnant is absorbed or extruded from the cell. At the same time, the endoplasmic reticulum is also reabsorbed. The cell at this stage is called a *reticulocyte* because it still contains a small amount of basophilic material, consisting of remnants of the Golgi apparatus, mitochondria, and a few other cytoplasmic organelles. During this reticulocyte stage, the cells pass from the bone marrow into the blood capillaries by *diapedesis* (squeezing through the pores of the capillary membrane).

The remaining basophilic material in the reticulocyte normally disappears within 1 to 2 days, and the cell is then a *mature erythrocyte*. Because of the short life of the reticulocytes, their concentration among all the RBCs is normally slightly less than 1%.

Erythropoietin Regulates Red Blood Cell Production

The total mass of RBCs in the circulatory system is regulated within narrow limits, and thus adequate numbers of RBCs are always available to provide sufficient transport of oxygen from the lungs to the tissues. However, the cells do not become so numerous that they impede blood flow. This control mechanism is diagrammed in **Fig. 33.4** and is described in the following sections.

Tissue Oxygenation Is an Essential Regulator of Red Blood Cell Production. Conditions that decrease the

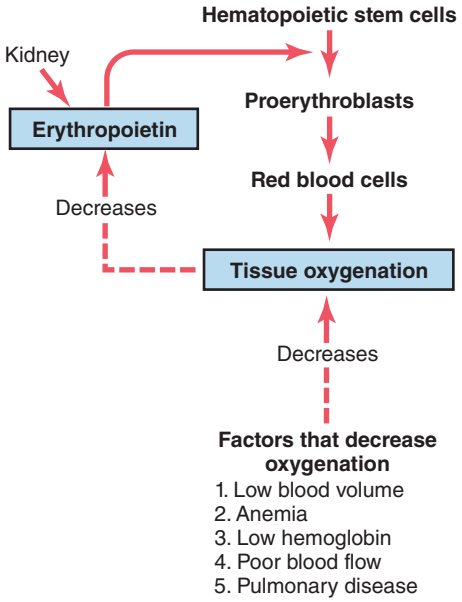

Figure 33.4 Function of the erythropoietin mechanism to increase production of red blood cells when tissue oxygenation decreases.

quantity of oxygen transported to the tissues ordinarily increase the RBC production rate. Thus, when a person becomes extremely *anemic* as a result of hemorrhage or other conditions, the bone marrow begins to produce large quantities of RBCs. Also, destruction of major portions of the bone marrow, especially by x-ray therapy, causes hyperplasia of the remaining bone marrow in an attempt to supply the body's need for RBCs.

At very *high altitudes*, where the quantity of oxygen in the air is greatly decreased, insufficient oxygen is transported to the tissues, and RBC production is greatly increased. In this case, it is not the concentration of RBCs in the blood that controls RBC production but the amount of oxygen transported to the tissues in relation to tissue demand for oxygen.

Various diseases of the circulation that decrease tissue blood flow, particularly those that cause failure of oxygen absorption by the blood as it passes through the lungs, can also increase the rate of RBC production. This result is especially apparent in prolonged *cardiac failure* and in many *lung diseases* because the tissue hypoxia resulting from these conditions increases RBC production, with a resultant increase in hematocrit and, usually, total blood volume.

Hypoxia Increases Formation of Erythropoietin, Which Stimulates Red Blood Cell Production. The principal stimulus for RBC production in a low oxygen state is a circulating hormone called *erythropoietin*, a glycoprotein with a molecular weight of about 34,000. In the absence of erythropoietin, hypoxia has little or no effect to stimulate RBC production. However, when the erythropoietin system is functional, hypoxia causes a marked increase in erythropoietin production and the erythropoietin, in turn, enhances RBC production until the hypoxia is relieved.

Erythropoietin Is Formed Mainly in the Kidneys. Normally, about 90% of all erythropoietin is formed in the kidneys, and the remainder is formed mainly in the liver. Some studies have suggested that erythropoietin is secreted mainly by fibroblast-like interstitial cells surrounding the tubules and peritubular capillaries in the cortex and outer medulla, where much of the kidney's oxygen consumption occurs. It is likely that other cells, including the renal epithelial cells and pericytes, also secrete erythropoietin in response to hypoxia.

Renal tissue hypoxia leads to increased tissue levels of *hypoxia-inducible factor-1* (HIF-1), which serves as a transcription factor for a large number of hypoxia-inducible genes, including the erythropoietin gene. HIF-1 binds to a *hypoxia response element* in the erythropoietin gene, inducing transcription of messenger RNA and, ultimately, increased erythropoietin synthesis.

At times, hypoxia in other parts of the body, but not in the kidneys, stimulates kidney erythropoietin secretion, which suggests that there might be some nonrenal sensor that sends an additional signal to the kidneys to produce this hormone. In particular, norepinephrine and epinephrine and several of the prostaglandins stimulate erythropoietin production.

When both kidneys are removed from a person, or when the kidneys are destroyed by renal disease, the person invariably becomes very anemic. This is because the 10% of the normal erythropoietin formed in other tissues (mainly in the liver) is sufficient to cause only one-third to one-half the RBC formation needed by the body.

Erythropoietin Stimulates Production of Proerythroblasts From Hematopoietic Stem Cells. When an animal or person is placed in an atmosphere of low oxygen, erythropoietin begins to be formed within minutes to hours, and it reaches maximum production within 24 hours. Yet, almost no new RBCs appear in the circulating blood until about 5 days later. From this, as well as from other studies, it has been determined that the important effect of erythropoietin is to stimulate production of proerythroblasts from hematopoietic stem cells in the bone marrow. In addition, once the proerythroblasts are formed, the erythropoietin causes these cells to pass more rapidly through the different erythroblastic stages than they normally do, further speeding up the production of new RBCs. The rapid production of cells continues as long as the person remains in a low oxygen state or until enough RBCs have been produced to carry adequate amounts of oxygen to the tissues despite the low level of oxygen; at this time, the rate of erythropoietin production decreases to a level that will maintain the required number of RBCs but not an excess.

In the absence of erythropoietin, few RBCs are formed by the bone marrow. At the other extreme, when large quantities of erythropoietin are formed, and if plenty of iron and other required nutrients are available, the rate of RBC production can rise to perhaps 10 or more times

normal. Therefore, the erythropoietin mechanism for controlling RBC production is a powerful one.

Maturation of Red Blood Cells Requires Vitamin B_{12} (Cyanocobalamin) and Folic Acid

Because of the continuing need to replenish RBCs, the erythropoietic cells of the bone marrow are among the most rapidly growing and reproducing cells in the entire body. Therefore, their maturation and rate of production are affected greatly by a person's nutritional status.

Especially important for final maturation of the RBCs are two vitamins, *vitamin B_{12}* and *folic acid*. Both these vitamins are essential for synthesis of DNA because each, in a different way, is required for formation of thymidine triphosphate, one of the essential building blocks of DNA. Therefore, lack of vitamin B_{12} or folic acid leads to failure of nuclear maturation and cell division. Furthermore, the erythroblastic cells of the bone marrow, in addition to failing to proliferate rapidly, produce mainly larger than normal RBCs called *macrocytes*, which have a flimsy membrane and are often irregular, large, and oval instead of the usual biconcave disc. These poorly formed cells, after entering the circulating blood, are capable of carrying oxygen normally, but their fragility causes them to have a short life, one-half to one-third normal. Therefore, deficiency of vitamin B_{12} or folic acid causes *maturation failure* in the process of erythropoiesis.

Maturation Failure Anemia Caused By Poor Absorption of Vitamin B_{12} From the Gastrointestinal Tract—Pernicious Anemia. A common cause of RBC maturation failure is failure to absorb vitamin B_{12} from the gastrointestinal tract. This disorder often occurs in the disease *pernicious anemia*, in which the basic abnormality is an *atrophic gastric mucosa* that fails to produce normal gastric secretions. The parietal cells of the gastric glands secrete a glycoprotein called *intrinsic factor*, which combines with vitamin B_{12} in food and makes the B_{12} available for absorption by the gut in the following way:

1. Intrinsic factor binds tightly with the vitamin B_{12}. In this bound state, vitamin B_{12} is protected from digestion by the gastrointestinal secretions.
2. Still in the bound state, intrinsic factor binds to specific receptor sites on the brush border membranes of the mucosal cells in the ileum.
3. Vitamin B_{12} is then transported into the blood during the next few hours by the process of pinocytosis, carrying intrinsic factor and the vitamin together through the membrane.

Lack of intrinsic factor, therefore, decreases availability of vitamin B_{12} because of faulty absorption of the vitamin.

After vitamin B_{12} has been absorbed from the gastrointestinal tract, it is stored in large quantities in the liver and then released slowly as needed by the bone marrow. The minimum amount of vitamin B_{12} required each day to maintain normal RBC maturation is only 1 to 3 micrograms, and the normal storage in the liver and other body tissues is about 1000 times this amount. Therefore, 3 to 4 years of defective vitamin B_{12} absorption are usually required to cause maturation failure anemia.

Maturation Failure Anemia Caused By Folic Acid (Pteroylglutamic Acid) Deficiency. Folic acid is a normal constituent of green vegetables, some fruits, and meats (especially liver). However, it is easily destroyed during cooking. Also, people with gastrointestinal absorption abnormalities, such as the small intestinal disease called *sprue* that leads to chronic diarrhea, often have serious difficulty absorbing both folic acid and vitamin B_{12}. Therefore, in many cases of maturation failure, the cause is deficiency of intestinal absorption of folic acid and vitamin B_{12}.

HEMOGLOBIN FORMATION

The synthesis of hemoglobin begins in polychromatophil erythroblasts and continues even into the reticulocyte stage of the RBCs. Therefore, when reticulocytes leave the bone marrow and pass into the bloodstream, they continue to form minute quantities of hemoglobin for another day or so until they become mature erythrocytes.

Fig. 33.5 shows the basic chemical steps in the formation of hemoglobin. First, succinyl-CoA, which is formed in the Krebs metabolic cycle (as explained in Chapter 68), binds with glycine to form a pyrrole molecule. In turn, four pyrroles combine to form protoporphyrin IX, which then combines with iron to form the *heme* molecule. Finally, each heme molecule combines with a long polypeptide chain, a *globin* synthesized by ribosomes, forming a subunit of hemoglobin called a *hemoglobin chain* (**Fig. 33.6**). Each chain has a molecular weight of about 16,000; four of these chains, in turn, bind together loosely to form the whole hemoglobin molecule.

There are several slight variations in the different subunit hemoglobin chains, depending on the amino acid composition of the polypeptide portion. The different types of chains are designated as *alpha (α) chains, beta (β) chains, (γ) gamma chains*, and *(δ) delta chains*. The most common form of hemoglobin in adults, *hemoglobin A*, is a combination of *two alpha chains* and *two beta chains*. Hemoglobin A has a molecular weight of 64,458.

Because each hemoglobin chain has a heme prosthetic group containing an atom of iron, and because there are

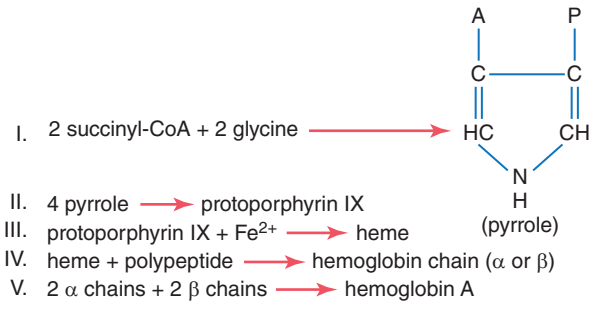

Figure 33.5 Formation of hemoglobin.

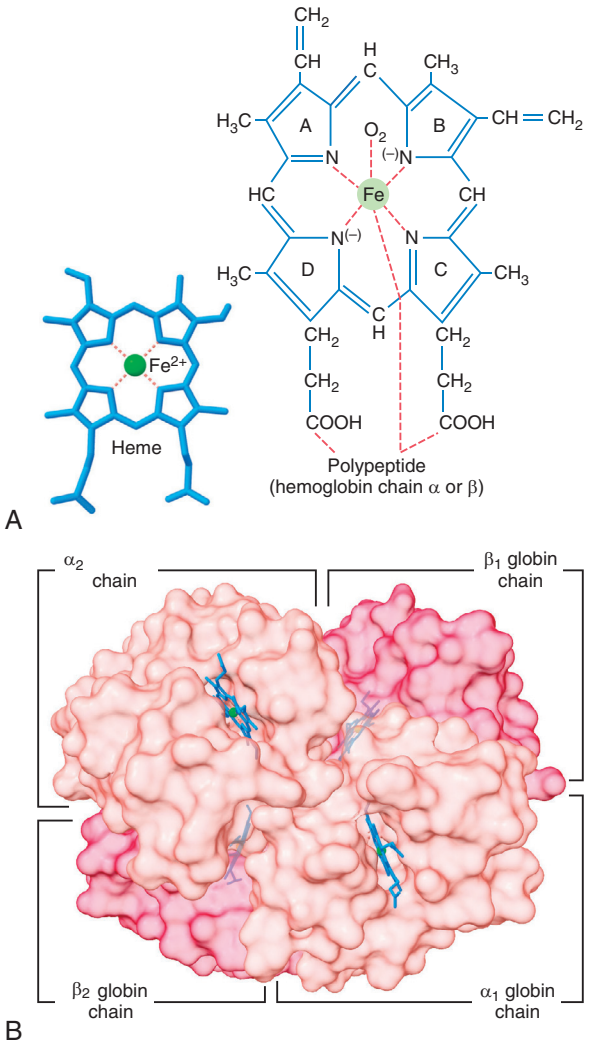

Figure 33.6 (A) Basic structure of the heme moiety, showing one of the four heme chains that, along with globin polypeptide, bind together to form the hemoglobin molecule. (B) Hemoglobin structure showing the two alpha chains and two beta chains, each centered around a heme moiety.

four hemoglobin chains in each hemoglobin molecule, one finds four iron atoms in each hemoglobin molecule. Each of these can bind loosely with one molecule of oxygen, making a total of four molecules of oxygen (or eight oxygen atoms) that can be transported by each hemoglobin molecule.

The types of hemoglobin chains in the hemoglobin molecule determine the binding affinity of the hemoglobin for oxygen. Abnormalities of the chains can alter the physical characteristics of the hemoglobin molecule as well. For example, in *sickle cell anemia*, the amino acid *valine* is substituted for *glutamic acid* at one point in each of the two beta chains. When this type of hemoglobin is exposed to low oxygen, it forms elongated crystals inside the RBCs that are sometimes 15 micrometers in length.

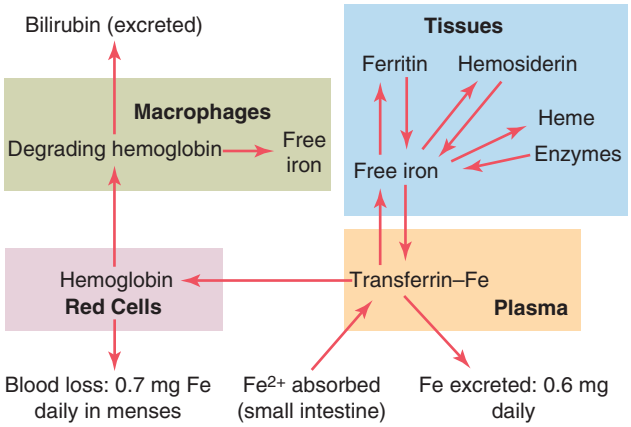

Figure 33.7 Iron transport and metabolism.

These crystals make it almost impossible for the cells to pass through many small capillaries, and the spiked ends of the crystals are likely to rupture the cell membranes, leading to sickle cell anemia.

Hemoglobin Combines Reversibly With Oxygen. The most important feature of the hemoglobin molecule is its ability to combine loosely and reversibly with oxygen. This ability is discussed in detail in Chapter 41 in relation to respiration because the primary function of hemoglobin in the body is to combine with oxygen in the lungs and then to release this oxygen readily in the peripheral tissue capillaries, where the gaseous tension of oxygen is much lower than in the lungs.

Oxygen *does not* combine with the two positive bonds of the iron in the hemoglobin molecule. Instead, it binds loosely with one of the so-called coordination bonds of the iron atom. This bond is extremely loose, so the combination is easily reversible. Furthermore, the oxygen does not become ionic oxygen but is carried as molecular oxygen (composed of two oxygen atoms) to the tissues where, because of the loose, readily reversible combination, it is released into the tissue fluids still in the form of molecular oxygen rather than ionic oxygen.

IRON METABOLISM

Iron is important for the formation not only of hemoglobin but also of other essential elements in the body (e.g., *myoglobin, cytochromes, cytochrome oxidase, peroxidase*, and *catalase*). The total quantity of iron in the body averages 4 to 5 grams, about 65% of which is in the form of hemoglobin. About 4% is in the form of myoglobin, 1% is in the form of the various heme compounds that promote intracellular oxidation, 0.1% is combined with the protein transferrin in the blood plasma, and 15% to 30% is stored for later use, mainly in the reticuloendothelial system and liver parenchymal cells, principally in the form of ferritin.

Transport and Storage of Iron. Transport, storage, and metabolism of iron in the body are diagrammed in **Fig. 33.7** and can be explained as follows. When iron is

absorbed from the small intestine, it immediately combines in the blood plasma with a beta globulin, *apotransferrin*, to form *transferrin*, which is then transported in the plasma. The iron is loosely bound in the transferrin and, consequently, can be released to any tissue cell at any point in the body. Excess iron in the blood is deposited *especially* in the liver hepatocytes and less in the reticuloendothelial cells of the bone marrow.

In the cell cytoplasm, iron combines mainly with a protein, *apoferritin*, to form *ferritin*. Apoferritin has a molecular weight of about 460,000, and varying quantities of iron can combine in clusters of iron radicals with this large molecule; therefore, ferritin may contain only a small or a large amount of iron. This iron stored as ferritin is called *storage iron*.

Smaller quantities of the iron in the storage pool are in an extremely insoluble form called *hemosiderin*. This is especially true when the total quantity of iron in the body is more than the apoferritin storage pool can accommodate. Hemosiderin collects in cells in the form of large clusters that can be observed microscopically as large particles. In contrast, ferritin particles are so small and dispersed that they usually can be seen in the cell cytoplasm only with an electron microscope.

When the quantity of iron in the plasma decreases, some of the iron in the ferritin storage pool is removed easily and transported in the form of transferrin in the plasma to the areas of the body where it is needed. A unique characteristic of the transferrin molecule is that it binds strongly with receptors in the cell membranes of erythroblasts in the bone marrow. Then, along with its bound iron, it is ingested into the erythroblasts by endocytosis. There the transferrin delivers the iron directly to the mitochondria, where heme is synthesized. In people who do not have adequate quantities of transferrin in their blood, failure to transport iron to the erythroblasts in this manner can cause severe *hypochromic anemia* (i.e., RBCs that contain much less hemoglobin than normal).

When RBCs have lived their life span of about 120 days and are destroyed, the hemoglobin released from the cells is ingested by monocyte-macrophage cells. There, iron is liberated and is stored mainly in the ferritin pool to be used as needed for the formation of new hemoglobin.

Daily Loss of Iron. An average man excretes about 0.6 mg of iron each day, mainly into the feces. Additional quantities of iron are lost when bleeding occurs. For a woman, additional menstrual loss of blood brings long-term iron loss to an average of about 1.3 mg/day.

Absorption of Iron From the Intestinal Tract

Iron is absorbed from all parts of the small intestine, mostly by the following mechanism. The liver secretes moderate amounts of *apotransferrin* into the bile, which flows through the bile duct into the duodenum. Here, the apotransferrin binds with free iron and also with certain iron compounds, such as hemoglobin and myoglobin from meat, the most important source of iron in the diet. This combination is called *transferrin*. In turn, it is attracted to and binds with receptors in the membranes of intestinal epithelial cells. Then, the transferrin molecule, carrying its iron store, is absorbed by pinocytosis into the epithelial cells and later released into the blood capillaries beneath these cells in the form of *plasma transferrin*.

Iron absorption from the intestines is extremely slow, at a maximum rate of only a few milligrams per day. This slow rate of absorption means that even when tremendous quantities of iron are present in the food, only small proportions can be absorbed.

Regulation of Total Body Iron By Controlling Absorption Rate. When the body becomes saturated with iron so that essentially all apoferritin in the iron storage areas is already combined with iron, the rate of additional iron absorption from the intestinal tract markedly decreases. Conversely, when the iron stores become depleted, the rate of absorption can probably accelerate five or more times normal. Thus, total body iron is regulated mainly by altering the rate of absorption.

LIFE SPAN OF RED BLOOD CELLS IS ABOUT 120 DAYS

When RBCs are delivered from the bone marrow into the circulatory system, they normally circulate an average of 120 days before being destroyed. Even though mature RBCs do not have a nucleus, mitochondria, or endoplasmic reticulum, they have cytoplasmic enzymes that are capable of metabolizing glucose and forming small amounts of adenosine triphosphate. These enzymes also do the following: (1) maintain pliability of the cell membrane; (2) maintain membrane transport of ions; (3) keep the iron of the cells' hemoglobin in the ferrous form rather than the ferric form; and (4) prevent oxidation of the proteins in the RBCs. Even so, the metabolic systems of old RBCs become progressively less active, and the cells become more and more fragile as their life processes wear out.

Once the RBC membrane becomes fragile, the cell ruptures during passage through some tight spot of the circulation. Many of the RBCs self-destruct in the spleen, where they squeeze through the red pulp of the spleen. There, the spaces between the structural trabeculae of the red pulp, through which most of the cells must pass, are only 3 micrometers wide, in comparison with the 8-micrometer diameter of the RBC. When the spleen is removed, the number of old abnormal RBCs circulating in the blood increases considerably.

Destruction of Hemoglobin By Macrophages. When RBCs burst and release their hemoglobin, the hemoglobin is rapidly phagocytized by macrophages in many parts of the body, but especially by the Kupffer cells of the liver and macrophages of the spleen and bone marrow. During the next few hours to days, the macrophages

release iron from the hemoglobin and pass it back into the blood to be carried by transferrin either to the bone marrow for production of new RBCs or to the liver and other tissues for storage in the form of ferritin. The porphyrin portion of the hemoglobin molecule is converted by the macrophages, through a series of stages, into the bile pigment *bilirubin*, which is released into the blood and later removed from the body by secretion through the liver into the bile. This process is discussed in relation to liver function in Chapter 71.

ANEMIAS

Anemia means deficiency of hemoglobin in the blood, which can be caused by too few RBCs or too little hemoglobin in the cells. Some types of anemia and their physiological causes are described in the following sections.

Blood Loss Anemia. After rapid hemorrhage, the body replaces the fluid portion of the plasma in 1 to 3 days, but this response results in a low concentration of RBCs. If a second hemorrhage does not occur, the RBC concentration usually returns to normal within 3 to 6 weeks.

When chronic blood loss occurs, a person frequently cannot absorb enough iron from the intestines to form hemoglobin as rapidly as it is lost. RBCs that are much smaller than normal and have too little hemoglobin inside them are then produced, giving rise to *microcytic hypochromic anemia*, which is shown in **Fig. 33.3**.

Aplastic Anemia Due to Bone Marrow Dysfunction. *Bone marrow aplasia* means lack of functioning bone marrow. For example, exposure to high-dose radiation or chemotherapy for cancer treatment can damage stem cells of the bone marrow, followed in a few weeks by anemia. Likewise, high doses of certain toxic chemicals, such as insecticides or benzene in gasoline, may cause the same effect. In autoimmune disorders, such as lupus erythematosus, the immune system begins to attack healthy cells such as bone marrow stem cells, which may lead to aplastic anemia. In about half of aplastic anemia cases the cause is unknown, a condition called *idiopathic aplastic anemia*.

People with severe aplastic anemia usually die unless they are treated with blood transfusions—which can temporarily increase the numbers of RBCs—or by bone marrow transplantation.

Megaloblastic Anemia—Abnormally Large, Poorly Developed RBCs. Based on the earlier discussions of vitamin B_{12}, folic acid, and intrinsic factor from the stomach mucosa, one can readily understand that loss of any one of these can lead to slow reproduction of erythroblasts in the bone marrow. As a result, the RBCs grow too large, with odd shapes, and are called *megaloblasts*. Thus, atrophy of the stomach mucosa, as occurs in *pernicious anemia*, or loss of the entire stomach after surgical total *gastrectomy* can lead to megaloblastic anemia. Also, megaloblastic anemia often develops in patients who have *intestinal sprue*, in which folic acid, vitamin B_{12}, and other vitamin B compounds are poorly absorbed. Because the erythroblasts in these states cannot proliferate rapidly enough to form normal numbers of RBCs, the RBCs that are formed are mostly oversized, have bizarre shapes, and have fragile membranes. These cells rupture easily, leaving the person in dire need of an adequate number of RBCs.

Hemolytic Anemia. Different abnormalities of the RBCs, many of which are acquired through heredity, make the cells fragile, so they rupture easily as they go through the capillaries, especially through the spleen. Even though the number of RBCs formed may be normal, or even much greater than normal in some hemolytic diseases, the life span of the fragile RBC is so short that the cells are destroyed faster than they can be formed, and serious anemia results.

In *hereditary spherocytosis*, the RBCs are very small and *spherical* rather than being biconcave discs. These cells cannot withstand compression forces because they do not have the normal loose, baglike cell membrane structure of the biconcave discs. On passing through the splenic pulp and some other tight vascular beds, they are easily ruptured by even slight compression.

In *sickle cell anemia*, the cells have an abnormal type of hemoglobin called *hemoglobin S*, containing faulty beta chains in the hemoglobin molecule, as explained earlier in this chapter. When this hemoglobin is exposed to low concentrations of oxygen, it precipitates into long crystals inside the RBC. These crystals elongate the cell and give it the appearance of a sickle rather than a biconcave disc. The precipitated hemoglobin also damages the cell membrane, so the cells become highly fragile, leading to serious anemia.

Patients with sickle cell anemia frequently experience a vicious circle of events called a *sickle cell disease crisis*, in which low oxygen tension in the tissues causes sickling, which leads to ruptured RBCs, which causes a further decrease in oxygen tension and still more sickling and RBC destruction. An important clinical feature of sickle cell crisis is acute pain associated with vascular occlusion due to plugging of small blood vessels by the sickled cells. Once the process starts, it may progress rapidly, eventuating in a serious decrease in RBCs within a few hours and, in some cases, target organ injury and even death.

In *erythroblastosis fetalis*, Rh-positive RBCs in the fetus are attacked by antibodies from an Rh-negative mother. These antibodies make the Rh-positive cells fragile, leading to rapid rupture and causing the child to be born with a serious case of anemia. This condition is discussed in Chapter 36 in relation to the Rh factor of blood. The extremely rapid formation of new RBCs to make up for the destroyed cells in erythroblastosis fetalis causes a large number of early *blast* forms of RBCs to be released from the bone marrow into the blood.

Effects of Anemia on Circulatory System Function

The viscosity of the blood, which was discussed in Chapter 14, depends largely on the blood concentration of RBCs. In persons with severe anemia, the blood viscosity may fall to as low as 1.5 times that of water rather than the normal value of about 3. This change decreases the resistance to blood flow in the peripheral blood vessels, so far greater than normal quantities of blood flow through the tissues and return to the heart, thereby greatly increasing cardiac output. Moreover, hypoxia resulting from diminished transport of oxygen by the blood causes the peripheral tissue blood vessels to dilate, allowing a further increase in the return of blood to the heart and increasing the cardiac output to a still higher level—sometimes three to four times normal. Thus, one of the major effects of anemia is greatly *increased cardiac output*, as well as *increased pumping workload on the heart*.

The increased cardiac output in persons with anemia partially offsets the reduced oxygen-carrying effect of the anemia because, even though each unit quantity of blood carries only small quantities of oxygen, the rate of blood flow may be increased enough that almost normal quantities of oxygen are actually delivered to the tissues. However, when a person with anemia begins to exercise, the heart is not capable of pumping much greater quantities of blood than it is already pumping. Consequently, during exercise, which greatly increases tissue demand for oxygen, extreme tissue hypoxia results and *acute cardiac failure* may ensue.

POLYCYTHEMIA

Secondary Polycythemia. Whenever the tissues become hypoxic because of too little oxygen in the breathed air, such as at high altitudes, or because of failure of oxygen delivery to the tissues, such as in cardiac failure, the blood-forming organs automatically produce large quantities of extra RBCs. This condition is called *secondary polycythemia*, and the RBC count commonly rises to 6 to 7 million/mm^3, about 30% above normal.

A common type of secondary polycythemia, called *physiological polycythemia*, occurs in those who live at altitudes of 14,000 to 17,000 feet, where the atmospheric oxygen is very low. The blood count is generally 6 to 7 million/mm^3, which allows these people to perform reasonably high levels of continuous work, even in a rarefied atmosphere.

Polycythemia Vera (Erythremia). A pathological type of polycythemia, known as *polycythemia vera*, is caused by a genetic aberration in the hemocytoblastic cells that produce the blood cells. The blast cells no longer stop producing RBCs when too many cells are already present. In polycythemia vera the RBC count may be 7 to 8 million/mm^3 and the hematocrit may be 60% to 70% instead of the normal 40% to 45%. Production of white blood cells and platelets is also usually increased in this disorder.

In polycythemia vera, not only does the hematocrit increase, but the total blood volume also increases, sometimes to almost twice normal. As a result, the entire vascular system becomes intensely engorged. Also, many blood capillaries become plugged by the viscous blood; the viscosity of the blood in polycythemia vera sometimes increases from the normal of 3 times the viscosity of water to 10 times that of water.

Effect of Polycythemia on Function of the Circulatory System

Because of the greatly increased viscosity of blood in polycythemia, blood flow through the peripheral blood vessels is often very sluggish. In accordance with the factors that regulate tissue blood flow and cardiac output, as discussed in Chapter 20, increasing blood viscosity *decreases* the rate of tissue blood flow and therefore reduces venous return and cardiac output. However, the blood volume is greatly increased in polycythemia, which tends to *increase* venous return and cardiac output. Therefore, the cardiac output in polycythemia is not far from normal because these two factors more or less neutralize each other.

The arterial pressure is also normal in most people with polycythemia, although in about one-third of them, the arterial pressure is elevated. This means that the mechanisms for blood pressure regulation can usually offset the tendency for increased blood viscosity to increase peripheral resistance and, thereby, increase arterial pressure. Beyond certain limits, however, these regulations fail, and hypertension develops.

The color of the skin depends to a great extent on the quantity of blood in the skin subpapillary venous plexus. In polycythemia vera, the quantity of blood in this plexus is greatly increased. Furthermore, because blood passes sluggishly through the skin capillaries before entering the venous plexus, a larger than normal quantity of hemoglobin is deoxygenated. The blue color of all this deoxygenated hemoglobin masks the red color of the oxygenated hemoglobin. Therefore, a person with polycythemia vera ordinarily has a ruddy complexion, with a bluish (cyanotic) tint to the skin.

CHAPTER 34

Resistance of the Body to Infection: I. Leukocytes, Granulocytes, the Monocyte-Macrophage System, and Inflammation

Our bodies are exposed continually to bacteria, viruses, fungi, and parasites, all of which occur normally and to varying degrees in the skin, mouth, respiratory passageways, intestinal tract, lining membranes of the eyes, and even the urinary tract. Many of these infectious agents are capable of causing serious abnormal physiological function or even death if they invade deeper tissues. We are also exposed intermittently to other highly infectious bacteria and viruses besides those that are normally present, and these agents can cause acute lethal diseases such as pneumonia, streptococcal infection, and typhoid fever.

Our bodies have a special system for combating the different infectious and toxic agents. This system is composed of blood leukocytes (white blood cells [WBCs]) and tissue cells derived from leukocytes. These cells work together in two ways to prevent disease: (1) by actually destroying invading bacteria or viruses by *phagocytosis;* and (2) by forming *antibodies* and *sensitized lymphocytes* that may destroy or inactivate the invader. This chapter discusses the first of these methods, and Chapter 35 discusses the second.

LEUKOCYTES (WHITE BLOOD CELLS)

The leukocytes, also called *white blood cells*, are the *mobile units* of the body's protective system. They are formed partially in the bone marrow (*granulocytes* and *monocytes* and a few *lymphocytes*) and partially in the lymph tissue (*lymphocytes* and *plasma cells*). After formation, they are transported in the blood to different parts of the body where they are needed.

The real value of WBCs is that most of them are specifically transported to areas of serious infection and inflammation, thereby providing a rapid and potent defense against infectious agents. As we see later, the granulocytes and monocytes have a special ability to "seek out and destroy" a foreign invader.

GENERAL CHARACTERISTICS OF LEUKOCYTES

Types of White Blood Cells. Six types of WBCs are normally present in the blood: *neutrophils* (polymorphonuclear), *eosinophils (*polymorphonuclear), *basophils (*polymorphonuclear), *monocytes, lymphocytes*, and, occasionally, *plasma cells*. In addition, there are large numbers of *platelets*, which are fragments of another type of cell similar to the WBCs found in the bone marrow, the *megakaryocyte*. The first three types of cells, the polymorphonuclear cells, all have a granular appearance, as shown in cell numbers 7, 10, and 12 in **Fig. 34.1**, and for this reason they are called *granulocytes*.

The granulocytes and monocytes protect the body against invading organisms by ingesting them (*phagocytosis*) or by releasing antimicrobial or inflammatory substances that have multiple effects that aid in destroying the offending organism. The lymphocytes and plasma cells function mainly in connection with the immune system, as discussed in Chapter 35. Finally, the function of platelets is specifically to activate the blood-clotting mechanism, discussed in Chapter 37.

Concentrations of Different White Blood Cells in Blood. An adult human has about 7000 WBCs per *microliter* of blood (in comparison with 5 million red blood cells [RBCs] per microliter). Of the total WBCs, the normal percentages of the different types are approximately the following:

- Neutrophils: 62.0%
- Eosinophils: 2.3%
- Basophils: 0.4%
- Monocytes: 5.3%
- Lymphocytes: 30.0%

The number of platelets, which are only cell fragments, in each microliter of blood is normally between 150,000 and 450,000, averaging about 300,000.

GENESIS OF WHITE BLOOD CELLS

Early differentiation of the multipotential hematopoietic stem cell into the different types of committed progenitor cells was shown in **Fig. 33.2** in the previous chapter. Aside from the cells committed to form RBCs, two major lineages of WBCs are formed, the myelocytic and lymphocytic lineages. The left side of **Fig. 34.1** shows the *myelocytic lineage*, beginning with the *myeloblast;* the right side shows the *lymphocytic lineage*, beginning with the *lymphoblast*.

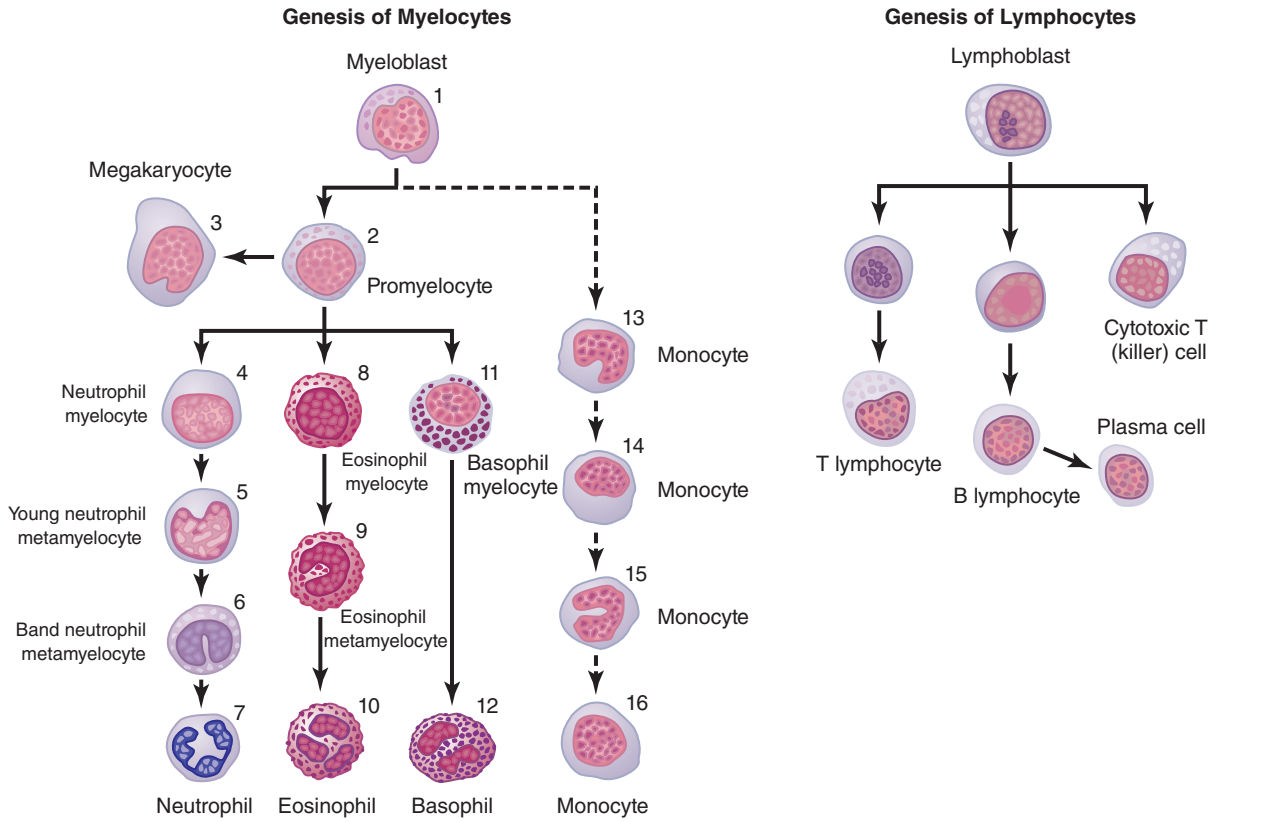

Figure 34.1 Genesis of white blood cells. The different cells of the myelocyte series are shown: 1, myeloblast; 2, promyelocyte; 3, megakaryocyte; 4, neutrophil myelocyte; 5, young neutrophil metamyelocyte; 6, band neutrophil metamyelocyte; 7, neutrophil; 8, eosinophil myelocyte; 9, eosinophil metamyelocyte; 10, eosinophil; 11, basophil myelocyte; 12, basophil; 13–16, stages of monocyte formation. The right side of the figure shows the genesis of the T lymphocytes, B lymphocytes, plasma cells, and cytotoxic killer cells.

The granulocytes and monocytes are formed only in the bone marrow. Lymphocytes and plasma cells are produced mainly in the various lymphogenous tissues—especially the lymph glands, spleen, thymus, tonsils, and various pockets of lymphoid tissue elsewhere in the body, such as in the bone marrow and in *Peyer patches* underneath the epithelium in the gut wall.

The WBCs formed in the bone marrow are stored in the marrow until they are needed in the circulatory system. When the need arises, various factors cause them to be released (these factors are discussed later). Normally, about three times as many WBCs are stored in the marrow as circulate in the entire blood. This quantity represents about a 6-day supply of these cells.

The lymphocytes are mostly stored in the various lymphoid tissues, except for a small number that are temporarily being transported in the blood.

As shown in **Fig. 34.1**, megakaryocytes (cell 3) are also formed in the bone marrow. These megakaryocytes fragment in the bone marrow, and the small fragments, known as *platelets* (or *thrombocytes*), then pass into the blood. They are very important in the initiation of blood clotting.

LIFE SPAN OF WHITE BLOOD CELLS

The life of the granulocytes after being released from the bone marrow is normally 4 to 8 hours circulating in the blood and another 4 to 5 days in tissues where they are needed. In times of serious tissue infection, this total life span is often shortened to only a few hours because the granulocytes proceed even more rapidly to the infected area, perform their functions, and in the process, are themselves destroyed.

The monocytes also have a short transit time, 10 to 20 hours in the blood, before wandering through the capillary membranes into the tissues. Once in the tissues, they swell to much larger sizes to become *tissue macrophages* and, in this form, they can live for months unless destroyed while performing phagocytic functions. These tissue macrophages are the basis of the *tissue macrophage system* (discussed in greater detail later), which provides continuing defense against infection.

Lymphocytes enter the circulatory system continually, along with drainage of lymph from the lymph nodes and other lymphoid tissue. After a few hours, they pass out of the blood back into the tissues by *extravasation* (also called *diapedesis*). Then, they reenter the lymph and return to the blood again and again; thus, there is continual circulation of lymphocytes through the body. Lymphocytes have life spans of weeks or months, depending on the body's need for these cells.

The platelets in the blood are replaced about once every 10 days. This amounts to about 30,000 platelets formed each day for each microliter of blood, or about

150 billion platelets needed each day to maintain a normal steady-state platelet count in 5 liters of blood.

NEUTROPHILS AND MACROPHAGES DEFEND AGAINST INFECTIONS

It is mainly the neutrophils and tissue macrophages that attack and destroy invading bacteria, viruses, and other harmful agents. The neutrophils are mature cells that can attack and destroy bacteria, even in the circulating blood. Conversely, the tissue macrophages begin life as blood monocytes, which are immature cells while still in the blood and have little ability to fight infectious agents at that time. However, once they enter the tissues, they begin to swell—sometimes increasing their diameters as much as 5-fold—to as great as 60 to 80 micrometers, a size that can barely be seen with the naked eye. These cells are now called *macrophages*, and they are extremely capable of combating disease agents in the tissues.

White Blood Cells Enter the Tissue Spaces By Extravasation (Diapedesis). Neutrophils and monocytes can squeeze through gaps between endothelial cells of the blood capillaries and postcapillary venules by *extravasation* (*diapedesis*). Although the intercellular gaps are much smaller than a cell, a small portion of the cell slides through the gap at a time; the portion sliding through is momentarily constricted to the size of the gap, as shown in **Fig. 34.2** (also see **Fig. 34.7**).

White Blood Cells Move Through Tissue Spaces By Ameboid Motion. Both neutrophils and macrophages can move through the tissues by ameboid motion, described in Chapter 2. Some cells move at velocities as great as 40 μm/min, a distance as great as their own length each minute.

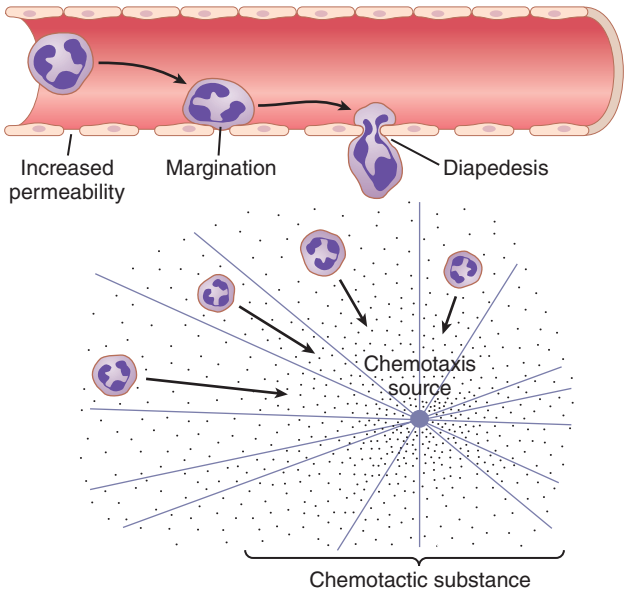

Figure 34.2 Movement of neutrophils by *diapedesis* or *extravasation* through capillary pores and by *chemotaxis* toward an area of tissue damage.

White Blood Cells Are Attracted to Inflamed Tissue Areas By Chemotaxis. Many different chemical substances in the tissues cause neutrophils and macrophages to move toward the source of the chemical. This phenomenon, shown in **Fig. 34.2**, is known as *chemotaxis*. When a tissue becomes inflamed, at least a dozen different products that can cause chemotaxis toward the inflamed area are formed (**Video 34.1**). They include the following: (1) some of the bacterial or viral toxins; (2) degenerative products of the inflamed tissues; (3) several reaction products of the complement complex (discussed in Chapter 35) activated in inflamed tissues; and (4) several reaction products caused by plasma clotting in the inflamed area, as well as other substances.

As shown in **Fig. 34.2**, chemotaxis depends on the concentration gradient of the chemotactic substance. The concentration is greatest near the source, which governs the unidirectional movement of the WBCs. Chemotaxis is effective up to 100 micrometers away from an inflamed tissue. Since almost no tissue area is more than 50 micrometers away from a capillary, the chemotactic signal can easily move hordes of WBCs from the capillaries into the inflamed area.

PHAGOCYTOSIS

A major function of the neutrophils and macrophages is *phagocytosis*, which means cellular ingestion of the offending agent. Phagocytes must be selective of the material that is phagocytized; otherwise, normal cells and structures of the body might be ingested. Whether phagocytosis will occur especially depends on three selective factors (**Fig. 34.3**).

First, most natural structures in the tissues have smooth surfaces, which resist phagocytosis. However, if the surface is rough, the likelihood of phagocytosis is increased.

Second, most natural substances of the body have protective protein coats that repel the phagocytes. Conversely, most dead tissues and foreign particles have no protective coats, which makes them subject to phagocytosis.

Third, the immune system of the body (described in Chapter 35) develops *antibodies* against infectious agents such as bacteria. The antibodies then adhere to the bacterial membranes and thereby make the bacteria especially susceptible to phagocytosis. To do this, the antibody molecule also combines with the C3 product of the *complement cascade*, which is an additional part of the immune system discussed in the next chapter. The C3 molecules, in turn, attach to receptors on the phagocyte membrane, thus initiating phagocytosis. This process whereby a pathogen is selected for phagocytosis and destruction is called *opsonization*.

Phagocytosis By Neutrophils. The neutrophils entering the tissues are already mature cells that can immediately begin phagocytosis. On approaching a particle to be phagocytized, the neutrophil first attaches itself to

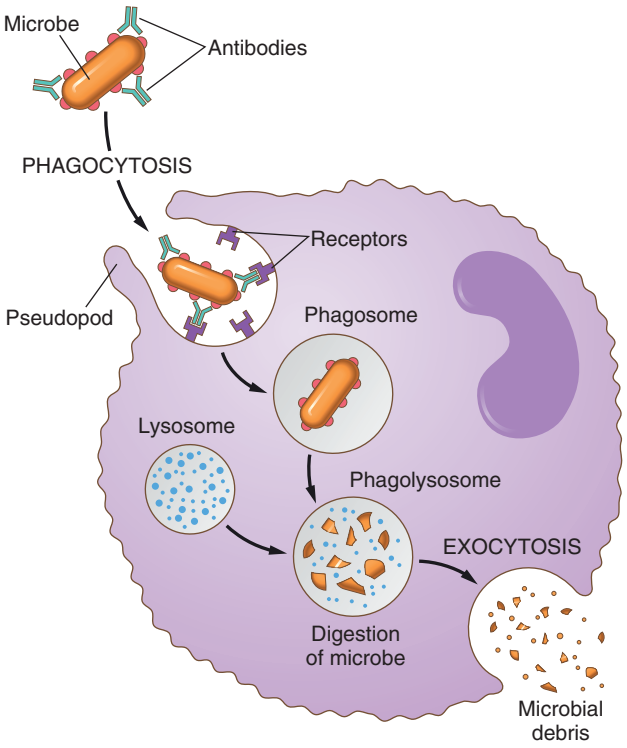

Figure 34.3 Phagocytosis of pathogens, such as bacteria, by a phagocytic cell, such as a macrophage. Antibodies coat the bacteria, making them more susceptible to phagocytosis by the macrophage, which engulfs the bacterium, bringing it into the cell and forming a *phagosome*. Lysosomes then attach to the phagosome to form a *phagolysosome*, which digests the invading pathogen. The phagocytic cell then releases the digested products by *exocytosis*.

the particle and then projects *pseudopodia* in all directions around the particle. The pseudopodia meet one another on the opposite side and fuse. This action creates an enclosed chamber that contains the phagocytized particle. Then, the chamber invaginates to the inside of the cytoplasmic cavity and breaks away from the outer cell membrane to form a free-floating *phagocytic vesicle* (also called a *phagosome*) inside the cytoplasm. A single neutrophil can usually phagocytize 3 to 20 bacteria before the neutrophil becomes inactivated and dies.

Phagocytosis By Macrophages. Macrophages are the end-stage product of monocytes that enter the tissues from the blood. When activated by the immune system, as described in Chapter 35, they are much more powerful phagocytes than neutrophils, often capable of phagocytizing as many as 100 bacteria. They also have the ability to engulf much larger particles, even whole RBCs or, occasionally, malarial parasites, whereas neutrophils are not capable of phagocytizing particles much larger than bacteria. Also, after digesting particles, macrophages can extrude the residual products and often survive and function for many more months.

Once Phagocytized, Most Particles Are Digested By Intracellular Enzymes. Once a foreign particle has been phagocytized, lysosomes and other cytoplasmic granules in the neutrophil or macrophage immediately come into contact with the phagocytic vesicle, and their membranes fuse, thereby dumping many digestive enzymes and bactericidal agents into the vesicle. Thus, the phagocytic vesicle now becomes a *digestive vesicle*, and digestion of the phagocytized particle begins immediately.

Both neutrophils and macrophages contain an abundance of lysosomes filled with *proteolytic enzymes* especially geared for digesting bacteria and other foreign protein matter. The lysosomes of macrophages (but not of neutrophils) also contain large amounts of *lipases*, which digest the thick lipid membranes possessed by some bacteria, such as the tuberculosis bacillus.

Neutrophils and Macrophages Can Kill Bacteria. In addition to the digestion of ingested bacteria in phagosomes, neutrophils and macrophages contain *bactericidal agents* that kill most bacteria, even when the lysosomal enzymes fail to digest them. This characteristic is especially important because some bacteria have protective coats or other factors that prevent their destruction by digestive enzymes. Much of the killing effect results from several powerful *oxidizing agents* formed by enzymes in the membrane of the phagosome or by a special organelle called the *peroxisome*. These oxidizing agents include large quantities of *superoxide* (O_2^-), *hydrogen peroxide* (H_2O_2), and *hydroxyl ions* (OH^-), which are lethal to most bacteria, even in small quantities. Also, one of the lysosomal enzymes, myeloperoxidase, catalyzes the reaction between H_2O_2 and chloride ions to form hypochlorite, which is exceedingly bactericidal.

Some bacteria, notably the tuberculosis bacillus, have coats that are resistant to lysosomal digestion and also secrete substances that partially resist the killing effects of the neutrophils and macrophages. These bacteria are responsible for many chronic diseases, such as tuberculosis.

MONOCYTE-MACROPHAGE CELL SYSTEM (RETICULOENDOTHELIAL SYSTEM)

We previously described the macrophages mainly as mobile cells capable of wandering through the tissues. However, after entering the tissues and becoming macrophages, another large portion of monocytes becomes attached to the tissues and remains attached for months or even years until they are called on to perform specific local protective functions. They have the same capabilities as the mobile macrophages to phagocytize large quantities of bacteria, viruses, necrotic tissue, or other foreign particles in the tissue. In addition, when appropriately stimulated, they can break away from their attachments and, once again, become mobile macrophages that respond to chemotaxis and all the other stimuli related to the inflammatory process. Thus, the body has a widespread monocyte-macrophage system in virtually all tissues.

The total combination of monocytes, mobile macrophages, fixed tissue macrophages, and a few specialized endothelial cells in the bone marrow, spleen, and lymph nodes is called the *reticuloendothelial system*. However, all or almost all these cells originate from monocytic stem cells; therefore, the reticuloendothelial system is almost synonymous with the monocyte-macrophage system. Because the term *reticuloendothelial system* is much better known in medical literature than the term *monocyte-macrophage system*, it should be remembered as a generalized phagocytic system located in all tissues, especially in tissue areas where large quantities of particles, toxins, and other unwanted substances must be destroyed.

Tissue Macrophages in Skin and Subcutaneous Tissues. The skin is mainly impregnable to infectious agents, except when it is broken. When infection begins in a subcutaneous tissue and local inflammation ensues, local tissue macrophages (also called *histiocytes*) can divide in situ and form still more macrophages. Then, they perform the usual functions of attacking and destroying the infectious agents, as described earlier.

Macrophages in Lymph Nodes. Essentially no particulate matter that enters the tissues, such as bacteria, can be absorbed directly through the capillary membranes into the blood. Instead, if the particles are not destroyed locally in the tissues, they enter the lymph and flow to the lymph nodes located intermittently along the course of the lymph flow. The foreign particles are then trapped in these nodes in a meshwork of sinuses lined by tissue macrophages.

Fig. 34.4 illustrates the general organization of a lymph node, showing lymph entering through the lymph node capsule via *afferent lymphatics*, then flowing through the *nodal medullary sinuses*, and finally passing out the *hilus* into *efferent lymphatics* that eventually empty into the venous blood.

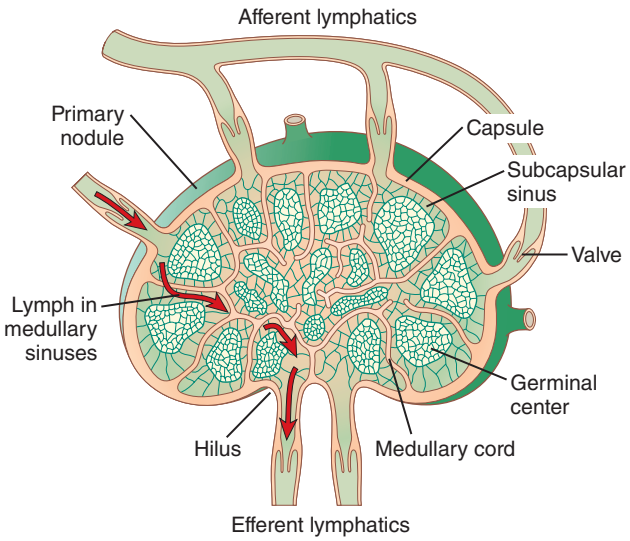

Figure 34.4 Functional diagram of a lymph node.

Large numbers of macrophages line the lymph sinuses, and if any particles enter the sinuses by way of the lymph, the macrophages phagocytize them and prevent general dissemination throughout the body.

Alveolar Macrophages in Lungs. Another route for invading organisms to enter the body is through the lungs. Large numbers of tissue macrophages are present as integral components of the alveolar walls. They can phagocytize particles that become entrapped in the alveoli. If the particles are digestible, the macrophages can also digest them and release the digestive products into the lymph. If the particle is not digestible, the macrophages often form a giant cell capsule around the particle until such time, if ever, that it can be slowly dissolved. Such capsules are frequently formed around tuberculosis bacilli, silica dust particles, and even carbon particles.

Macrophages (Kupffer Cells) in Liver Sinusoids. Another route whereby bacteria invade the body is through the gastrointestinal tract. Large numbers of bacteria from ingested food constantly pass through the gastrointestinal mucosa into the portal blood. Before this blood enters the general circulation, it passes through the liver sinusoids, which are lined with tissue macrophages called *Kupffer cells*, shown in **Fig. 34.5**. These cells form such an effective particulate filtration system that almost none of the bacteria from the gastrointestinal tract pass from the portal blood into the general systemic circulation. Indeed, videos of phagocytosis by Kupffer cells have demonstrated phagocytosis of a single bacterium in less than 0.01 second.

Macrophages of Spleen and Bone Marrow. If an invading organism succeeds in entering the general circulation, there are other lines of defense by the tissue

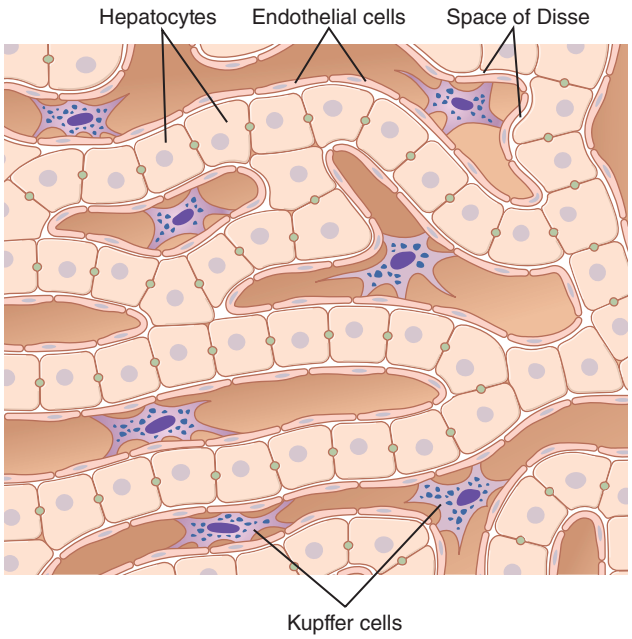

Figure 34.5 Kupffer cells lining the liver sinusoids, showing phagocytosis of India ink particles into the cytoplasm of the Kupffer cells.

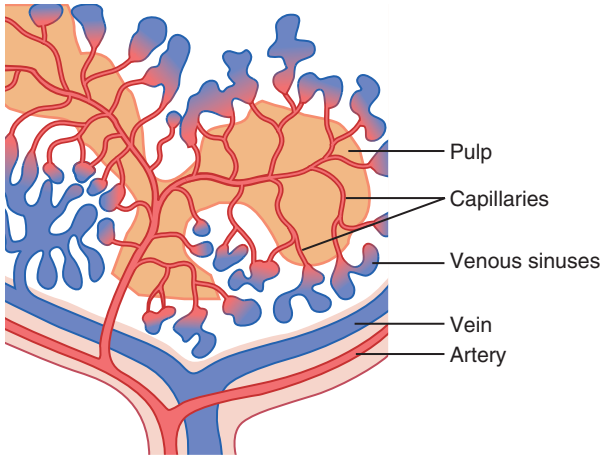

Figure 34.6 Functional structures of the spleen.

macrophage system, especially by macrophages of the spleen and bone marrow. In both these tissues, macrophages become entrapped by the reticular meshwork of the organs, and when foreign particles come into contact with these macrophages, they are phagocytized.

The spleen is similar to the lymph nodes, except that blood, instead of lymph, flows through the tissue spaces of the spleen. **Fig. 34.6** shows a small peripheral segment of spleen tissue. Note that a small artery penetrates from the splenic capsule into the *splenic pulp* and terminates in small capillaries. The capillaries are highly porous, allowing whole blood to pass out of the capillaries into *cords of red pulp*. The blood then gradually *squeezes* through the trabecular meshwork of these cords and eventually returns to the circulation through the endothelial walls of the *venous sinuses*. The trabeculae of the red pulp and venous sinuses are lined with vast numbers of macrophages. This peculiar passage of blood through the cords of the red pulp provides an exceptional means of phagocytizing unwanted debris in the blood, including especially old and abnormal RBCs.

The absence of a spleen (*asplenia*) or reduced function of the spleen (*hyposplenism*) are both associated with increased susceptibility to severe invasive infections. The most common cause of asplenia is surgical removal of the spleen following trauma-related injuries to the spleen. Hyposplenism often occurs in patients with gastrointestinal and liver diseases, as well as in those who have severe infectious diseases that damage the spleen, such as severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), a strain of coronavirus that is also called the COVID-19 virus.

INFLAMMATION: ROLE OF NEUTROPHILS AND MACROPHAGES

Inflammation

When tissue injury occurs, whether caused by bacteria, trauma, chemicals, heat, or any other phenomenon, multiple substances are released by the injured tissues and cause dramatic secondary changes in the surrounding uninjured tissues. This entire complex of tissue changes is called *inflammation*.

Inflammation is characterized by the following: (1) vasodilation of the local blood vessels, with consequent increased local blood flow; (2) increased permeability of the capillaries, allowing leakage of large quantities of fluid into the interstitial spaces; (3) often, clotting of the fluid in the interstitial spaces because of increased amounts of fibrinogen and other proteins leaking from the capillaries; (4) migration of large numbers of granulocytes and monocytes into the tissue; and (5) swelling of the tissue cells. Some of the many tissue products that cause these reactions are *histamine, bradykinin, serotonin, prostaglandins*, several different *reaction products of the complement system* (described in Chapter 35), *reaction products of the blood clotting system*, and multiple substances called *lymphokines* that are released by sensitized T cells (part of the immune system; also discussed in Chapter 35). Several of these substances strongly activate the macrophage system and, within a few hours, the macrophages begin to devour the destroyed tissues. At times, however, excessive, prolonged inflammation and macrophage activation may also further injure the still-living tissue cells.

Walling-Off Effect of Inflammation. One of the first results of inflammation is to wall off the area of injury from the remaining tissues. The tissue spaces and the lymphatics in the inflamed area are blocked by fibrinogen clots so that after a while, fluid barely flows through the spaces. This walling-off process delays the spread of bacteria or toxic products.

The intensity of the inflammatory process is usually proportional to the degree of tissue injury. For example, when *staphylococci* invade tissues, they release extremely lethal cellular toxins. As a result, inflammation develops rapidly—indeed, much more rapidly than the staphylococci can multiply and spread. Therefore, local staphylococcal infection is characteristically walled off rapidly and prevented from spreading through the body. Streptococci, in contrast, do not cause such intense local tissue destruction. Therefore, the walling-off process develops slowly over many hours, while many streptococci reproduce and migrate. As a result, streptococci often have a far greater tendency to spread through the body and cause death than staphylococci, even though staphylococci are far more destructive to the tissues.

Macrophage and Neutrophil Responses During Inflammation

Tissue Macrophages Provide the First Line of Defense Against Infection. Within minutes after inflammation begins, the macrophages already present in the tissues, whether histiocytes in the subcutaneous tissues, alveolar macrophages in the lungs, microglia in the brain, or others, immediately begin their phagocytic actions. When activated by the products of infection and inflammation, the first effect is rapid enlargement of each of these cells.

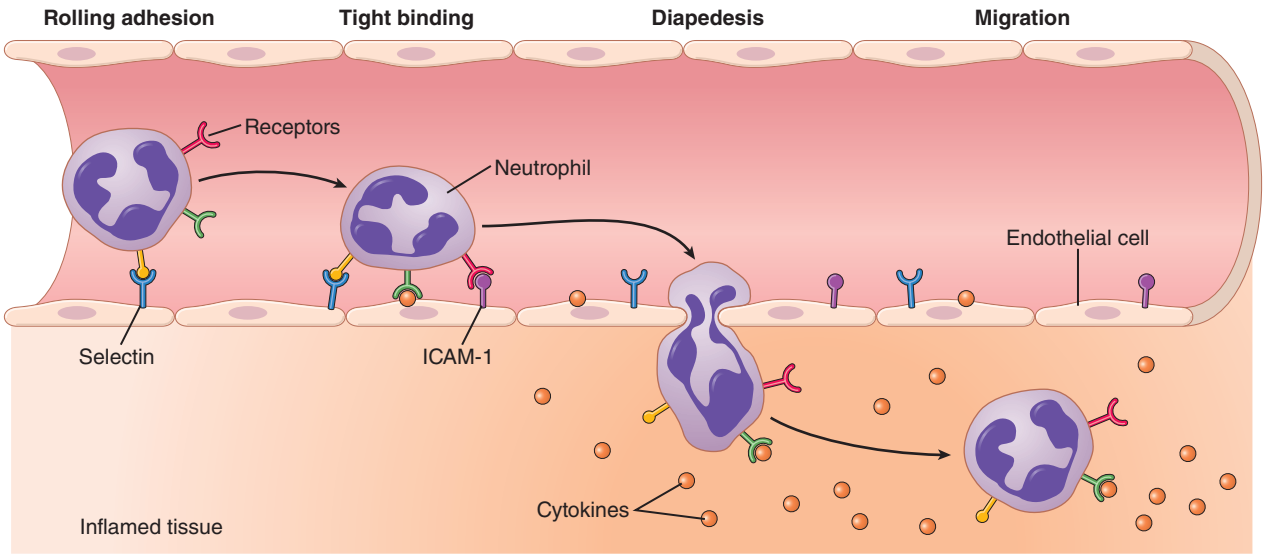

Figure 34.7 Migration of neutrophils from the blood into inflamed tissue. Cytokines and other biochemical products of the inflamed tissue cause increased expression of selectins and intercellular adhesion molecule-1 (ICAM-1) on the surface of endothelial cells. These adhesion molecules bind to complementary molecules or receptors on the neutrophil, causing it to adhere to the wall of the capillary or venule. The neutrophil then migrates through the vessel wall by diapedesis or extravasation toward the site of tissue injury.

Next, many of the previously sessile macrophages break loose from their attachments and become mobile, forming the first line of defense against infection during the first hour or so. The numbers of these early mobilized macrophages often are not great, but they are lifesaving.

Neutrophil Invasion of the Inflamed Area Is a Second Line of Defense. Within the first hour or so after inflammation begins, large numbers of neutrophils begin to invade the inflamed area from the blood. This invasion is caused by inflammatory cytokines (e.g., tumor necrosis factor and interleukin-1) and other biochemical products produced by the inflamed tissues that initiate the following reactions:

1. They cause increased expression of *adhesion molecules*, such as *selectins* and *intercellular adhesion molecule-1* (ICAM-1) on the surface of endothelial cells in the capillaries and venules. These adhesion molecules, reacting with complementary *integrin* molecules on the neutrophils, cause the neutrophils to stick to the capillary and venule walls in the inflamed area. This effect is called *margination* and is shown in **Fig. 34.2** and in more detail in **Fig. 34.7**.
2. They also cause the intercellular attachments between the endothelial cells of the capillaries and small venules to loosen, allowing openings large enough for neutrophils to crawl through the capillaries by diapedesis into the tissue spaces.
3. They then cause *chemotaxis* of the neutrophils toward the injured tissues, as explained earlier. The entire process of translocation of neutrophils (or other substances and cells such as monocytes) through the capillaries into the tissues surrounding them is called *extravasation;* the specific passage of blood cells through the intact walls of the capillaries is called *diapedesis*, although this term is often used interchangeably with extravasation when discussing blood cell movement through the capillaries into tissues.

Thus, within several hours after tissue damage begins, the area becomes well supplied with neutrophils. Because the blood neutrophils are already mature cells, they are ready to begin their scavenger functions of killing bacteria and removing foreign matter immediately.

Acute Increase in the Number of Neutrophils in Blood—Neutrophilia. Also, within a few hours after the onset of acute severe inflammation, the number of neutrophils in the blood sometimes increases 4-fold to 5-fold—from a normal of 4,000 to 5,000 to 15,000 to 25,000 neutrophils/μL. This *neutrophilia* is caused by products of inflammation that enter the bloodstream, are transported to the bone marrow, and act there on the stored neutrophils of the marrow to mobilize these into the circulating blood. This makes even more neutrophils available to the inflamed tissue area.

Second Macrophage Invasion Into the Inflamed Tissue Is a Third Line of Defense. Along with the invasion of neutrophils, monocytes from the blood enter the inflamed tissue and enlarge to become macrophages. However, the number of monocytes in the circulating blood is normally low. Also, the storage pool of monocytes in the bone marrow is much less than that of neutrophils. Therefore, the buildup of macrophages in the inflamed tissue area is much slower than that of neutrophils, requiring several days to become effective. Furthermore, even after invading the inflamed tissue, monocytes are still immature cells, requiring 8 hours or more to swell to much larger sizes and develop tremendous quantities of lysosomes. Only then do they acquire the full capacity

of *tissue macrophages* for phagocytosis. After several days to several weeks, the macrophages finally become the dominant phagocytic cells of the inflamed area because of greatly increased bone marrow production of new monocytes, as explained later.

As already noted, macrophages can phagocytize far more bacteria (about five times as many) and far larger particles, including even neutrophils and large quantities of necrotic tissue, than can neutrophils. Also, the macrophages play an important role in initiating development of antibodies, as discussed in Chapter 35.

Increased Production of Granulocytes and Monocytes By Bone Marrow Is a Fourth Line of Defense. The fourth line of defense is greatly increased production of granulocytes and monocytes by the bone marrow due to stimulation of a pool of committed granulocytic and monocytic progenitor cells of the marrow. However, it takes 3 to 4 days before newly formed granulocytes and monocytes reach the stage of leaving the bone marrow. If the stimulus from the inflamed tissue continues, the bone marrow can continue to produce these cells in large quantities for months and even years, sometimes at a rate 20 to 50 times normal.

Feedback Control of Macrophage and Neutrophil Responses. Although more than two dozen factors have been implicated in control of the macrophage response to inflammation, five of these are believed to play dominant roles. They are shown in **Fig. 34.8** and consist of the following: (1) *tumor necrosis factor* (TNF); (2) *interleukin-1* (IL-1); (3) *granulocyte-monocyte colony-stimulating factor* (GM-CSF); (4) *granulocyte colony-stimulating factor* (G-CSF); and (5) *monocyte colony-stimulating factor* (M-CSF). These factors are formed by activated macrophage cells in the inflamed tissues and in smaller quantities by other inflamed tissue cells.

The cause of increased production of granulocytes and monocytes by the bone marrow is mainly the three colony-stimulating factors; one of these, GM-CSF, stimulates both granulocyte and monocyte production; the other two, G-CSF and M-CSF, stimulate granulocyte and monocyte production, respectively. This combination of TNF, IL-1, and colony-stimulating factors provides a powerful feedback mechanism that begins with tissue inflammation and proceeds to formation of large numbers of defensive WBCs that help remove the cause of the inflammation.

Formation of Pus

When neutrophils and macrophages engulf large numbers of bacteria and necrotic tissue, essentially all the neutrophils and many, if not most, of the macrophages eventually die. After several days, a cavity is often excavated in the inflamed tissues. This cavity contains varying portions of necrotic tissue, dead neutrophils, dead macrophages, and tissue fluid. This mixture is commonly known as *pus*. After the infection has been suppressed, the dead cells and necrotic tissue in the pus gradually autolyze over a period of days, and the end products are eventually absorbed into the surrounding tissues and lymph until most of the evidence of tissue damage is gone.

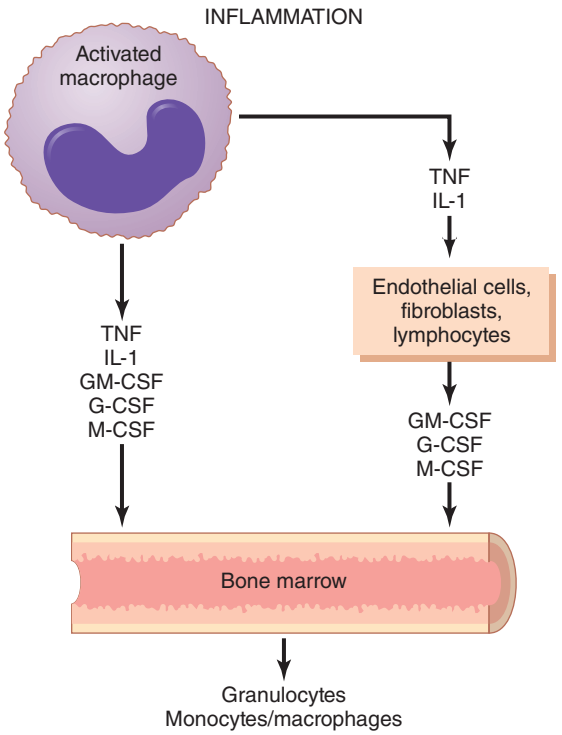

Figure 34.8 Control of bone marrow production of granulocytes and monocyte-macrophages in response to multiple growth factors released from activated macrophages in an inflamed tissue. *G-CSF*, Granulocyte colony-stimulating factor; *GM-CSF*, granulocyte-monocyte colony-stimulating factor; *IL-1*, interleukin-1; *M-CSF*, monocyte colony-stimulating factor; *TNF*, tumor necrosis factor.

EOSINOPHILS

The eosinophils normally constitute about 2% of all the blood leukocytes. Eosinophils are weak phagocytes and they exhibit chemotaxis, but in comparison with neutrophils, it is doubtful that eosinophils are significant in protecting against the usual types of infection.

Eosinophils, however, are often produced in large numbers in people with parasitic infections, and they migrate into tissues diseased by parasites. Although most parasites are too large to be phagocytized by eosinophils or any other phagocytic cells, eosinophils attach themselves to the parasites by way of special surface molecules and release substances that kill many of the parasites. For example, one of the most widespread infections is *schistosomiasis*, a parasitic infection found in as much as one-third of the population of some developing countries in Africa, Asia, and South America. An estimated 85% to 90% of the world's cases of schistosomiasis are in Africa.

The schistosome parasitic worms can invade any part of the body. Eosinophils attach themselves to the juvenile forms of the parasite and kill many of them. They do so in several ways: (1) by releasing hydrolytic enzymes from their granules, which are modified lysosomes; (2) probably

also by releasing highly reactive forms of oxygen that are especially lethal to parasites; and (3) by releasing from the granules a highly larvicidal polypeptide called *major basic protein*.

In a few areas of the world, another parasitic disease that causes eosinophilia is *trichinosis*. This disease results from invasion of the body's muscles by the *Trichinella* parasite (pork worm) after a person eats undercooked infested pork.

Eosinophils also have a special propensity to collect in tissues in which allergic reactions occur, such as in the peribronchial tissues of the lungs in people with asthma and in the skin after an allergic skin reaction. This action is caused at least partly by the fact that many mast cells and basophils participate in allergic reactions, as discussed in the next paragraph. The mast cells and basophils release an *eosinophil chemotactic factor* that causes eosinophils to migrate toward the inflamed allergic tissue. The eosinophils may detoxify some of the inflammation-inducing substances released by the mast cells and basophils, as well as phagocytize and destroy allergen-antibody complexes, thus preventing excess spread of the local inflammatory process. However, excessive and sustained eosinophil infiltration may ultimately exacerbate breathing difficulties by causing inflammation-induced tissue damage and airway remodeling in people with asthma.

BASOPHILS

The basophils in the circulating blood are similar to the large tissue *mast cells* located immediately outside many of the capillaries in the body. Both mast cells and basophils liberate *heparin* into the blood. Heparin is a substance that can prevent blood coagulation.

The mast cells and basophils also release *histamine*, as well as smaller quantities of *bradykinin* and *serotonin*. It is mainly the mast cells in inflamed tissues that release these substances during inflammation.

The mast cells and basophils play an important role in some types of allergic reactions because the type of antibody that causes allergic reactions, immunoglobulin E (IgE), has a special propensity to become attached to mast cells and basophils. Then, when the specific antigen for the specific IgE antibody subsequently reacts with the antibody, the resulting attachment of antigen to antibody causes the mast cell or basophil to release increased quantities of *histamine, bradykinin, serotonin, heparin, slow-reacting substance of anaphylaxis* (a mixture of three *leukotrienes*), and several *lysosomal enzymes*. These substances cause local vascular and tissue reactions that mediate many, if not most, of the allergic manifestations. These reactions are discussed in greater detail in Chapter 35.

LEUKOPENIA

A clinical condition known as *leukopenia*, in which the bone marrow produces very few WBCs, occasionally occurs. This condition leaves the body unprotected against many bacteria and other agents that might invade the tissues.

Normally, the human body lives in symbiosis with many bacteria because the mucous membranes of the body are constantly exposed to large numbers of bacteria. The mouth almost always contains various spirochetal, pneumococcal, and streptococcal bacteria, and these same bacteria are present to a lesser extent in the entire respiratory tract. The distal gastrointestinal tract is especially loaded with colon bacilli. Furthermore, one can always find bacteria on the surfaces of the eyes, urethra, and vagina. Any decrease in the number of WBCs immediately allows invasion of adjacent tissues by bacteria that are already present.

Within 2 days after the bone marrow stops producing WBCs, ulcers may appear in the mouth and colon, or some form of severe respiratory infection might develop. Bacteria from the ulcers rapidly invade surrounding tissues and the blood. Without treatment, death often ensues in less than 1 week after acute total leukopenia begins.

Irradiation of the body by x-rays or gamma rays, or exposure to drugs and chemicals that contain benzene or anthracene nuclei, is likely to cause aplasia of the bone marrow. Some common drugs such as chloramphenicol (an antibiotic), thiouracil (used to treat thyrotoxicosis), and even various barbiturate hypnotics on rare occasions cause leukopenia, thus setting off the entire infectious sequence of this disorder.

After moderate irradiation injury to the bone marrow, some stem cells, myeloblasts, and hemocytoblasts may remain undestroyed in the marrow and are capable of regenerating the bone marrow, provided sufficient time is available. A patient properly treated with transfusions, plus antibiotics and other drugs to ward off infection, usually develops enough new bone marrow within weeks to months for blood cell concentrations to return to normal.

LEUKEMIAS

Uncontrolled production of WBCs can be caused by cancerous mutation of a myelogenous or lymphogenous cell. This process causes *leukemia*, which is usually characterized by greatly increased numbers of abnormal WBCs in the circulating blood.

There are two general types of leukemia—lymphocytic and myelogenous. The *lymphocytic leukemias* are caused by cancerous production of lymphoid cells in the bone marrow. The incompetent lymphocytes produced then circulate and accumulate in lymph nodes or other lymphocytic tissue, ultimately spreading to other areas of the body. The second type of leukemia, *myelogenous leukemia*, begins by cancerous production of young myelogenous cells in the bone marrow and then spreads throughout the body so that WBCs are produced in many extramedullary tissues—especially in the lymph nodes, spleen, and liver.

In myelogenous leukemia, the cancerous process occasionally produces partially differentiated cells, resulting in what might be called *neutrophilic leukemia, eosinophilic leukemia, basophilic leukemia*, or *monocytic leukemia*. More frequently, however, the leukemia cells are bizarre and undifferentiated and not identical to any of the normal WBCs. Usually, the more undifferentiated the cell, the more *acute* is the leukemia, often leading to death within a few months if untreated. With some of the more differentiated cells, the process can be *chronic*, sometimes developing slowly over 10 to 20 years. Leukemic cells, especially the very undifferentiated cells, are usually nonfunctional for providing normal protection against infection.

Effects of Leukemia on the Body

The first effect of leukemia is metastatic growth of leukemic cells in abnormal areas of the body. Leukemic cells from the bone marrow may reproduce so much that they invade the surrounding bone, causing pain and, eventually, a tendency for bones to fracture easily.

Almost all leukemias eventually spread to the spleen, lymph nodes, liver, and other vascular regions, regardless of whether the leukemia originated in the bone marrow or lymph nodes. Common effects in leukemia include the development of infection, severe anemia, and a bleeding tendency caused by *thrombocytopenia* (lack of platelets). These effects result mainly from displacement of the normal bone marrow and lymphoid cells by the nonfunctional leukemic cells.

Finally, an important effect of leukemia on the body is excessive use of metabolic substrates by the growing cancerous cells. The leukemic tissues reproduce new cells so rapidly that tremendous demands are made on the body reserves for nutrients, specific amino acids, and vitamins. Consequently, the energy of the patient is greatly depleted, and excessive utilization of amino acids by leukemic cells causes especially rapid deterioration of the normal protein tissues of the body. Thus, while the leukemic tissues grow, other tissues become debilitated. After metabolic starvation has continued long enough, this factor alone is sufficient to cause death.

CHAPTER 35

Resistance of the Body to Infection: II. Immunity and Allergy

The human body has the ability to resist almost all types of organisms or toxins that tend to damage the tissues and organs. This capability is called *immunity*. Much of the immunity is *acquired immunity* that does not develop until after the body is first attacked by a bacterium, virus, or toxin; often, weeks or months are required for the immunity to develop. An additional element of immunity that results from general processes, rather than from processes directed at specific disease organisms, is called *innate immunity*, which includes barriers that prevent harmful materials from entering the body, as well as the first line of defense against invasion by organisms as follows:

1. Physical barriers, including the skin, digestive tract and urogenital membranes, respiratory tract ciliated epithelium, and mucus that resist invasion by organisms
2. Physiological secretions, including sweat, tears, and saliva that help prevent the growth of microorganisms, and acid secreted by the stomach and digestive enzymes that destroy swallowed organisms
3. Phagocytosis of bacteria and other invaders by white blood cells and cells of the tissue macrophage system, as described in Chapter 34
4. Presence in the blood of certain chemicals and cells that attach to foreign organisms or toxins and destroy them

Some of these components of the innate immune system are: (1) *lysozyme*, a mucolytic polysaccharide that causes lysis of bacteria; (2) *basic polypeptides*, which react with and inactivate certain types of gram-positive bacteria; (3) the *complement complex*, described later, a system of about 20 proteins that can be activated in various ways to destroy bacteria; and (4) *natural killer lymphocytes* that can recognize and destroy foreign cells, tumor cells, and even some infected cells.

This innate immunity makes the human body resistant to diseases such as some paralytic viral infections of animals, including hog cholera, cattle plague, and distemper—a viral disease that kills a large percentage of dogs that become afflicted with it. Likewise, many animals are resistant or even immune to many human diseases, such as poliomyelitis, mumps, human cholera, measles, and syphilis, which are very damaging or even lethal to humans.

ACQUIRED (ADAPTIVE) IMMUNITY

In addition to its generalized innate immunity, the human body has the ability to develop extremely powerful specific immunity against individual invading agents, such as lethal bacteria, viruses, toxins, and even foreign tissues from other animals. This ability is called *acquired* or *adaptive immunity*. Acquired immunity is caused by a special immune system that forms antibodies and/or activated lymphocytes that attack and destroy the specific invading organism or toxin.

Acquired immunity can often bestow an extreme degree of protection. For example, certain toxins, such as the paralytic botulinum toxin or the tetanizing toxin of tetanus, can be protected against in doses as high as 100,000 times the amount that would be lethal without immunity. It is for this reason that the treatment process known as *immunization* is so important in protecting people against disease and against toxins, as explained later in this chapter.

BASIC TYPES OF ACQUIRED IMMUNITY—HUMORAL AND CELL-MEDIATED

Two basic but closely allied types of acquired immunity occur in the body. In one of these, the body develops circulating antibodies, which are globulin molecules in the blood plasma capable of attacking the invading agent. This type of immunity is called *humoral immunity* or *B-cell immunity* because B lymphocytes produce the antibodies. The second type of acquired immunity is achieved through formation of large numbers of activated *T lymphocytes*, which are specifically crafted in the lymph nodes to destroy the foreign agent. This type of immunity is called *cell-mediated immunity* or *T-cell immunity* because the activated lymphocytes are T lymphocytes. Both the antibodies and activated lymphocytes are formed in the lymphoid tissues of the body.

Both Types of Acquired Immunity Are Initiated By Antigens

Because acquired immunity does not develop until after invasion by a foreign organism or toxin, the body must have some mechanism for recognizing this invasion. Each

toxin or organism almost always contains one or more specific chemical compounds that are different from all other compounds. In general, these are proteins or large polysaccharides that initiate the acquired immunity and are called *antigens* (*anti*body *gen*erators).

For a substance to be antigenic, it usually must have a high molecular weight of 8000 or more. Furthermore, the process of antigenicity usually depends on regularly recurring molecular groups, called *epitopes*, on the surface of the large molecule. This factor also explains why proteins and large polysaccharides are almost always antigenic because both these substances have this stereochemical characteristic.

LYMPHOCYTES ARE RESPONSIBLE FOR ACQUIRED IMMUNITY

Acquired immunity is the product of the body's lymphocytes. In people who have a genetic lack of lymphocytes or whose lymphocytes have been destroyed by radiation or chemicals, no acquired immunity can develop. In the absence of lymphocytes, a newborn will die of fulminating bacterial infection within days after birth unless they are treated by heroic measures. Therefore, it is clear that lymphocytes are essential to survival of humans.

Lymphocytes are located most extensively in the lymph nodes, but are also found in special lymphoid tissues such as the spleen, submucosal areas of the gastrointestinal tract, thymus, and bone marrow. The lymphoid tissue is distributed advantageously in the body to intercept invading organisms or toxins before they can spread too widely.

In most cases, the invading agent first enters the tissue fluids and then is carried by lymph vessels to the lymph node or other lymphoid tissue. For example, the lymphoid tissue of the gastrointestinal walls is exposed immediately to antigens invading from the gut. The lymphoid tissue of the throat and pharynx (including the tonsils and adenoids) is well located to intercept antigens that enter by way of the upper respiratory tract. The lymphoid tissue in the lymph nodes is exposed to antigens that invade the peripheral tissues of the body, and the lymphoid tissue of the spleen, thymus, and bone marrow plays the specific role of intercepting antigenic agents that have succeeded in reaching the circulating blood.

T and B Lymphocytes Promote Cell-Mediated and Humoral Immunity. Although most lymphocytes in normal lymphoid tissue look alike when studied under a microscope, these cells are distinctly divided into two major populations. One of the populations, the *T lymphocytes*, is responsible for forming the activated lymphocytes that provide cell-mediated immunity, and the other population, the *B lymphocytes*, is responsible for forming antibodies that provide humoral immunity.

Both types of lymphocytes are derived originally in the embryo from *multipotent hematopoietic stem cells* that form *common lymphoid progenitor cells* as one of their most important offspring as they differentiate. Almost all the lymphocytes that are formed eventually end up in the lymphoid tissue, but before doing so, they are further differentiated or preprocessed in the following ways.

The lymphoid progenitor cells that are eventually destined to form activated T lymphocytes first migrate to and are preprocessed in the thymus gland; thus, they are called *T* lymphocytes to designate the role of the thymus. They are responsible for cell-mediated immunity.

The other population of lymphocytes—the B lymphocytes that are destined to form antibodies—are preprocessed in the liver during mid–fetal life and in the bone marrow in late fetal life and after birth. This population of cells was first discovered in birds, which have a special preprocessing organ called the *bursa of Fabricius*. For this reason, these lymphocytes are called *B* lymphocytes to designate the role of the bursa, and they are responsible for humoral immunity. **Fig. 35.1** shows the two lymphocyte systems for formation, respectively, of (1) activated T lymphocytes and (2) antibodies.

DEVELOPMENT AND MATURATION OF T AND B LYMPHOCYTES

Although all lymphocytes in the body originate from *lymphocyte-committed stem cells* of the embryo, these stem cells are incapable of forming activated T lymphocytes or antibodies directly. Before they can do so, they must be further differentiated in appropriate processing areas, as follows.

T Lymphocytes Are Preprocessed in the Thymus Gland. The T lymphocytes, after origination in the bone marrow, first migrate to the thymus gland. Here they divide rapidly and, at the same time, develop extreme diversity for reacting against different specific antigens. That is, one thymic lymphocyte develops specific reactivity against one antigen, and then the next lymphocyte develops specificity against another antigen. This process continues until there are thousands of different types of thymic lymphocytes with specific reactivities against many thousands of different antigens. These different types of T lymphocytes now leave the thymus and spread via the blood throughout the body to lodge in lymphoid tissue everywhere.

The thymus also makes certain that any T lymphocytes leaving the thymus will not react against proteins or other antigens that are present in the body's own tissues; otherwise, the T lymphocytes would be lethal to the person's own body in only a few days. The thymus selects which T lymphocytes will be released by first mixing them with virtually all the specific *self-antigens* from the body's own tissues. If a T lymphocyte reacts, it is destroyed and phagocytized instead of being released, which happens in to up to 90% of the cells. Thus, the only cells that are finally released are those that are nonreactive against the body's own antigens—they react only against antigens from an outside source, such as from a bacterium, toxin, or even transplanted tissue from another person.

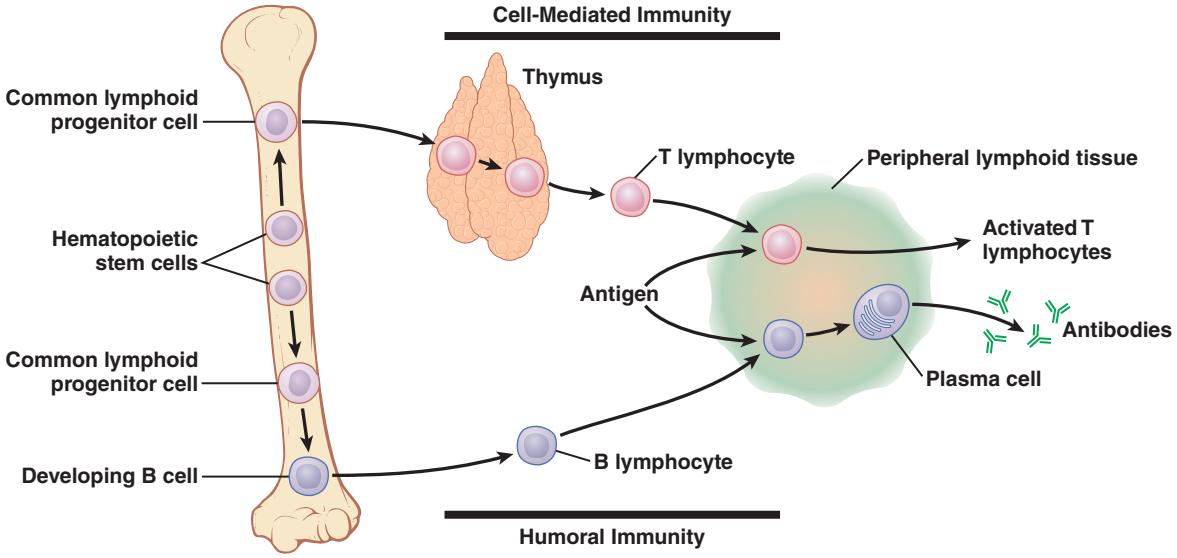

Figure 35.1 Formation of antibodies and sensitized lymphocytes by a lymph node in response to antigens. This figure also shows the origin of thymic (*T*) and bursal (*B*) lymphocytes that, respectively, are responsible for the cell-mediated and humoral immune processes.

Most of the preprocessing of T lymphocytes in the thymus occurs shortly before the birth of a baby and for a few months after birth. Beyond this period, removal of the thymus gland diminishes (but does not eliminate) the T-lymphocytic immune system. However, removal of the thymus several months before birth can prevent development of all cell-mediated immunity, including rejection of transplanted organs.

B Lymphocytes Are Preprocessed in the Liver and Bone Marrow. In humans, B lymphocytes are preprocessed in the liver during midfetal life and in the bone marrow during late fetal life and after birth. B lymphocytes are different from T lymphocytes in two ways:

1. Instead of the whole cell developing reactivity against the antigen, as occurs for the T lymphocytes, the B lymphocytes actively secrete *antibodies* that are the reactive agents. These agents are large proteins that are capable of combining with and destroying the antigenic substance, explained elsewhere in this chapter and in Chapter 34.
2. The B lymphocytes have even greater diversity than the T lymphocytes, thus forming many millions of types of B-lymphocyte antibodies with different specific reactivities. After preprocessing, the B lymphocytes, like the T lymphocytes, migrate to lymphoid tissue throughout the body, where they lodge near but slightly removed from the T-lymphocyte areas.

T LYMPHOCYTES AND B-LYMPHOCYTE ANTIBODIES REACT AGAINST SPECIFIC ANTIGENS—ROLE OF LYMPHOCYTE CLONES

When specific antigens come into contact with T and B lymphocytes in the lymphoid tissue, some of the T lymphocytes become activated to form activated T cells, and some of the B lymphocytes become activated to form antibodies. The activated T cells and antibodies, in turn, react specifically against the particular types of antigens that initiated their development. The mechanism of this specificity is described next.

Millions of Specific Types of Lymphocytes Are Stored in Lymphoid Tissue. Millions of different types of preformed B lymphocytes capable of forming highly specific types of antibodies and preformed T cells are stored in the lymph tissue, as explained earlier. Each of these preformed lymphocytes is capable of forming only one type of antibody or one type of T cell with a single type of specificity, and only the specific type of antigen can activate it. Once the specific lymphocyte is activated by its antigen, it reproduces wildly, forming tremendous numbers of duplicate lymphocytes (**Fig. 35.2**). If it is a B lymphocyte, its progeny will eventually secrete the specific type of antibody that then circulates throughout the body. If it is a T lymphocyte, its progeny are specific sensitized T cells that are released into the lymph, carried to the blood, and then circulated through all the tissue fluids and back into the lymph, sometimes circulating around and around in this circuit for months or years.

All the different lymphocytes that are capable of forming one specific antibody or T cell are called a *clone of lymphocytes*. That is, the lymphocytes in each clone are alike, derived originally from one or a few early lymphocytes of its specific type.

ORIGIN OF THE MANY CLONES OF LYMPHOCYTES

Only several hundred to a few thousand genes code for the millions of different types of antibodies and T lymphocytes. How is it possible for so few genes to code for the millions of different specificities of antibodies or T cells produced by the lymphoid tissue?

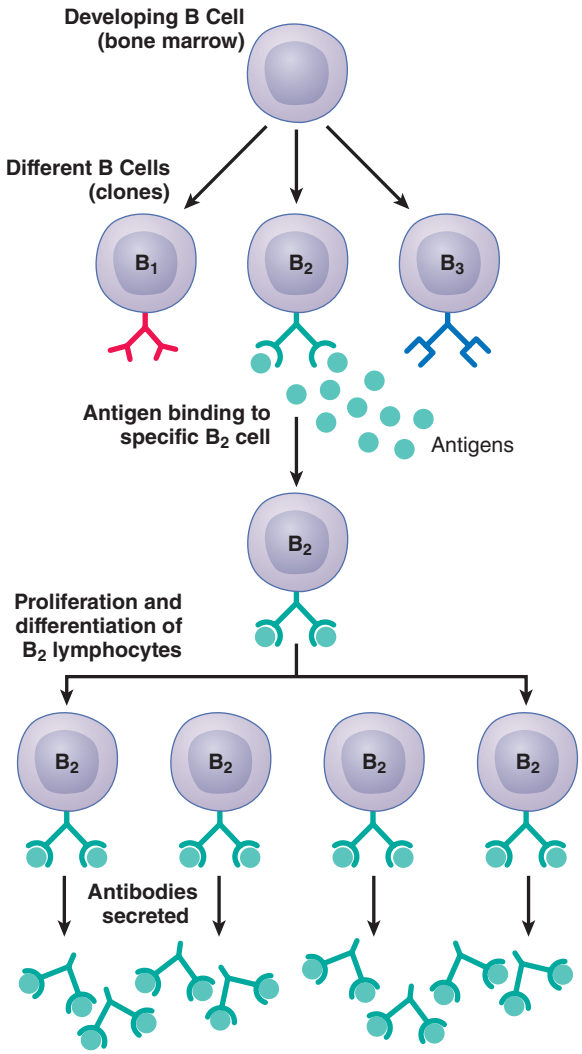

Figure 35.2 An antigen activates only the lymphocytes that have cell surface receptors that are complementary and recognize a specific antigen. Millions of different clones of lymphocytes exist (shown as B_1, B_2, and B_3). When the lymphocyte clone (B_2 in this example) is activated by its antigen, it reproduces to form large numbers of duplicate lymphocytes, which then secrete antibodies.

The whole gene for forming each type of T cell or B cell is never present in the original stem cells from which the functional immune cells are formed. Instead, there are only gene segments—actually, hundreds of such segments—but not whole genes. During preprocessing of the respective T- and B-cell lymphocytes, these gene segments become mixed with one another in random combinations, finally forming whole genes.

Because there are several hundred types of gene segments, as well as millions of different combinations in which the segments can be arranged in single cells, one can understand the millions of different cell gene types that can occur. For each functional T or B lymphocyte that is finally formed, the gene structure codes for only a single antigen specificity. These mature cells then become the highly specific T and B cells that spread to and populate the lymphoid tissue.

MECHANISM FOR ACTIVATING LYMPHOCYTE CLONES

Each clone of lymphocytes is responsive to only a single type of antigen (or to several similar antigens that have almost exactly the same stereochemical characteristics). The reason for this is the following. In the case of the B lymphocytes, each of these has on its cell surface membrane about 100,000 antibody molecules that will react highly specifically with only one type of antigen. Therefore, when the appropriate antigen comes along, it immediately attaches to the antibody in the cell membrane; this leads to the activation process, described in more detail subsequently.

In the case of the T lymphocytes, molecules similar to antibodies, called *surface receptor proteins* (or *T-cell receptors*), are on the surface of the T-cell membrane, and these are also highly specific for one specified activating antigen. An antigen therefore stimulates only those cells that have complementary receptors for the antigen and are already committed to respond to it.

Role of Macrophages in the Activation Process. Aside from the lymphocytes in lymphoid tissue, millions of macrophages are also present in the same tissue. These macrophages line the sinusoids of the lymph nodes, spleen, and other lymphoid tissue, and they lie in apposition to many of the lymph node lymphocytes. Most invading organisms are first phagocytized and partially digested by the macrophages, and the antigenic products are liberated into the macrophage cytosol. The macrophages then pass these antigens by cell-to-cell contact directly to the lymphocytes, thus leading to activation of the specified lymphocytic clones. The macrophages, in addition, secrete a special activating substance, *interleukin-1*, that promotes still further growth and reproduction of the specific lymphocytes.

Role of T Cells in Activation of B Lymphocytes. Most antigens activate T lymphocytes and B lymphocytes at the same time. Some of the T cells that are formed, called *T-helper cells*, secrete specific substances (collectively called *lymphokines*) that activate specific B lymphocytes. Indeed, without the aid of these T-helper cells, the quantity of antibodies formed by the B lymphocytes is usually small. We discuss this cooperative relationship between helper T cells and B cells after describing the mechanisms of the T-cell system of immunity.

SPECIFIC ATTRIBUTES OF THE B-LYMPHOCYTE SYSTEM—HUMORAL IMMUNITY AND ANTIBODIES

Antibody Formation By Plasma Cells. Before exposure to a specific antigen, the clones of B lymphocytes remain dormant in the lymphoid tissue. On entry of a foreign antigen, macrophages in lymphoid tissue phagocytize the antigen and then present it to adjacent B lymphocytes. In addition, the antigen is presented to T cells at the same

time, and activated T-helper cells are formed. These helper cells also contribute to extreme activation of the B lymphocytes, as discussed later.

The B lymphocytes specific for the antigen immediately enlarge and take on the appearance of *lymphoblasts*. Some of the lymphoblasts further differentiate to form *plasmablasts*, which are precursors of plasma cells. In the plasmablasts, the cytoplasm expands, and the rough endoplasmic reticulum proliferates vastly. The plasmablasts then begin to divide at a rate of about once every 10 hours for about nine divisions in 4 days, giving a total population of about 500 cells for each original plasmablast. The mature plasma cell then produces gamma globulin antibodies at an extremely rapid rate—about 2000 molecules per second for each plasma cell. In turn, the antibodies are secreted into the lymph and carried to the circulating blood. This process continues for several days or weeks until, finally, exhaustion and death of the plasma cells occur.

Formation of Memory Cells Enhances Antibody Response to Subsequent Antigen Exposure. A few of the lymphoblasts formed by activation of a clone of B lymphocytes do not go on to form plasma cells but, instead, form moderate numbers of new B lymphocytes similar to those of the original clone. In other words, the B-cell population of the specifically activated clone becomes greatly enhanced, and the new B lymphocytes are added to the original lymphocytes of the same clone. They also circulate throughout the body to populate all the lymphoid tissue; immunologically, however, they remain dormant until activated once again by a new quantity of the same antigen. These lymphocytes are called *memory cells*. Subsequent exposure to the same antigen will cause a much more rapid and potent antibody response this second time around because there are many more memory cells than there were original B lymphocytes of the specific clone.

Fig. 35.3 shows the differences between the primary response for forming antibodies that occurs on first exposure to a specific antigen and the secondary response that occurs after second exposure to the same antigen. Note the 1-week delay in the appearance of the primary response, its weak potency, and its short life. The secondary response, by contrast, begins rapidly after exposure to the antigen (often within hours), is far more potent, and forms antibodies for many months rather than for only a few weeks. The increased potency and duration of the secondary response explain why immunization is usually accomplished by injecting antigen in multiple doses, with periods of several weeks or several months between injections.

Generation of Lifelong Immunity By Plasma Cells. When naïve B lymphocytes encounter their associated antigens, become activated, and undergo clonal expansion, they differentiate into *short-lived* or *long-lived plasma cells* that produce large amounts of antibodies. The short-lived plasma cells provide rapid protection but

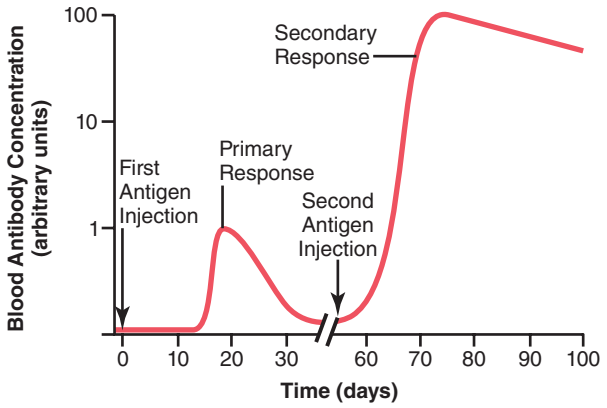

Figure 35.3 Time course of the antibody response in the circulating blood to a primary injection of antigen and to a secondary injection several weeks later.

undergo apoptosis after a few days of intense antibody secretion. However, the long-lived plasma cells reside in tissues such as the bone marrow and gut-associated lymphoid tissue and can continue producing antibodies for many years, providing lifelong immunity against infectious diseases such as measles and smallpox.

High titers of smallpox-specific antibodies, for example, have been detected in the blood of subjects vaccinated in childhood, 70 years previously. Also, older survivors of the 1918 H1N1 influenza virus pandemic were shown to possess highly functional, virus-neutralizing antibodies to this virulent virus 90 years after they were infected. Thus, plasma cells that produce virus-neutralizing antibodies can be sustained for many decades after exposure, even into the tenth decade of life in humans.

Nature of Antibodies

Antibodies are gamma globulins called *immunoglobulins* (Igs) that have molecular weights between 160,000 and 970,000 and constitute about 20% of all the plasma proteins. All the immunoglobulins are composed of combinations of *light* and *heavy polypeptide chains*. Most are a combination of two light and two heavy chains, as shown in **Fig. 35.4**. However, some immunoglobulins have combinations of as many as 10 heavy and 10 light chains, which give rise to high-molecular-weight immunoglobulins. Yet, in all immunoglobulins, each heavy chain is paralleled by a light chain at one of its ends, thus forming a heavy-light pair; there are always at least two and as many as 10 such pairs in each immunoglobulin molecule.

Fig. 35.4 shows a designated end of each light and heavy chain, called the *variable region*; the remainder of each chain is called the *constant region*. The variable region is different for each specific antibody, and it is this region that attaches specifically to a particular type of antigen. The constant region determines other properties of the antibody, establishing such factors as antibody diffusivity in the tissues, adherence to specific structures in the tissues, attachment to the complement complex, ease with which the antibodies pass through membranes, and

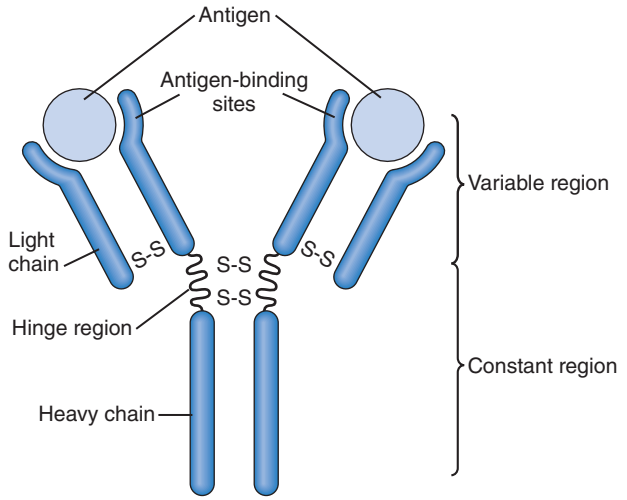

Figure 35.4 Structure of the typical IgG antibody, showing it to be composed of two heavy polypeptide chains and two light polypeptide chains. The antigen binds at two different sites on the variable regions of the chains.

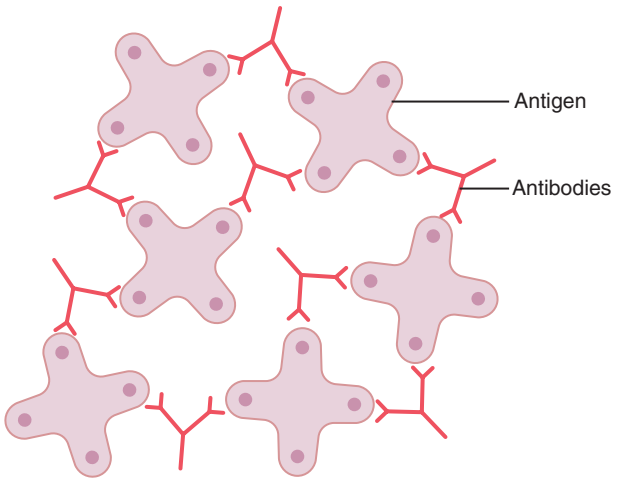

Figure 35.5 Binding of antigen molecules to one another by bivalent antibodies.

other biological properties of the antibody. A combination of noncovalent and covalent bonds (disulfide) holds the light and heavy chains together.

Each Antibody Is Specific for a Particular Antigen. Antibody specificity is a result of the unique structural organization of amino acids in the variable regions of the light and heavy chains. The amino acid organization has a different steric shape for each antigen specificity, so when an antigen comes into contact with it, multiple prosthetic groups of the antigen fit as a mirror image with those of the antibody, thus allowing for rapid and tight bonding between the antibody and antigen. When the antibody is highly specific, there are so many bonding sites that the antibody-antigen coupling is exceedingly strong, held together by (1) hydrophobic bonding; (2) hydrogen bonding; (3) ionic attractions; and (4) van der Waals forces. It also obeys the thermodynamic mass action law:

$$k_a = \frac{\text{Concentration of bound antibody–antigen}}{\text{Concentration of antibody} \times \text{Concentration of antigen}}$$

K_a is called the *affinity constant* and is a measure of how tightly the antibody binds with the antigen.

Note especially in **Fig. 35.4** that there are two variable sites on the illustrated antibody for attachment of antigens, making this type of antibody *bivalent*. A small proportion of the antibodies, which consist of combinations of up to 10 light and 10 heavy chains, has as many as 10 binding sites.

Five General Classes of Antibodies. There are five general classes of antibodies, respectively named *IgM, IgG, IgA, IgD,* and *IgE*. "Ig" stands for immunoglobulin, and the other five letters designate the respective classes.

For the purpose of our limited discussion, two of these classes of antibodies are of particular importance—IgG, which is a bivalent antibody and constitutes about 75% of the antibodies of the normal person, and IgE, which constitutes only a small percentage of the antibodies but is especially involved in allergies. The IgM class is also interesting because a large share of the antibodies formed during the primary response are of this type. These antibodies have 10 binding sites that make them exceedingly effective in protecting the body against invaders, even though there are not many IgM antibodies.

Mechanisms of Action of Antibodies

Antibodies act mainly in two ways to protect the body against invading agents: (1) by direct attack on the invader; and (2) by activation of the complement system that then has multiple means of its own for destroying the invader.

Direct Action of Antibodies on Invading Agents. **Fig. 35.5** shows antibodies (designated by the red Y-shaped bars) reacting with antigens (designated by the shaded objects). Because of the bivalent nature of the antibodies and the multiple antigen sites on most invading agents, the antibodies can inactivate the invading agent in one of several ways, as follows:

1. Agglutination, in which multiple large particles with antigens on their surfaces (e.g., bacteria or red cells) are bound together into a clump
2. Precipitation, in which the molecular complex of soluble antigen (e.g., tetanus toxin) and antibody becomes so large that it is rendered insoluble and precipitates
3. Neutralization, in which the antibodies cover the toxic sites of the antigenic agent
4. Lysis, in which some potent antibodies are occasionally capable of directly attacking membranes of cellular agents and causing rupture of the agent

These direct actions of antibodies often are not strong enough to play a major role in protecting the body against the invader. Most of the protection occurs through the amplifying effects of the complement system, described next.

COMPLEMENT SYSTEM FOR ANTIBODY ACTION

The main function of the complement system is to enhance (complement) the actions of antibodies and phagocytic cells in neutralizing and destroying pathogens, removing damaged cells from the body, and promoting inflammation. *Complement* is a collective term that describes a system of about 20 proteins, many of which are enzyme precursors. The principal actors in this system are 11 proteins designated C1 through C9, B, and D, shown in **Fig. 35.6**. All these are present normally among the plasma proteins in the blood, as well as among the proteins that leak out of the capillaries into the tissue spaces. The enzyme precursors are normally inactive but can be activated by the so-called *classical pathway*.

Classical Pathway. The classical pathway is initiated by an antigen-antibody reaction. When an antibody binds with an antigen, a specific reactive site on the constant region of the antibody becomes uncovered, or activated, and this in turn binds directly with the C1 molecule of the complement system. This sets into motion a cascade of sequential reactions, shown in **Fig. 35.6**, beginning with activation of the proenzyme C1. The C1 enzymes that are formed then activate successively increasing quantities of enzymes in the later stages of the system so that from a small beginning, an extremely large, amplified reaction occurs. Multiple end products are formed, as shown at the right in the figure, and several of these have important effects that help prevent damage to the body's tissues caused by the invading organism or toxin. Among the more important effects are the following:

1. *Opsonization and phagocytosis*. One of the products of the complement cascade, C3b, strongly activates phagocytosis by neutrophils and macrophages, causing these cells to engulf the bacteria to which the antigen-antibody complexes are attached. This process is called *opsonization*. It often enhances the number of bacteria that can be destroyed by many hundredfold.
2. *Lysis*. One of the most important of all the products of the complement cascade is the *membrane attack complex* (also called the *cytolytic complex*), which is a combination of multiple complement factors designated as C5b6789. This membrane attack complex inserts itself into the lipid bilayer of the cell membrane, creating pores that are permeable to ions and causing osmotic rupture of the cell membranes of bacteria or other invading organisms.
3. *Agglutination*. The complement products also change the surfaces of invading organisms, causing them to adhere to one another, thus promoting agglutination.
4. *Neutralization of viruses*. The complement enzymes and other complement products can attack the structures of some viruses and thereby render them nonvirulent.
5. *Chemotaxis*. Fragment C5a initiates chemotaxis of neutrophils and macrophages, thus causing large numbers of these phagocytes to migrate into the tissue area adjacent to the antigenic agent.
6. *Activation of mast cells and basophils*. Fragments C3a, C4a, and C5a activate mast cells and basophils, causing them to release histamine, heparin, and several other substances into the local fluids. These substances, in turn, cause increased local blood flow, increased leakage of fluid and plasma protein into the tissue, and other local tissue reactions that help inactivate or immobilize the antigenic agent. These same factors play a major role in inflammation (discussed in Chapter 34) and allergy, discussed later.

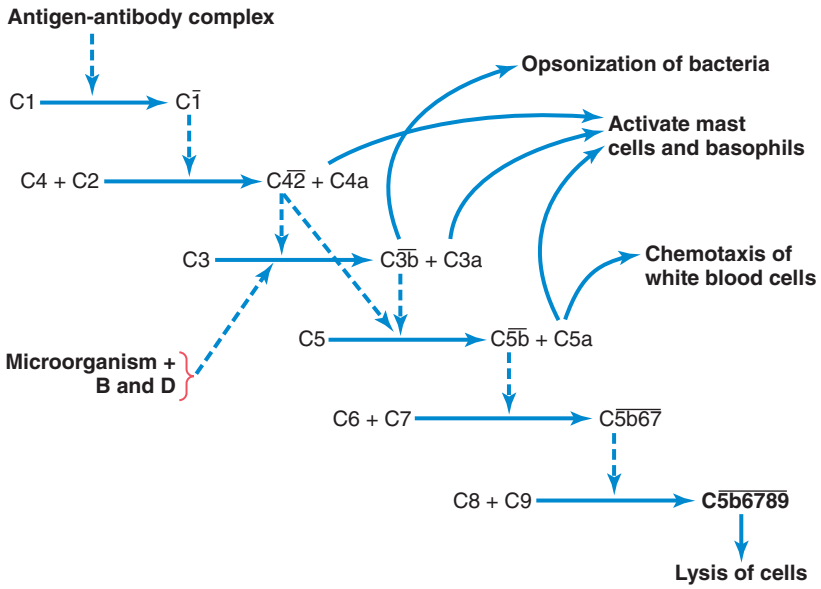

Figure 35.6 Cascade of reactions during activation of the classical pathway of complement.

7. *Inflammatory effects*. In addition to inflammatory effects caused by activation of the mast cells and basophils, several other complement products contribute to local inflammation. These products cause (1) the already increased blood flow to increase still further; (2) the capillary leakage of proteins to be increased; and (3) the interstitial fluid proteins to coagulate in the tissue spaces, thus preventing movement of the invading organism through the tissues.

SPECIFIC ATTRIBUTES OF T-LYMPHOCYTE SYSTEM—ACTIVATED T CELLS AND CELL-MEDIATED IMMUNITY

Release of Activated T Cells From Lymphoid Tissue and Formation of Memory Cells. On exposure to the proper antigen, as presented by adjacent macrophages, the T lymphocytes of a specific lymphocyte clone proliferate and release large numbers of activated, specifically reacting T cells in ways that parallel antibody release by activated B cells. The principal difference is that instead of releasing antibodies, whole activated T cells are formed and released into the lymph. These T cells then pass into the circulation, are distributed throughout the body, pass through the capillary walls into the tissue spaces, back into the lymph and blood again, and circulate again and again throughout the body, sometimes lasting for months or even years.

Also, *T-lymphocyte memory cells* are formed in the same way that B memory cells are formed in the antibody system. That is, when a clone of T lymphocytes is activated by an antigen, many of the newly formed lymphocytes are preserved in lymphoid tissue to become additional T lymphocytes of that specific clone; in fact, these memory cells spread throughout the lymphoid tissue of the entire body. Therefore, on subsequent exposure to the same antigen anywhere in the body, release of activated T cells occurs far more rapidly and much more powerfully than during first exposure.

Antigen-Presenting Cells, Major Histocompatibility Complex Proteins, and Antigen Receptors on T Lymphocytes. T-cell responses are extremely antigen-specific, like the antibody responses of B cells, and are at least as important as antibodies in defending against infection. In fact, acquired immune responses usually require assistance from T cells to begin the process, and T cells play a major role in helping eliminate invading pathogens.

Although B lymphocytes recognize intact antigens, T lymphocytes respond to antigens only when they are bound to specific molecules called *MHC proteins* on the surface of *antigen-presenting cells* in the lymphoid tissues (**Fig. 35.7**). The three major types of antigen-presenting cells are *macrophages, B lymphocytes*, and *dendritic cells*. The dendritic cells (also known as *accessory cells*), the most potent of the antigen-presenting cells, are located throughout the body, and their main function is to present antigens to T cells. The interaction of cell adhesion proteins is critical in permitting the T cells to bind to antigen-presenting cells long enough to become activated.

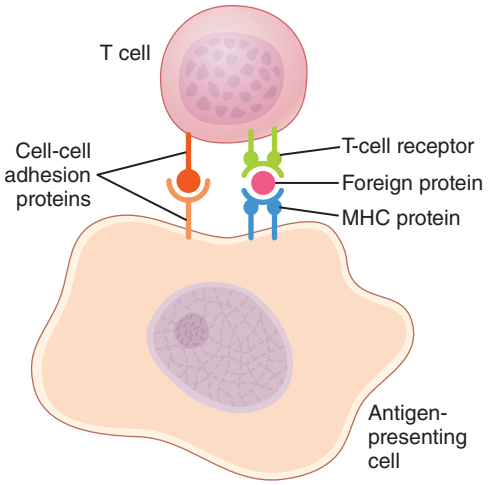

Figure 35.7 Activation of T cells requires interaction of T-cell receptors with an antigen (foreign protein) that is transported to the surface of the antigen-presenting cell by a major histocompatibility complex (MHC) protein. Cell-to-cell adhesion proteins enable the T cell to bind to the antigen-presenting cell long enough to become activated.

The MHC proteins are encoded by a large group of genes called the *major histocompatibility complex* (MHC). The MHC proteins bind peptide fragments of antigen proteins that are degraded inside antigen-presenting cells and then transport them to the cell surface. There are two types of MHC proteins: (1) *MHC I proteins*, which present antigens to *cytotoxic T cells;* and (2) *MHC II proteins*, which present antigens to *T-helper cells* and *regulatory T cells*. The specific functions of cytotoxic T cells, T-helper cells and regulatory T cells are discussed later.

The antigens on the surface of antigen-presenting cells bind with receptor molecules on the surfaces of T cells in the same way that they bind with plasma protein antibodies. These receptor molecules are composed of a variable unit similar to the variable region of the humoral antibody, but its stem section is firmly bound to the cell membrane of the T lymphocyte. There are as many as 100,000 receptor sites on a single T cell.

DIFFERENT TYPES OF T CELLS AND THEIR FUNCTIONS

It has become clear that there are multiple types of T cells, classified into three major groups: (1) *T-helper cells;* (2) *cytotoxic T cells;* and (3) *regulatory T cells* (also called *suppressor T cells*). The functions of each of these T cells are distinct.

T-Helper Cells Are the Most Numerous T Cells

The T-helper cells usually constitute more than 75% of all T cells. As their name implies, they help in the functions of the immune system in many ways. They serve as the major regulator of virtually all immune functions, as

shown in **Fig. 35.8**, by forming a series of protein mediators, called *lymphokines*. The lymphokines then act on other cells of the immune system, as well as on bone marrow cells.

When stimulated, naïve CD4+ T-helper cells can differentiate into subsets that produce different lymphokines and perform multiple functions. **Table 35.1** summarizes the main subsets of T-helper cells, the lymphokines that induce each subset, the lymphokines produced by the subsets, and the immunological reactions that each subset triggers.

Specific Regulatory Functions of Lymphokines

In the absence of the lymphokines from the T-helper cells, the remainder of the immune system is almost paralyzed. In fact, it is the T-helper cells that are inactivated or destroyed by the *human immunodeficiency virus* (HIV), which leaves the body almost totally unprotected against infectious disease, therefore leading to the now well-known debilitating and lethal effects of *acquired immunodeficiency syndrome* (AIDS). Some of the specific regulatory functions are described in the following sections.

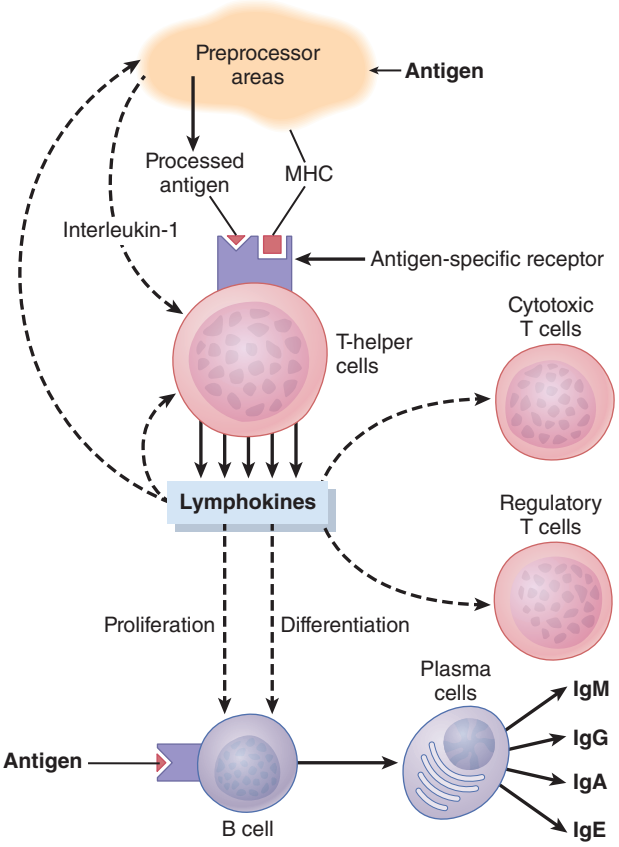

Figure 35.8 Regulation of the immune system, emphasizing a pivotal role of the T-helper cells. *MHC*, Major histocompatibility complex.

Lymphokine Stimulation of Growth and Proliferation of Cytotoxic T Cells and Regulatory T Cells. In the absence of T-helper cells, the clones for producing cytotoxic T cells and regulatory T cells are activated only slightly by most antigens. The lymphokine *interleukin-2* has an especially strong stimulatory effect in causing growth and proliferation of cytotoxic and regulatory T cells. In addition, several of the other lymphokines have less potent effects.

Lymphokine Stimulation of B-Cell Growth and Differentiation to Form Plasma Cells and Antibodies. The direct actions of antigens to cause B-cell growth, proliferation, formation of plasma cells, and secretion of antibodies are also weak without the help of the T-helper cells. Almost all the interleukins participate in the B-cell response, but especially *interleukins 4, 5, and 6*. These three interleukins have such potent effects on the B cells that they have been called *B-cell stimulating factors* or *B-cell growth factors*.

Activation of the Macrophage System By Lymphokines. Lymphokines also affect the macrophages. First, they slow or stop the migration of macrophages after they have been chemotactically attracted into the inflamed tissue, thus causing much accumulation of macrophages. Second, they activate macrophages to cause more efficient phagocytosis, allowing them to attack and destroy increasing numbers of invading bacteria or other tissue-destroying agents.

Feedback Stimulatory Effect of Lymphokines on T-Helper Cells. Some of the lymphokines, especially interleukin-2, have a direct positive feedback effect in stimulating activation of T-helper cells. This acts as an amplifier by further enhancing the helper cell response, as well as the entire immune response to an invading antigen.

Cytotoxic T Cells Are Killer Cells

The cytotoxic T cell is a direct attack cell that is capable of killing microorganisms and, at times, even some of the

Table 35.1 Subsets of T-Helper Cells

	T_H1	T_H2	T_H17
Lymphokines that induce subset	IFN-γ, IL-12	IL-4	TGF-β, IL-1, IL-6, IL-23

Major immune reactions	Macrophage activation Stimulate IgG antibody production	Stimulate IgE production Activation of mast cells and eosinophils	Recruitment of neutrophils and monocytes

body's own cells. For this reason, these cells are called *killer cells*. The receptor proteins on the surfaces of the CD8+ cytotoxic cells cause them to bind tightly to the organisms or cells that contain the appropriate binding-specific antigen. They then kill the attacked cell in the manner shown in **Fig. 35.9**. After binding, the cytotoxic T cell secretes hole-forming proteins, called *perforins*, that literally punch holes in the membrane of the attacked cell. Fluid then flows rapidly into the cell from the interstitial space. In addition, the cytotoxic T cell releases cytotoxic substances directly into the attacked cell. Almost immediately, the attacked cell becomes greatly swollen, and it usually dissolves shortly thereafter.

Of special importance is that these cytotoxic killer cells can pull away from the victim cells after they have punched holes and delivered cytotoxic substances and then move on to kill more cells. Some of these cells persist for months in the tissues.

Some of the cytotoxic T cells are especially lethal to tissue cells that have been invaded by viruses because many virus particles become entrapped in the membranes of the tissue cells and attract T cells in response to the viral antigenicity. The cytotoxic cells also play an important role in destroying cancer cells, heart transplant cells, or other types of cells that are foreign to the person's own body.

Regulatory T Cells

Regulatory T cells (Tregs) are capable of suppressing the functions of cytotoxic and T-helper cells. These suppressor functions of the CD4+ Tregs help prevent the cytotoxic cells from causing excessive immune reactions that might damage the body's own tissues. This suppressor T-cell system therefore plays an important role in limiting the ability of the immune system to attack a person's own body tissues, called *immune tolerance* (discussed in the next section), preventing autoimmunity, and limiting chronic inflammatory diseases. However, Tregs may also suppress the immune responses to tumors and hinder the innate ability of the body to control growth of cancer cells. Therefore, considerable research has been aimed at immunotherapy to downregulate Tregs in cancer and to upregulate Tregs in autoimmune disorders.

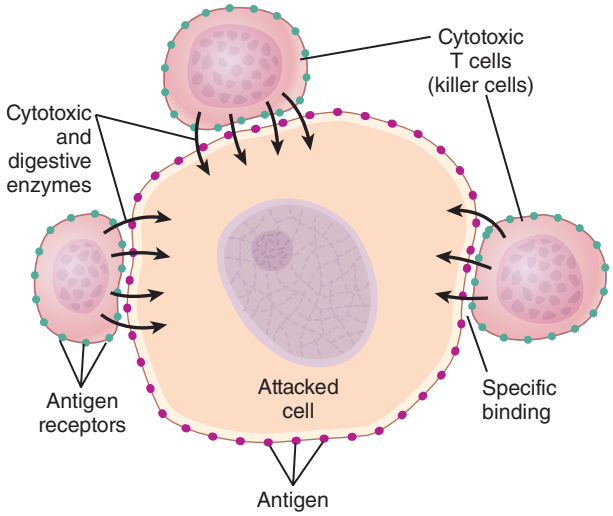

Figure 35.9 Direct destruction of an invading cell by sensitized lymphocytes (cytotoxic T cells).

TOLERANCE OF ACQUIRED IMMUNITY SYSTEM TO THE BODY'S OWN TISSUES—ROLE OF PREPROCESSING IN THYMUS AND BONE MARROW

The process of acquired immunity would destroy an individual's own body if that person became immune to their own tissues. The immune mechanism normally recognizes a person's own tissues as being distinctive from bacteria or viruses, and the immune system therefore forms few antibodies or activated T cells against a person's own antigens.

Most Tolerance Results From Clone Selection During Preprocessing and Maturation. Most tolerance is believed to develop during the preprocessing and maturation of T lymphocytes in the thymus and of B lymphocytes in the bone marrow. This is because injecting a strong antigen into a fetus while the lymphocytes are being preprocessed in these two areas prevents development of clones of lymphocytes in the lymphoid tissue that are specific for the injected antigen. Experiments have shown that specific immature lymphocytes in the thymus, when exposed to a strong antigen, become lymphoblastic, proliferate considerably, and then combine with the stimulating antigen—an effect that is believed to cause the cells to be destroyed by the thymic epithelial cells before they can migrate to and colonize the total body lymphoid tissue. This process is called *negative selection* and eliminates any developing T or B lymphocytes that are autoreactive (i.e., reactive to the body itself).

During the preprocessing of lymphocytes in the thymus and bone marrow, all or most of the clones of lymphocytes that are specific to damaging the body's own tissues appear to be self-destroyed because of their continual exposure to the body's antigens. In addition, the thymus generates Tregs that inhibit autoreactivity of T lymphocytes that may escape negative selection. Because of these functions, the thymus is essential for induction of tolerance.

Failure of the Tolerance Mechanism Causes Autoimmune Diseases. Sometimes, people lose immune tolerance of their own tissues. This phenomenon occurs to a greater extent the older a person becomes. It usually occurs after destruction of some of the body's own tissues, which releases considerable quantities of *self-antigens* that circulate in the body and presumably cause acquired immunity in the form of activated T cells or antibodies.

Over 100 diseases that result from autoimmunity have been described and include: (1) *rheumatic fever*, in which

the body becomes immunized against tissues in the joints and heart, especially the heart valves, after exposure to a specific type of streptococcal toxin that has an epitope in its molecular structure similar to the structure of some of the body's own self-antigens; (2) one type of *glomerulonephritis*, in which the person becomes immunized against the basement membranes of glomeruli; (3) *myasthenia gravis*, in which immunity develops against the acetylcholine receptor proteins of the neuromuscular junction, causing paralysis; (4) *multiple sclerosis* (MS), in which the immune system attacks the myelin that covers nerve fibers, disrupting nervous system communication; and (5) *systemic lupus erythematosus* (SLE), in which the person becomes immunized against many different body tissues at the same time, a disease that causes extensive damage and even death when SLE is severe.

IMMUNIZATION BY INJECTION OF ANTIGENS

Immunization has been used for many years to produce acquired immunity against specific diseases. A person can be immunized by injecting dead organisms that are no longer capable of causing disease but that still have some of their chemical antigens. This type of immunization is used to protect against typhoid fever, whooping cough, diphtheria, and many other types of bacterial diseases.

Immunity can be achieved against toxins that have been treated with chemicals so that their toxic nature has been destroyed, even though their antigens for causing immunity are still intact. This procedure is used in immunizing against tetanus, botulism, and other similar toxic diseases.

A person can also be immunized by being infected with live organisms that have been attenuated. That is, these organisms have been grown in special culture media or have been passed through a series of animals until they have mutated enough that they will not cause disease but do still carry specific antigens required for immunization. This procedure is used to protect against smallpox, yellow fever, poliomyelitis, measles, and many other viral diseases.

mRNA-Based Vaccines. The *mRNA vaccines* are composed of synthetic mRNA molecules that direct the production of an antigen that, in turn, generates an immune response against a specific pathogen (**Fig. 35.10**). Because mRNA is a large molecule and negatively charged, it cannot pass through cell membranes to induce synthesis of the antigen. However, various lipid-based nanoparticles can be used as vehicles for mRNA delivery. The nanoparticles containing the mRNA fuse with cell membranes to form endosomes that can enter the cytoplasm. After the mRNA escapes the endosome and enters the cytoplasm of antigen-presenting cells, the mRNA is translated by the ribosomes into antigen protein that activates the immune system in multiple ways, including stimulation of B lymphocytes to produce antibodies, activation of phagocytic macrophages, activation of cytotoxic T cells, and activation of T helper cells.

In 2020, the COVID pandemic stimulated the rapid development of mRNA vaccines for the *severe acute respiratory syndrome coronavirus-2* (*SARS-CoV-2*). The mRNA-based vaccines for SARS-CoV-2 have been administered worldwide, and mRNA-based approaches are being tested for prevention and therapy of other diseases.

PASSIVE IMMUNITY

Thus far, all the acquired immunity we have discussed has been *active immunity*—that is, the person's own body develops antibodies or activated T cells in response to invasion of the body by a foreign antigen. However, temporary immunity can be achieved in a person without injecting any antigen. This temporary immunity is achieved by infusing antibodies, activated T cells, or both obtained from the blood of someone else or from some other animal that has been actively immunized against the antigen.

Antibodies last in the body of the recipient for 2 to 3 weeks and, during that time, the person is protected against the invading disease. Such transfusion of antibodies or T lymphocytes to confer immunity is called *passive immunity*.

ALLERGY AND HYPERSENSITIVITY

An important undesirable side effect of immunity is the development, under some conditions, of an allergy or other type of *immune hypersensitivity*. There are several types of allergy and other hypersensitivities, some of which occur only in people who have a specific allergic tendency.

Allergy Caused By Activated T Cells: Delayed-Reaction Allergy

Delayed-reaction allergy is caused by activated T cells and not by antibodies. In the case of *poison ivy*, the toxin of poison ivy in itself does not cause much harm to the tissues. However, on repeated exposure, it causes formation of activated helper and cytotoxic T cells. Then, after subsequent exposure to the poison ivy toxin, within a day or so, the activated T cells diffuse from the circulating blood in large numbers into the skin to respond to the poison ivy toxin. At the same time, these T cells elicit a cell-mediated type of immune reaction.

This type of immunity can cause release of many toxic substances from the activated T cells, as well as extensive invasion of the tissues by macrophages, along with their subsequent effects. The eventual result of some delayed-reaction allergies can be serious tissue damage. The damage normally occurs in the tissue area where the instigating antigen is present, such as in the skin in the case of poison ivy or in the lungs to cause lung edema or *asthmatic attacks* in the case of some airborne antigens.

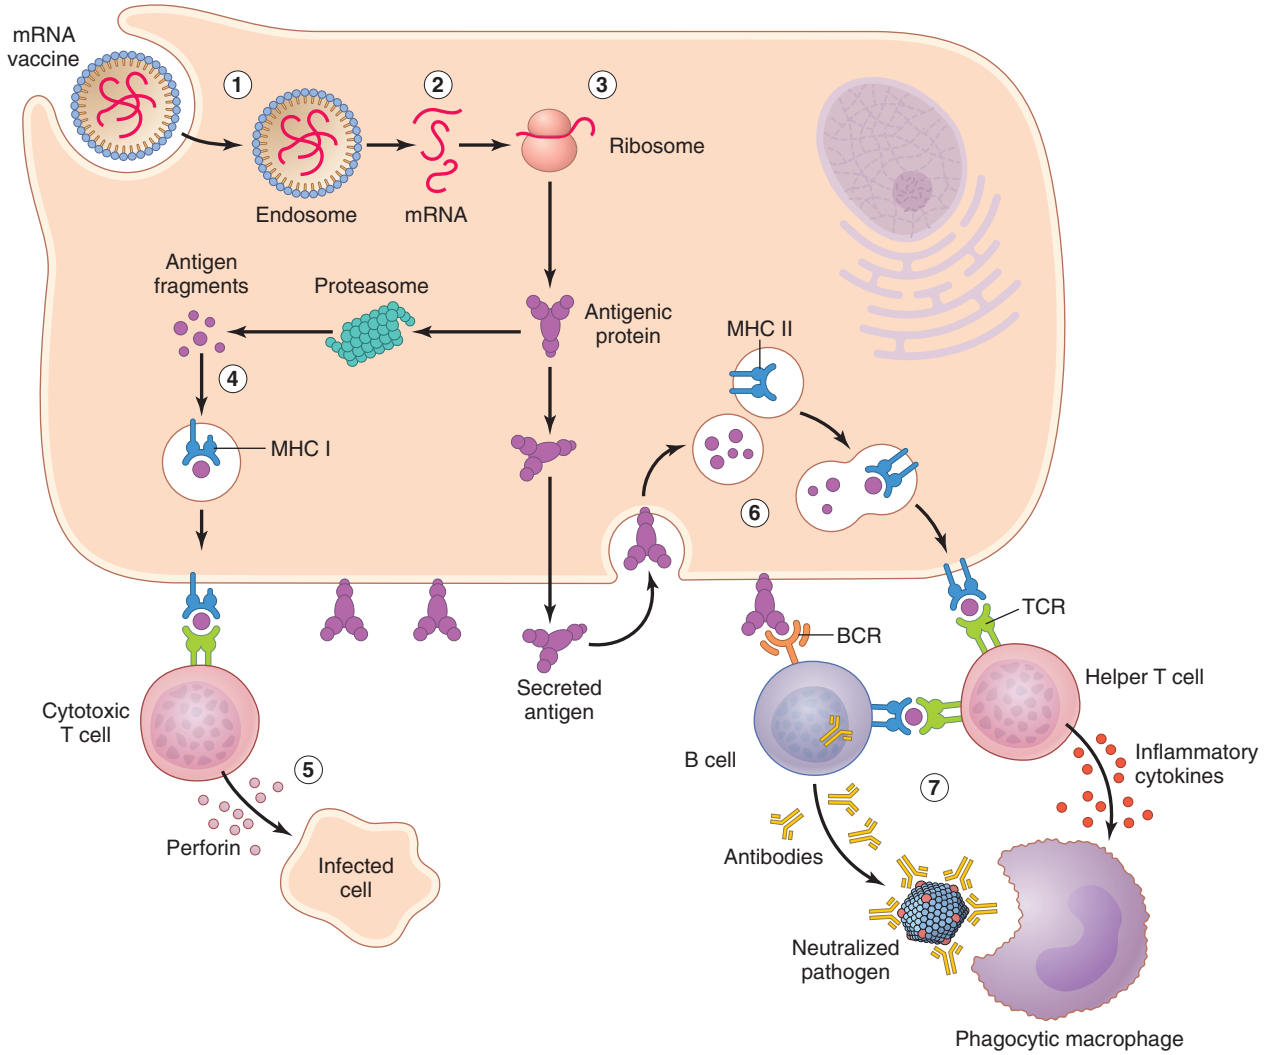

Figure 35.10 Mechanism of action of mRNA vaccines. (1) mRNA contained in lipid carrier is injected and enters antigen-presenting cells by endocytosis. (2) The vaccine mRNA escapes the endosome and enters the cytoplasm. (3) The vaccine mRNA is translated into protein by the ribosome. The translated antigenic protein activates the immune system in multiple ways. (4) The proteasome complex breaks down the antigen into fragments that attach to major histocompatibility complex (MHC I) class I proteins. (5) The antigen is presented to cytotoxic T cells that kill infected cells by releasing cytotoxic substances (e.g., perforins). (6) Secreted antigens are taken up by endosomes, degraded into fragments, and presented to helper T cells by MHC II proteins. (7) Helper T cells stimulate B cells to produce neutralizing antibodies and activate phagocytes (e.g., macrophages) by releasing inflammatory cytokines. *BCR*, B cell receptor; *ER*, endoplasmic reticulum; *TCR*, T-cell receptor. Atopic Allergies Associated With Excess IgE Antibodies

Some people have an allergic tendency. Their allergies are called *atopic allergies* because they are caused by a nonordinary response of the immune system. The allergic tendency is genetically passed from parent to child and is characterized by the presence of large quantities of IgE antibodies in the blood. These antibodies are called *reagins* or *sensitizing antibodies* to distinguish them from the more common IgG antibodies. When an *allergen* (defined as an antigen that reacts specifically with a specific type of IgE reagin antibody) enters the body, an allergen-reagin reaction takes place, and a subsequent allergic reaction occurs.

A special characteristic of the IgE antibodies (the reagins) is a strong propensity to attach to mast cells and basophils. Indeed, a single mast cell or basophil can bind as many as a half-million molecules of IgE antibodies. Then, when an antigen (an allergen) that has multiple binding sites binds with several IgE antibodies that are already attached to a mast cell or basophil, there is an immediate change in the membrane of the mast cell or basophil, perhaps resulting from a physical effect of the antibody molecules to contort the cell membrane. Many of the mast cells and basophils rupture; others release special agents immediately or shortly thereafter, including *histamine, protease, slow-reacting substance of anaphylaxis* (a mixture of toxic leukotrienes), *eosinophil chemotactic substance, neutrophil chemotactic substance, heparin*, and *platelet-activating factors*. These substances cause effects such as dilation of the local blood vessels, attraction of eosinophils and neutrophils to the reactive

site, increased permeability of the capillaries with loss of fluid into the tissues, and contraction of local smooth muscle cells. Therefore, several different tissue responses can occur, depending on the type of tissue in which the allergen-reagin reaction occurs. Some of the different types of allergic reactions caused in this manner are described next.

Anaphylaxis—Widespread Allergic Reaction. When a specific allergen is injected directly into the circulation, the allergen can react with basophils of the blood and mast cells in the tissues located immediately outside the small blood vessels if the basophils and mast cells have been sensitized by the attachment of IgE reagins. Therefore, a widespread allergic reaction occurs throughout the vascular system and closely associated tissues. This reaction is called *anaphylaxis*. Histamine is released into the circulation and causes vasodilation throughout the body, as well as increased permeability of the capillaries, with a resultant marked loss of plasma from the circulation. Occasionally, a person who experiences this reaction dies of circulatory shock within a few minutes unless treated with epinephrine to counteract the effects of the histamine.

Also released from the activated basophils and mast cells is a mixture of leukotrienes called *slow-reacting substance of anaphylaxis*. These leukotrienes can cause spasm of the smooth muscle of the bronchioles, eliciting an asthma-like attack and sometimes causing death by suffocation.

Urticaria—Localized Anaphylactoid Reactions. Urticaria results from antigen entering specific skin areas and causing localized anaphylactoid reactions. Histamine released locally causes: (1) vasodilation that induces an immediate red flare; and (2) increased local permeability of the capillaries, which leads to local circumscribed areas of swelling of the skin within another few minutes. The swellings are commonly called *hives*. Administration of antihistamine drugs to a person before exposure will prevent the hives.

Hay Fever. In hay fever, the allergen-reagin reaction occurs in the nose. Histamine released in response to the reaction causes local intranasal vascular dilation, with resultant increased capillary pressure and increased capillary permeability. Both these effects cause rapid fluid leakage into the nasal cavities and into associated deeper tissues of the nose, and the nasal linings become swollen and secretory. Here again, the use of antihistamine drugs can prevent this swelling reaction. However, other products of the allergen-reagin reaction can still cause irritation of the nose, eliciting the typical sneezing syndrome.

Asthma. Asthma often occurs in the hypersensitive allergic person. In these individuals, the allergen-reagin reaction occurs in the bronchioles of the lungs. Here, an important product released from the mast cells is believed to be the *slow-reacting substance of anaphylaxis* (a mixture of three leukotrienes), which causes spasm of the bronchiolar smooth muscle. Consequently, the person has difficulty breathing until the reactive products of the allergic reaction have been removed. The administration of antihistamine medication has less effect on the course of asthma because histamine does not appear to be the major factor eliciting the asthmatic reaction.

SEX DIFFERENCES IN INNATE AND ADAPTIVE IMMUNITY

Sex chromosomes and gonadal hormones (e.g., testosterone and estrogen) modulate the number of immune cells, as well as their function. For example, activation and phagocytic activity of certain macrophage and monocyte populations are greater in females than in males. Also, *interferons*, a group of signaling proteins with antiviral activity, are produced to a greater extent by immune cells of females than of males after viral infections. Compared to males, females also have a stronger adaptive immune response, including greater expansion of T cells and humoral responses; this immune response enables more rapid clearing of pathogens and enhances antibody responses to subsequent antigen exposures. Therefore, immune responses to vaccines are also generally greater in women than in men.

Although more robust responses of the innate and adaptive immune systems appear to be protective against invading pathogens, they may also contribute to increased prevalence of autoimmunity in females compared with males. For example, various autoimmune diseases affect about 5% of the human population, but about 80% of those affected are female. *Systemic lupus erythematosus*, an autoimmune disease that causes widespread inflammation and tissue damage, affects women nearly 10 times more frequently than men. Although sex-related differences in immunity are still not fully understood, progress in defining sex-based mechanisms may help refine vaccine development, as well as treatment of immune-mediated diseases.

CHAPTER 36

Blood Types, Transfusion, and Tissue and Organ Transplantation

ANTIGENICITY CAUSES IMMUNE REACTIONS OF BLOOD

Blood types of different people have different antigenic and immune properties so that antibodies in the plasma of one blood type will react with antigens on the surfaces of the red blood cells (RBCs) of another blood type. When blood is transfused from one person to another and the blood types are not appropriately matched, immediate or delayed agglutination (clumping) and hemolysis of the red blood cells (RBCs) will occur. However, one can determine ahead of time whether the antibodies and antigens present in the donor and recipient blood will cause a transfusion reaction.

Multiplicity of Antigens in the Blood Cells

At least 30 commonly occurring antigens and hundreds of other rare antigens, each of which can at times cause antigen-antibody reactions, have been found on the cell membrane surfaces of human blood cells. Most of the antigens are weak and therefore are of importance principally for studying the inheritance of genes to establish parentage.

Two particular types of antigens are much more likely than the others to cause blood transfusion reactions. They are the *O-A-B* system of antigens and the *Rh* system.

O-A-B BLOOD TYPES

A and B Antigens—Agglutinogens

Two antigens—type A and type B—occur on the surfaces of the RBCs in a large proportion of people. It is these antigens (also called *agglutinogens* because they often cause RBC agglutination) that cause most blood transfusion reactions. Because of how these agglutinogens are inherited, people may have neither of them on their cells, they may have one, or they may have both simultaneously.

Major O-A-B Blood Types. In transfusing blood from one person to another, the blood of donors and recipients is normally classified into four major O-A-B blood types, as shown in **Table 36.1**, depending on the presence or absence of the A and B agglutinogens. When neither A nor B agglutinogen is present, the blood is *type O*. When only type A agglutinogen is present, the blood is *type A*. When only type B agglutinogen is present, the blood is *type B*. When both A and B agglutinogens are present, the blood is *type AB*.

Genetic Determination of the Agglutinogens. The ABO blood group genetic locus has three *alleles*, which means three different forms of the same gene. These three alleles—I^A, I^B, and I^O—determine the three blood types. We typically call these alleles *A, B*, and *O*, but geneticists often represent alleles of a gene by variations of the same symbol. In this case, the common symbol is the letter "I," which stands for *immunoglobulin*.

The type O allele causes no significant type O agglutinogen on the cells. Conversely, the type A and type B alleles cause strong agglutinogens on the cells. Thus, the O allele is recessive to both the A and B alleles, which show *co-dominance*.

Because each person has only two sets of chromosomes, only one of these alleles is present on each of the two chromosomes in any individual. However, the presence of three different alleles means that there are six possible combinations of alleles, as shown in **Table 36.1**: OO, OA, OB, AA, BB, and AB. These combinations of alleles are known as the *genotypes*, and each person is one of the six genotypes.

One can also observe from **Table 36.1** that a person with genotype OO produces no agglutinogens, and therefore the blood type is O. A person with genotype OA or AA produces type A agglutinogens and therefore has blood type A. Genotypes OB and BB give type B blood, and genotype AB gives type AB blood.

Relative Frequencies of Different Blood Types. Although there is some variation among different populations, the prevalence of the different blood types among one group of persons studied was approximately as follows:

- O: 47%
- A: 41%
- B: 9%
- AB: 3%

It is obvious from these percentages that the O and A genes occur much more frequently than the B gene occurs.

Table 36.1 Blood Types With Their Genotypes and Constituent Agglutinogens and Agglutinins

Genotypes	Blood Types	Agglutinogens	Agglutinins
OO	O	–	Anti-A and Anti-B
OA or AA	A	A	Anti-B
OB or BB	B	B	Anti-A
AB	AB	A and B	–

Agglutinins

When type A agglutinogen *is not present* in a person's RBCs, antibodies known as *anti-A agglutinins* develop in the plasma. Also, when type B agglutinogen *is not present* in the RBCs, antibodies known as *anti-B agglutinins* develop in the plasma.

Referring once again to **Table 36.1**, note that type O blood, although containing no agglutinogens, does contain both *anti-A* and *anti-B agglutinins*. Type A blood contains type A agglutinogens and anti-B agglutinins, and type B blood contains type B agglutinogens and anti-A agglutinins. Finally, type AB blood contains both A and B agglutinogens but no agglutinins.

Titer of Agglutinins at Different Ages. Immediately after birth, the quantity of agglutinins in the plasma is almost zero. At 2 to 8 months after birth, an infant begins to produce agglutinins—anti-A agglutinins when type A agglutinogens are not present in the cells, and anti-B agglutinins when type B agglutinogens are not in the cells. **Fig. 36.1** shows the changing titers of the anti-A and anti-B agglutinins at different ages. A maximum titer is usually reached at 8 to 10 years of age, and this titer gradually declines throughout the remaining years of life.

Origin of Agglutinins in Plasma. The agglutinins are gamma globulins, as are almost all antibodies, and they are produced by the same bone marrow and lymph gland cells that produce antibodies to other antigens. Most of them are IgM and IgG immunoglobulin molecules.

But why are these agglutinins produced in people who do not have the respective agglutinogens in their RBCs? A possible answer to this question is that small amounts of type A and B antigens enter the body in food, bacteria, and other ways, and these substances initiate the development of the anti-A and anti-B agglutinins.

For example, infusion of group A antigen into a recipient having a non-A blood type causes a typical immune response, with formation of more anti-A agglutinins than ever. Also, neonates have few, if any, agglutinins, showing that agglutinin formation occurs almost entirely after birth.

Agglutination Process in Transfusion Reactions

When bloods are mismatched so that anti-A or anti-B plasma agglutinins are mixed with RBCs that contain A or B agglutinogens, respectively, the RBCs agglutinate as a result of the agglutinins attaching themselves to the RBCs. Because the agglutinins have two binding sites (IgG type) or 10 binding sites (IgM type), a single agglutinin can attach to two or more RBCs at the same time, thereby causing the cells to be bound together by the agglutinin. This binding causes the cells to clump, which is the process of *agglutination*. Then these clumps plug small blood vessels throughout the circulatory system. During the ensuing hours to days, physical distortion of the cells or attack by phagocytic white blood cells destroys the membranes of the agglutinated cells, releasing hemoglobin into the plasma, called *hemolysis* of the RBCs.

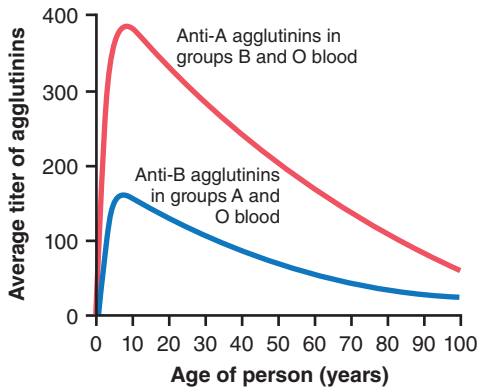

Figure 36.1 Average titers of anti-A and anti-B agglutinins in the plasma of people with different blood types.

Acute Hemolysis Occurs in Some Transfusion Reactions. Sometimes, when recipient and donor bloods are mismatched, immediate hemolysis of RBCs occurs in the circulating blood. In this case, the antibodies cause lysis of the RBCs by activating the complement system and forming a *membrane attack complex* (also called *cytolytic complex*) that inserts itself into the lipid bilayer of the cell membranes; this insertion creates membrane pores that are permeable to ions and causes osmotic lysis of the cells, as described in Chapter 35. *Immediate* intravascular hemolysis is far less common than agglutination followed by *delayed* hemolysis, because not only does there have to be a high titer of antibodies for lysis to occur, but also a different type of antibody seems to be required, mainly the IgM antibodies; these antibodies are called *hemolysins*.

Blood Typing

Before giving a transfusion to a person, it is necessary to determine the blood type of the recipient and donor blood so that the bloods can be appropriately matched. This process is called *blood typing* and *blood matching*, and these procedures are performed in the following way. The RBCs are first separated from the plasma and diluted with saline solution. One portion is then mixed with anti-A agglutinin and another portion is mixed with anti-B agglutinin. After several minutes, the mixtures are observed under a microscope. If the RBCs have become clumped—that is, *agglutinated*—then an antibody-antigen reaction has resulted.

Table 36.2 lists the presence (+) or absence (−) of agglutination of the four types of RBCs. Type O RBCs have no agglutinogens and therefore do not react with the anti-A or anti-B agglutinins. Type A blood has A agglutinogens and therefore agglutinates with anti-A agglutinins. Type B blood has B agglutinogens and agglutinates with anti-B agglutinins. Type AB blood has both A and B agglutinogens and agglutinates with both types of agglutinins.

Rh BLOOD TYPES

Along with the O-A-B blood type system, the Rh blood type system is also important when transfusing blood. In the O-A-B system, the plasma agglutinins responsible for causing transfusion reactions develop spontaneously, whereas in the Rh system, spontaneous agglutinins almost never occur. Instead, the person must first be massively exposed to an Rh antigen—such as by transfusion of blood containing the Rh antigen—before enough agglutinins to cause a significant transfusion reaction will develop.

Rh Antigens—Rh-Positive and Rh-Negative. There are six common types of Rh antigens, each of which is called an *Rh factor*. These types are designated C, D, E, c, d, and e. A person who has a C antigen does not have the c antigen, but the person missing the C antigen always has the c antigen. The same is true for the D-d and E-e antigens. Also, because of the manner of inheritance of these factors, each person has one of each of the three pairs of antigens.

The type D antigen is widely prevalent in the population and is considerably more antigenic than the other Rh antigens. Anyone who has this type of antigen is said to be *Rh positive*, whereas a person who does not have type D antigen is said to be *Rh negative*. However, it must be noted that even in Rh-negative people, some of the other Rh antigens can still cause transfusion reactions, although the reactions are usually much milder.

About 85% of all Whites are Rh positive, and 15% are Rh negative. In Black Americans, the percentage of Rh-positives is about 95%, whereas in Black Africans, it is nearly 100%. Over 95% of Native Americans and Asians living in China, Japan, and Korea are also Rh positive, and it is estimated that the worldwide frequencies of Rh-positive and Rh-negative blood types are 95% and 6%, respectively.

Table 36.2 Blood Typing: Agglutination of Cells of Different Blood Types With Anti-A or Anti-B Agglutinins in the Sera

Red Blood Cell Types	Sera	
	Anti-A	Anti-B
O	−	−
A	+	−
B	−	+
AB	+	+

RH IMMUNE RESPONSE

Formation of Anti-Rh Agglutinins. When RBCs containing Rh factor are injected into a person whose blood does not contain the Rh factor—that is, into an Rh-negative person—anti-Rh agglutinins develop slowly, reaching a maximum concentration of agglutinins about 2 to 4 months later. This immune response occurs to a much greater extent in some people than in others. With multiple exposures to the Rh factor, an Rh-negative person eventually becomes strongly sensitized to Rh factor.

Characteristics of Rh Transfusion Reactions. If an Rh-negative person has never been exposed to Rh-positive blood, transfusion of Rh-positive blood into that person will likely cause no immediate reaction. However, anti-Rh antibodies can develop in sufficient quantities during the next 2 to 4 weeks to cause agglutination of the transfused cells that are still circulating in the blood. These cells are then hemolyzed by the tissue macrophage system. Thus, a *delayed* transfusion reaction occurs, although it is usually mild. On subsequent transfusion of Rh-positive blood into the same person, who is now already immunized against the Rh factor, the transfusion reaction is greatly enhanced and can be immediate and as severe as a transfusion reaction caused by mismatched type A or B blood.

Erythroblastosis Fetalis (Hemolytic Disease of the Newborn)

Erythroblastosis fetalis is a disease of the fetus and newborn child that is characterized by agglutination and phagocytosis of the fetus's RBCs. In most cases of erythroblastosis fetalis, the mother is Rh negative and the father is Rh positive. The baby has inherited the Rh-positive antigen from the father, and the mother develops anti-Rh agglutinins from exposure to the fetus's Rh antigen. In turn, the mother's agglutinins diffuse through the placenta into the fetus and cause RBC agglutination.

Incidence of Erythroblastosis Fetalis. An Rh-negative mother having her first Rh-positive child usually does not develop sufficient anti-Rh agglutinins to cause harm. However, about 3% of second Rh-positive babies exhibit some signs of erythroblastosis fetalis, about 10% of third babies exhibit the disease, and the incidence rises progressively with subsequent pregnancies.

Effect of Mother's Antibodies on the Fetus. After anti-Rh antibodies have formed in the mother, they diffuse slowly through the placental membrane into the fetus's blood. There they cause agglutination of the fetus's blood. The agglutinated RBCs subsequently hemolyze, releasing hemoglobin into the blood. The fetus's macrophages then convert the hemoglobin into bilirubin, which causes the baby's skin to become yellow (jaundiced). The antibodies can also attack and damage other cells of the body.

Clinical Picture of Erythroblastosis. The jaundiced, erythroblastotic newborn baby is usually anemic at birth,

and the anti-Rh agglutinins from the mother usually circulate in the infant's blood for another 1 to 2 months after birth, destroying more and more RBCs.

The hematopoietic tissues of the infant attempt to replace the hemolyzed RBCs. The liver and spleen become greatly enlarged and produce RBCs in the same manner that they normally do during the middle of gestation. Because of the rapid production of RBCs, many early forms of RBCs, including many *nucleated blastic forms*, are passed from the baby's bone marrow into the circulatory system, and it is because of the presence of these nucleated blastic RBCs that the disease is called *erythroblastosis fetalis*.

Although the severe anemia of erythroblastosis fetalis is usually the cause of death, many children who barely survive the anemia exhibit permanent mental impairment or damage to motor areas of the brain because of precipitation of bilirubin in the neuronal cells, causing the destruction of many of these cells, a condition called *kernicterus*.

Treatment of Neonates With Erythroblastosis Fetalis. One treatment for erythroblastosis fetalis is to replace the neonate's blood with Rh-negative blood. The Rh-negative blood is infused over a period of 1.5 or more hours while the neonate's own Rh-positive blood is being removed. This procedure may be repeated several times during the first few weeks of life, mainly to keep the bilirubin level low and thereby prevent kernicterus. By the time these transfused Rh-negative cells are replaced with the infant's own Rh-positive cells, a process that requires 6 weeks or more, the anti-Rh agglutinins that came from the mother will have been destroyed.

Prevention of Erythroblastosis Fetalis. The D antigen of the Rh blood group system is the primary culprit in causing immunization of an Rh-negative mother to an Rh-positive fetus. In the 1970s, a dramatic reduction in the incidence of erythroblastosis fetalis was achieved with the development of *Rh immunoglobulin globin, an anti-D antibody* that is administered to the expectant mother starting at 28 to 30 weeks of gestation. The anti-D antibody is also administered to Rh-negative women who deliver Rh-positive babies to prevent sensitization of the mothers to the D antigen. This step greatly reduces the risk of developing large amounts of D antibodies during the second pregnancy.

The mechanism whereby Rh immunoglobulin globin prevents sensitization of the D antigen is not completely understood, but one effect of the anti-D antibody is to inhibit antigen-induced, B lymphocyte antibody production in the expectant mother. The administered anti-D antibody also attaches to D antigen sites on Rh-positive fetal RBCs that may cross the placenta and enter the circulation of the expectant mother, thereby interfering with the immune response to the D antigen.

TRANSFUSION REACTIONS RESULTING FROM MISMATCHED BLOOD TYPES

If donor blood of one blood type is transfused into a recipient who has another blood type, a transfusion reaction is likely to occur in which the RBCs *of the donor blood* are agglutinated. It is rare that the transfused blood causes agglutination *of the recipient's cells*, for the following reason. The plasma portion of the donor blood immediately becomes diluted by all the plasma of the recipient, thereby decreasing the titer of the infused agglutinins to a level usually too low to cause agglutination. However, the small amount of infused blood does not significantly dilute the agglutinins in the recipient's plasma. Therefore, the recipient's agglutinins can still agglutinate the mismatched donor cells.

As explained earlier, all transfusion reactions eventually cause immediate hemolysis resulting from hemolysins or delayed hemolysis resulting from phagocytosis of agglutinated cells. Hemoglobin released from the RBCs is then converted by the phagocytes into bilirubin and later excreted in the bile by the liver, as discussed in Chapter 71. The concentration of bilirubin in the body fluids often rises high enough to cause *jaundice*—that is, the person's internal tissues and skin become *colored with yellow bile pigment*. However, if liver function is normal, the bile pigment will be excreted into the intestines by way of the liver bile, so jaundice usually does not appear in an adult unless more than 400 milliliters of blood are hemolyzed in less than a day.

Acute Kidney Failure After Transfusion Reactions. One of the most lethal effects of transfusion reactions is *acute kidney injury*, which can begin within a few minutes to a few hours and continue until the person dies of acute renal failure.

The kidney shutdown seems to have three main causes:

1. *Renal vasoconstriction*. The antigen-antibody reaction of the transfusion reaction releases toxic substances from the hemolyzing blood that cause powerful renal vasoconstriction.
2. *Decreased arterial pressure*. Loss of circulating RBCs in the recipient, along with production of toxic substances from the hemolyzed cells and the immune reaction, often causes circulatory shock. The arterial blood pressure falls very low, and renal blood flow and urine output decrease.
3. *Blockade of the renal tubules* by precipitated hemoglobin. If the total amount of free hemoglobin released into the circulating blood is greater than the quantity that can bind with *haptoglobin* (a plasma protein that binds small amounts of hemoglobin), much of the excess leaks through the glomerular membranes into the kidney tubules. If this amount is still slight, it can be reabsorbed through the tubular epithelium into the blood and will cause no harm; if large, then only a small percentage is reabsorbed.

Yet, water continues to be reabsorbed, causing the tubular hemoglobin concentration to rise so high that the hemoglobin precipitates and blocks many of the kidney tubules.

Thus, renal vasoconstriction, circulatory shock, and renal tubular blockage together cause acute renal shutdown. If the shutdown is complete and fails to resolve, the patient dies within 7 to 12 days, as explained in Chapter 32, unless treated with an artificial kidney.

TRANSPLANTATION OF TISSUES AND ORGANS

Most of the different antigens of RBCs that cause transfusion reactions are also widely present in other cells of the body, and each tissue has its own additional complement of antigens. Consequently, foreign cells transplanted anywhere into the body of a recipient can produce an immune reaction. In other words, most recipients are just as able to resist invasion by foreign tissue cells as to resist invasion by foreign bacteria, viruses, or RBCs.

Autografts, Isografts, Allografts, and Xenografts. A transplant of a tissue or whole organ from one part of the same animal to another part is called an *autograft*; from one identical twin to another, an *isograft*; from one person to another or from an animal to another animal of the same species, an *allograft*; and from a nonhuman animal to a human or from an animal of one species to one of another species, a *xenograft*.

Transplantation of Cellular Tissues. In the case of *autografts* and *isografts*, cells in the transplant contain virtually the same types of antigens as in the tissues of the recipient and will almost always continue to live normally and indefinitely if an adequate blood supply is provided. At the other extreme, severe immune reactions almost always occur in *xenografts*, causing death of the cells in the graft within 1 day to 5 weeks after transplantation unless some specific therapy is used to prevent the immune reactions.

Some of the different cellular tissues and organs that have been transplanted from one person to another as allografts, either experimentally or for therapeutic purposes, are skin, kidney, heart, liver, glandular tissue, bone marrow, and lung. With proper matching of tissues between persons, many kidney allografts have been successful for at least 5 to 15 years and allograft liver and heart transplants for at least 1 to 15 years. With improved tissue typing and immunosuppressive therapies, many transplanted organs survive for 20 or more years.

ATTEMPTS TO OVERCOME IMMUNE REACTIONS IN TRANSPLANTED TISSUE

Because of the extreme potential importance of transplanting certain tissues and organs, serious attempts have been made to prevent antigen-antibody reactions associated with transplantation. The following specific procedures have met with some clinical or experimental success.

Tissue Typing—Human Leukocyte Antigen Complex of Antigens. The most important antigens for causing graft rejection are a complex called *human leukocyte antigens* (HLAs). Six of these antigens are present on the tissue cell membranes of each person, but there are about 150 different HLAs to choose from, representing more than 1 trillion possible combinations. Consequently, it is virtually impossible for two persons, except in the case of identical twins, to have the same six HLAs. Development of significant immunity against any of these antigens can cause graft rejection.

The HLAs are on the white blood cells, as well as on the tissue cells. Therefore, tissue typing for these antigens is done on the membranes of lymphocytes that have been separated from the person's blood. The lymphocytes are mixed with appropriate antisera and complement; after incubation, the cells are tested for membrane damage, usually by determining the rate of transmembrane uptake by the lymphocytic cells of a special dye.

Some of the HLAs are not severely antigenic. Therefore, a precise match of some antigens between donor and recipient is not always essential to allow allograft acceptance. By using a more advanced method of genetic testing and obtaining the best possible match between donor and recipient, the grafting procedure has become far less hazardous. The best success has been with tissue type matches between siblings and between parent and child. The match in identical twins is exact, so transplants between identical twins are almost never rejected because of an immune reaction.

Prevention of Graft Rejection By Suppressing the Immune System

If the immune system were completely suppressed, graft rejection would not occur. In fact, in a person who has serious depression of the immune system, grafts can be successful without the use of significant therapy to prevent rejection. However, in persons with healthy immune systems, allografts seldom resist rejection for more than a few days or weeks without the use of specific therapy to suppress the immune system. Furthermore, because the T cells are mainly the portion of the immune system important for killing grafted cells, their suppression is important for preventing rejection of tissue grafts. Some of the therapeutic agents that have been used for this purpose include the following:

1. *Glucocorticoid hormones* from adrenal cortex glands (or drugs with glucocorticoid-like activity). These drugs inhibit genes that code for several cytokines, especially interleukin-2 (IL-2). IL-2 is an essential factor that induces T-cell proliferation and antibody formation.

2. Various drugs that have a toxic effect on the lymphoid system and therefore block formation of antibodies and T cells, especially the drug *azathioprine*.
3. *Cyclosporine and tacrolimus* inhibit *calcineurin*, an enzyme that activates transcription factors for interleukin-2 (IL-2) and several other cytokines in T cells. By inhibiting synthesis of these cytokines in T cells, calcineurin inhibitors suppress T-cell and T-cell–dependent B-cell activation. These drugs are highly valuable because they do not depress some other portions of the immune system.
4. *Immunosuppressive antibody therapy*, including specific antilymphocyte or IL-2 receptor antibodies.

Use of these agents often leaves the person unprotected from infectious disease; therefore, sometimes bacterial and viral infections become rampant. In addition, the incidence of cancer is several times greater in an immunosuppressed person, presumably because the immune system is important in destroying many early cancer cells before they can begin to proliferate.

Transplantation of living tissues in people has been successful mainly because of the development of drugs that suppress the responses of the immune system. With the introduction of improved immunosuppressive agents, successful organ transplantation has become much more common. The current approach to immunosuppressive therapy attempts to balance acceptable rates of rejection with moderation of the adverse effects of immunosuppressive drugs.

CHAPTER 37

Hemostasis and Blood Coagulation

HEMOSTASIS EVENTS

Hemostasis is the process that prevents blood loss. Whenever a blood vessel is severed or ruptured, hemostasis is achieved by several mechanisms: (1) vascular constriction; (2) formation of a platelet plug; (3) formation of a blood clot as a result of blood coagulation; and (4) eventual growth of fibrous tissue into the blood clot to close the hole in the vessel permanently.

VASCULAR CONSTRICTION OF A SEVERED BLOOD VESSEL

Immediately after a blood vessel has been cut or ruptured, the trauma to the vessel wall causes smooth muscle in the wall to contract; this rapidly reduces flow of blood from the ruptured vessel. The contraction results from the following: (1) local myogenic spasm; (2) local autacoid factors from the traumatized tissues, vascular endothelium, and blood platelets; and (3) nervous reflexes. The nervous reflexes are initiated by pain nerve impulses or other sensory impulses that originate from the traumatized vessel or nearby tissues. However, even more vasoconstriction probably results from local *myogenic contraction* of the blood vessels initiated by direct damage to the vascular wall. And, for the smaller vessels, the platelets are responsible for much of the vasoconstriction by releasing a vasoconstrictor substance, *thromboxane* A_2.

The more severely a vessel is traumatized, the greater the degree of vascular spasm. The spasm can last for many minutes or even hours, during which time the processes of platelet plugging and blood coagulation can take place.

FORMATION OF THE PLATELET PLUG

If the cut in the blood vessel is very small, the cut is often sealed by a *platelet plug* rather than by a blood clot. Also, many minute vascular holes develop throughout the body each day and these are normally sealed by platelets.

Physical and Chemical Characteristics of Platelets

Platelets (also called *thrombocytes*) are minute discs 1 to 4 micrometers in diameter. They are formed in the bone marrow from *megakaryocytes*, which are extremely large hematopoietic cells in the marrow; the megakaryocytes fragment into the minute platelets in the bone marrow or soon after entering the blood, especially as they squeeze through capillaries. The normal concentration of platelets in the blood is between 150,000 and 450,000/μL.

Platelets have many functional characteristics of whole cells, even though they do not have nuclei and cannot reproduce. In their cytoplasm are the following: (1) *actin* and *myosin molecules*, which are contractile proteins similar to those found in muscle cells, as well as another contractile protein, *thrombosthenin*, which can cause the platelets to contract; (2) residuals of both the *endoplasmic reticulum* and *Golgi apparatus* that synthesize various enzymes and store large quantities of calcium ions; (3) mitochondria and enzyme systems that are capable of forming *adenosine triphosphate* (ATP) and *adenosine diphosphate* (ADP); (4) enzyme systems that synthesize *prostaglandins*, which are local hormones that cause many vascular and other local tissue reactions; (5) an important protein called *fibrin-stabilizing factor*, which we discuss later in relation to blood coagulation; and (6) *platelet-derived growth factor* that causes vascular endothelial cells, vascular smooth muscle cells, and fibroblasts to multiply and grow, thus causing cellular growth that eventually helps repair damaged vascular walls.

On the platelet cell membrane surface is a coat of *glycoproteins* that repulses adherence to normal endothelium and yet causes adherence to *injured* areas of the vessel wall, especially to injured endothelial cells and even more so to any exposed collagen from deep within the vessel wall. In addition, the platelet membrane contains *phospholipids* that activate multiple stages in the blood-clotting process, as discussed later.

Thus, the platelet is an active structure. It has a half-life in the blood of only 8 to 12 days, so over several weeks its functional processes run out; it is then eliminated from the circulation mainly by the tissue macrophage system. More than half of the platelets are removed by macrophages in the spleen, where the blood passes through a latticework of tight trabeculae.

Mechanism of Platelet Plug Formation

Platelet repair of vascular openings is based on several important functions of the platelet. When platelets

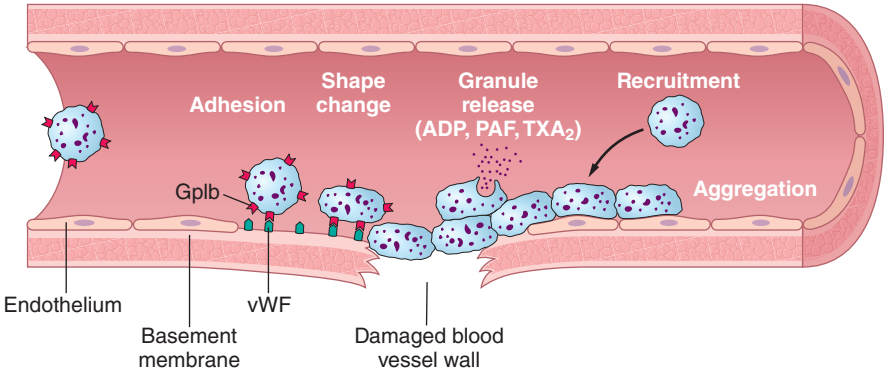

Figure 37.1 Formation of a platelet plug in a severed blood vessel. Endothelial injury and exposure of the vascular extracellular matrix facilitates platelet adhesions and activation, which changes their shape and causes release of adenosine diphosphate (ADP), thromboxane A_2 (T_xA_2), and platelet-activating factor (PAF). These platelet-secreted factors recruit additional platelets (aggregation) to form a hemostatic plug. Von Willebrand factor (vWF) serves as an adhesion bridge between subendothelial collagen and the glycoprotein Ib (GpIb) platelet receptor.

come in contact with a damaged vascular surface, especially with collagen fibers in the vascular wall, the platelets rapidly change their own characteristics drastically (**Fig. 37.1**). They begin to swell, and they assume irregular forms with numerous irradiating *pseudopods* protruding from their surfaces. Contractile proteins of the platelets contract forcefully and cause release of granules that contain multiple active factors, and they become sticky so that they adhere to collagen in the tissues and to a protein called *von Willebrand factor* (vWF), which leaks into the traumatized tissue from the plasma. The *platelet surface glycoproteins* bind to vWF in the exposed matrix below the damaged endothelium. The platelets then secrete increased quantities of *ADP* and *platelet-activating factor* (PAF), and their enzymes form *thromboxane* A_2. Thromboxane is a vasoconstrictor and, along with ADP and PAF, acts on nearby platelets to activate them as well; the stickiness of these additional activated platelets causes them to adhere to the original activated platelets.

Therefore, at the site of a puncture in a blood vessel wall, the damaged vascular wall activates successively increasing numbers of platelets that attract more and more additional platelets, thus forming a *platelet plug*. This plug is loose at first but is usually successful in blocking blood loss if the vascular opening is small. Then, during the subsequent process of blood coagulation, *fibrin threads* form. These threads attach tightly to the platelets, thus constructing an unyielding plug.

Importance of Platelet Mechanism for Closing Small Vascular Holes. The platelet-plugging mechanism is extremely important for closing minute ruptures in very small blood vessels that occur many thousands of times daily. Indeed, multiple small holes through the endothelial cells themselves are often closed by platelets actually fusing with the endothelial cells to form additional endothelial cell membranes. Literally thousands of small hemorrhagic areas develop each day under the skin (*petechiae*, which appear as purple or red dots on the skin) and throughout the internal tissues of a person who has few blood platelets. These petechiae do not occur in persons with normal numbers of platelets.

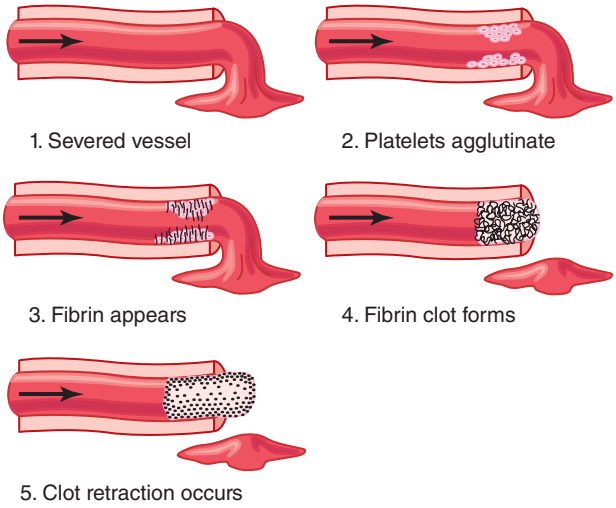

Figure 37.2 Clotting process in a traumatized blood vessel. (*Modified from Seegers WH.* Hemostatic Agents. *Springfield, IL: Charles C Thomas; 1948.*)

BLOOD COAGULATION IN THE RUPTURED VESSEL

The third mechanism for hemostasis is formation of the blood clot. The clot begins to develop in 15 to 20 seconds if the trauma to the vascular wall is severe and in 1 to 2 minutes if the trauma is minor. Activator substances from the traumatized vascular wall, from platelets, and from blood proteins adhering to the traumatized vascular wall initiate the clotting process. The physical events of this process are shown in **Fig. 37.2**; **Table 37.1** lists the most important clotting factors.

Within 3 to 6 minutes after rupture of a vessel, the entire opening or broken end of the vessel is filled with clot if the vessel opening is not too large. After 20 to 60 minutes, the clot retracts, which closes the vessel still further. Platelets also play an important role in this clot retraction, as discussed later.

FIBROUS ORGANIZATION OR DISSOLUTION OF BLOOD CLOTS

Once a blood clot has formed, it can follow one of two courses: (1) it can become invaded by *fibroblasts*, which

Table 37.1 Clotting Factors in Blood and Their Synonyms[a]

Clotting Factor	Synonym(s)
Fibrinogen	Factor I
Prothrombin	Factor II
Tissue factor	Factor III; tissue thromboplastin
Calcium	Factor IV
Factor V	Proaccelerin; labile factor; Ac-globulin (Ac-G)
Factor VII	Serum prothrombin conversion accelerator (SPCA); proconvertin; stable factor
Factor VIII	Antihemophilic factor (AHF); antihemophilic globulin (AHG); antihemophilic factor A
Factor IX	Plasma thromboplastin component (PTC); Christmas factor; antihemophilic factor B
Factor X	Stuart factor; Stuart-Prower factor
Factor XI	Plasma thromboplastin antecedent (PTA); antihemophilic factor C
Factor XII	Hageman factor
Factor XIII	Fibrin-stabilizing factor
Prekallikrein	Fletcher factor
High-molecular-weight kininogen	Fitzgerald factor; high-molecular-weight kininogen (HMWK)
Platelets	

[a]These are listed here mainly for historical interest.

subsequently form connective tissue all through the clot; or (2) it can dissolve. The usual course for a clot that forms in a small hole of a vessel wall is invasion by fibroblasts, beginning within a few hours after the clot is formed, which is promoted at least partially by *growth factor* secreted by platelets. This process continues to complete organization of the clot into fibrous tissue within about 1 to 2 weeks.

Conversely, when excess blood has leaked into the tissues, and tissue clots have formed where they are not needed, special substances in the clot usually become activated. These substances function as enzymes to dissolve the clot, as discussed later in the chapter.

MECHANISM OF BLOOD COAGULATION

GENERAL MECHANISM

More than 50 important substances that cause or affect blood coagulation have been found in the blood and in the tissues, including *procoagulants* that promote coagulation and *anticoagulants* that inhibit coagulation. Whether blood will coagulate depends on the balance between these two groups of substances. In the bloodstream, the anticoagulants normally predominate, so the blood does not coagulate while it is circulating in the blood vessels. However, when a vessel is ruptured, procoagulants from the area of tissue damage become activated and override the anticoagulants, and then a clot does develop.

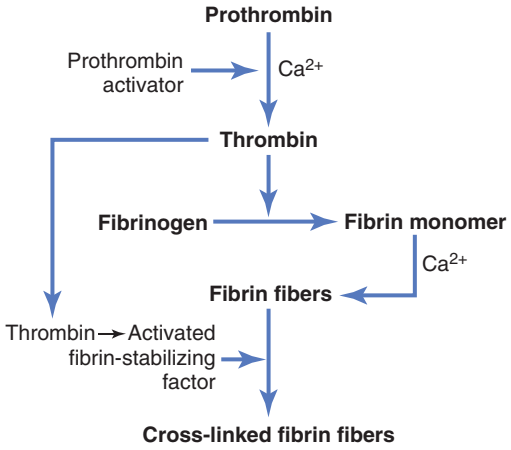

Figure 37.3 Schema for conversion of prothrombin to thrombin and polymerization of fibrinogen to form fibrin fibers.

Clotting takes place in three essential steps:

1. In response to rupture of the vessel or damage to the blood, a complex cascade of chemical reactions occurs in the blood involving more than 12 blood coagulation factors. The net result is formation of a complex of activated substances collectively called *prothrombin activator*.
2. The prothrombin activator catalyzes conversion of prothrombin into thrombin.
3. The thrombin acts as an enzyme to convert fibrinogen into fibrin fibers that enmesh platelets, blood cells, and plasma to form the clot.

We will first discuss the mechanism whereby the blood clot is formed, beginning with conversion of prothrombin to thrombin, and then come back to the initiating stages in the clotting process whereby prothrombin activator is formed.

CONVERSION OF PROTHROMBIN TO THROMBIN

1. Prothrombin activator is formed as a result of rupture of a blood vessel or damage to special substances in the blood.
2. Prothrombin activator, in the presence of sufficient amounts of ionic calcium (Ca^{2+}), causes conversion of prothrombin to thrombin (**Figs. 37.3** and **37.4**).
3. Thrombin causes polymerization of fibrinogen molecules into fibrin fibers within another 10 to 15 seconds.

Thus, the rate-limiting factor in causing blood coagulation is usually the formation of prothrombin activator and not the subsequent reactions beyond that point because these terminal steps normally occur rapidly to form the clot.

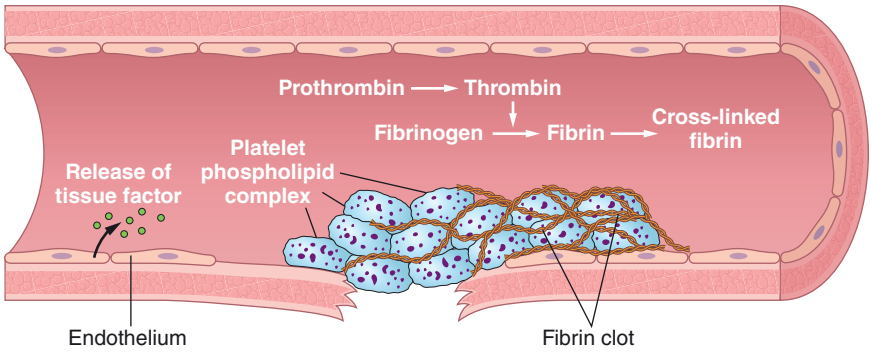

Figure 37.4 Coagulation cascade after vascular injury. Exposure of blood to the vascular wall causes release of tissue factor (also called factor III or thromboplastin) from endothelial cells, phospholipid expression, activation of thrombin, which then acts on fibrinogen to form fibrin, and fibrin polymerization to form a meshwork that stabilizes the platelet plug.

Platelets also play an important role in converting prothrombin to thrombin because much of the prothrombin first attaches to prothrombin receptors on the platelets that are already bound to the damaged tissue.

Prothrombin and Thrombin. Prothrombin is a plasma protein, an α_2-globulin, having a molecular weight of 68,700. It is present in normal plasma in a concentration of about 15 mg/dL. It is an unstable protein that can split easily into smaller compounds, one of which is *thrombin*, which has a molecular weight of 33,700, almost half that of prothrombin.

Prothrombin is formed continually by the liver, and it is continually being used throughout the body for blood clotting. If the liver fails to produce prothrombin, in a day or so prothrombin concentration in the plasma falls too low to provide normal blood coagulation.

Vitamin K is required by the liver for normal activation of prothrombin, as well as a few other clotting factors. Therefore, lack of vitamin K or the presence of liver disease that prevents normal prothrombin formation can decrease the prothrombin to such a low level that a bleeding tendency results.

CONVERSION OF FIBRINOGEN TO FIBRIN—FORMATION OF THE CLOT

Fibrinogen Formed in the Liver Is Essential for Clot Formation. Fibrinogen is a high-molecular-weight protein (molecular weight ~340,000) that occurs in the plasma in quantities of 100 to 700 mg/dL. Fibrinogen is formed in the liver, and liver disease can decrease the concentration of circulating fibrinogen, as well as prothrombin, noted earlier.

Because of its large molecular size, little fibrinogen normally leaks from the blood vessels into the interstitial fluids, and because fibrinogen is one of the essential factors in the coagulation process, interstitial fluids ordinarily do not coagulate. Yet, when the permeability of the capillaries becomes pathologically increased, fibrinogen leaks into the tissue fluids in sufficient quantities to allow clotting of these fluids in much the same way that plasma and whole blood can clot.

Thrombin Acts on Fibrinogen to Form Fibrin. Thrombin is a protein *enzyme* with weak proteolytic capabilities. It acts on fibrinogen to remove four low-molecular-weight peptides from each molecule of fibrinogen, forming one molecule of *fibrin monomer* that has the automatic capability to polymerize with other fibrin monomer molecules to form fibrin fibers. Therefore, many fibrin monomer molecules polymerize within seconds into *long fibrin fibers* that constitute the *reticulum* of the blood clot.

In the early stages of polymerization, the fibrin monomer molecules are held together by weak noncovalent hydrogen bonding, and the newly forming fibers are not cross-linked with one another. Therefore, the resultant clot is weak and can be broken apart with ease. However, another process occurs during the next few minutes that greatly strengthens the fibrin reticulum. This process involves a substance called *fibrin stabilizing factor* that is present in small amounts in normal plasma globulins but is also released from platelets entrapped in the clot.

Before fibrin stabilizing factor can have an effect on the fibrin fibers, it must be activated. The same thrombin that causes fibrin formation also activates the fibrin stabilizing factor. This activated substance then operates as an enzyme to form *covalent bonds* between more and more of the fibrin monomer molecules, as well as multiple cross-linkages between adjacent fibrin fibers, thus adding tremendously to the three-dimensional strength of the fibrin meshwork.

Blood Clot. The clot is composed of a meshwork of fibrin fibers running in all directions and entrapping blood cells, platelets, and plasma (**Fig. 37.4**). The fibrin fibers also adhere to damaged surfaces of blood vessels; therefore, the blood clot becomes adherent to any vascular opening and prevents further blood loss.

Clot Retraction and Expression of Serum. Within a few minutes after a clot is formed, it begins to contract and usually expresses most of the fluid from the clot within 20 to 60 minutes. The fluid expressed is called *serum* because all its fibrinogen and most of the other clotting factors have been removed; in this way, serum differs from plasma and cannot clot because it lacks these factors.

Platelets are necessary for clot retraction to occur. Therefore, failure of clot retraction is an indication that the number of platelets in the circulating blood might

be low. Platelets in blood clots become attached to fibrin fibers in such a way that they actually bond different fibers together. Furthermore, platelets entrapped in the clot continue to release procoagulant substances, one of the most important of which is *fibrin stabilizing factor*, which causes more and more cross-linking bonds between adjacent fibrin fibers.

Platelets also contribute directly to clot contraction by activating platelet thrombosthenin, actin, and myosin molecules, which are all contractile proteins in the platelets; they cause strong contraction of the platelet spicules attached to the fibrin. This action also helps compress the fibrin meshwork into a smaller mass. The contraction is activated and accelerated by thrombin and by calcium ions released from calcium stores in the mitochondria, endoplasmic reticulum, and Golgi apparatus of the platelets.

As the clot retracts, the edges of the broken blood vessel are pulled together, thus contributing still further to hemostasis.

POSITIVE FEEDBACK OF CLOT FORMATION

Once a blood clot starts to develop, it normally extends within minutes into the surrounding blood, initiating a positive feedback to promote more clotting. One of the most important causes of this clot promotion is that the proteolytic action of thrombin allows it to act on many of the other blood-clotting factors in addition to fibrinogen. For example, thrombin has a direct proteolytic effect on prothrombin, tending to convert it into still more thrombin, and it acts on some of the blood-clotting factors responsible for formation of prothrombin activator. These effects, discussed in subsequent paragraphs, include acceleration of the actions of factors VIII, IX, X, XI, and XII and aggregation of platelets. Once a critical amount of thrombin is formed, a positive feedback develops that causes still more blood clotting and more and more thrombin to be formed; thus, the blood clot continues to grow until blood leakage ceases.

INITIATION OF COAGULATION: FORMATION OF PROTHROMBIN ACTIVATOR

Now that we have discussed the clotting process, the more complex mechanisms that initiate clotting in the first place will be described. These mechanisms are set into play by the following: (1) trauma to the vascular wall and adjacent tissues; (2) trauma to the blood; or (3) contact of the blood with damaged endothelial cells or with collagen and other tissue elements outside the blood vessel. In each case, this leads to the formation of *prothrombin activator*, which then causes prothrombin conversion to thrombin and all the subsequent clotting steps.

Prothrombin activator is generally considered to be formed in two ways although, in reality, the two ways interact constantly with each other: (1) by the *extrinsic pathway* that begins with trauma to the vascular wall and surrounding tissues; and (2) by the *intrinsic pathway* that begins in the blood.

In both the extrinsic and the intrinsic pathways, a series of different plasma proteins called *blood-clotting factors* plays a major role. Most of these proteins are *inactive* forms of proteolytic enzymes. When converted to the active forms, their enzymatic actions cause the successive, cascading reactions of the clotting process.

Most of the clotting factors listed in **Table 37.1** are designated by Roman numerals. To indicate the activated form of the factor, a small letter "a" is added after the Roman numeral, such as factor VIIIa to indicate the activated state of factor VIII.

Extrinsic Pathway for Initiating Clotting

The extrinsic pathway for initiating the formation of prothrombin activator begins with a traumatized vascular wall or traumatized extravascular tissues that come in contact with the blood. This condition leads to the following steps, as shown in **Fig. 37.4** and **Fig. 37.5**:

1. *Release of tissue factor*. Traumatized tissue releases a complex of several factors called *tissue factor* or *tissue thromboplastin*. This factor is composed especially of *phospholipids* from the tissue membranes plus a *lipoprotein complex* that functions mainly as a *proteolytic enzyme*.
2. *Activation of factor X—role of factor VII and tissue factor*. The lipoprotein complex of tissue factor further complexes with blood coagulation factor VII and, in the presence of calcium ions, acts enzymatically on factor X to form *activated factor X* (Xa).
3. *Effect of Xa to form prothrombin activator—role of factor V*. The activated factor X combines immedi-

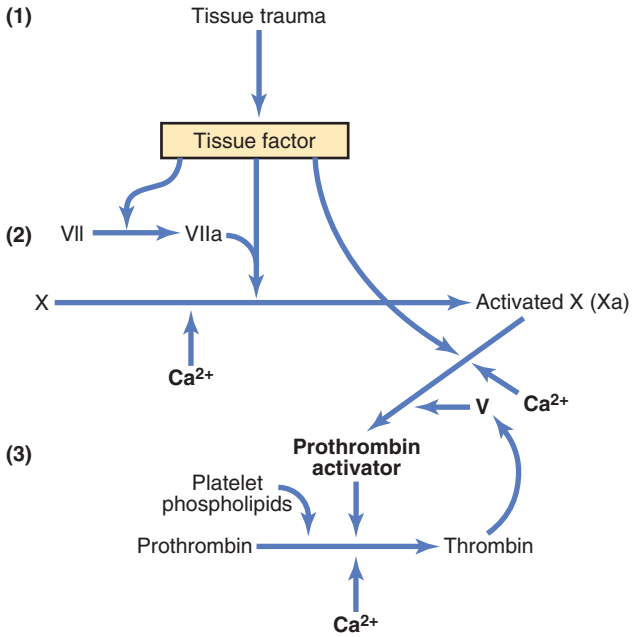

Figure 37.5 Extrinsic pathway for initiating blood clotting.

ately with tissue phospholipids that are part of tissue factors or with additional phospholipids released from platelets, as well as with factor V, to form the complex called *prothrombin activator*. Within a few seconds, in the presence of Ca^{2+}, prothrombin is split to form thrombin, and the clotting process proceeds as already explained. At first, factor V in the prothrombin activator complex is inactive, but once clotting begins and thrombin begins to form, the proteolytic action of thrombin activates factor V. This activation then becomes an additional strong accelerator of prothrombin activation. Thus, in the final prothrombin activator complex, activated factor X is the actual protease that causes splitting of prothrombin to form thrombin. Activated factor V greatly accelerates this protease activity, and platelet phospholipids act as a vehicle that further accelerates the process. Note especially the *positive feedback* effect of thrombin, acting through factor V, to accelerate the entire process once it begins.

Intrinsic Pathway for Initiating Clotting

The second mechanism for initiating formation of prothrombin activator, and therefore for initiating clotting, *begins with trauma to the blood or exposure of the blood to collagen* from a traumatized blood vessel wall. Then the process continues through the series of cascading reactions shown in **Fig. 37.6**.

1. *Blood trauma causes (1) activation of factor XII and (2) release of platelet phospholipids*. Trauma to the blood or exposure of the blood to vascular wall collagen alters two important clotting factors in the blood: factor XII and the platelets. When factor XII is disturbed, such as by coming into contact with collagen or with a wettable surface such as glass, it takes on a new molecular configuration that converts it into a proteolytic enzyme called *activated factor XII*. Simultaneously, the blood trauma also damages the platelets because of adherence to collagen or to a wettable surface (or by damage in other ways); this releases platelet phospholipids that contain the lipoprotein called *platelet factor 3*, which also plays a role in subsequent clotting reactions.
2. *Activation of factor XI*. The activated factor XII also acts enzymatically on factor XI to activate this factor, which is the second step in the intrinsic pathway. This reaction also requires *high-molecular-weight kininogen* and is accelerated by prekallikrein.
3. *Activation of factor IX by activated factor XI*. The activated factor XI then acts enzymatically on factor IX to activate this factor as well.
4. *Activation of factor X—role of factor VIII*. The activated factor IX, acting in concert with activated factor VIII and the platelet phospholipids and factor III from the traumatized platelets, activates factor X. When either factor VIII or platelets are in short supply, this step is deficient. Factor VIII is the factor that is missing in a person who has classic *hemophilia*, so it is called *antihemophilic factor*. Platelets are the clotting factor that is lacking in the bleeding disease called *thrombocytopenia*.
5. *Action of activated factor X to form prothrombin activator—role of factor V*. This step in the intrinsic pathway is the same as the last step in the extrinsic pathway. That is, activated factor X combines with factor V and platelet or tissue phospholipids to form the complex called *prothrombin activator*. The prothrombin activator, in turn, initiates the cleavage of prothrombin to form thrombin within seconds, thereby setting into motion the final clotting process, as described earlier.

Role of Calcium Ions in the Intrinsic and Extrinsic Pathways

Except for the first two steps in the intrinsic pathway, calcium ions are required for promotion or acceleration of all the blood-clotting reactions. Therefore, in the absence of calcium ions, blood clotting by either pathway does not occur.

In the living body, the calcium ion concentration seldom falls low enough to affect blood-clotting kinetics significantly. However, when blood is removed from someone, it can be prevented from clotting by reducing the calcium ion concentration below the threshold level for clotting. Calcium can be deionized by causing it to react with substances such as *citrate ion* or by precipitating the calcium with substances such as *oxalate ion*.

Interaction Between Extrinsic and Intrinsic Pathways—Summary of Blood-Clotting Initiation

It is clear from the schemas of the intrinsic and extrinsic systems that after blood vessels rupture, clotting occurs by both pathways simultaneously. Tissue factor initiates the extrinsic pathway, whereas contact of factor XII and platelets with collagen in the vascular wall initiates the intrinsic pathway.

An especially important difference between the extrinsic and intrinsic pathways is that *the extrinsic pathway* can be explosive; once initiated, its speed of completion to the final clot is limited only by the amount of tissue factor released from the traumatized tissues and by the quantities of factors X, VII, and V in the blood. With severe tissue trauma, clotting can occur in as little as 15 seconds. The intrinsic pathway is much slower to proceed, usually requiring 1 to 6 minutes to cause clotting.

Intravascular Anticoagulants Prevent Blood Clotting in the Normal Vascular System

Endothelial Surface Factors. Probably the most important factors for preventing clotting in the normal vascular system are the following: (1) the *smoothness* of the endothelial cell surface, which prevents contact activation of

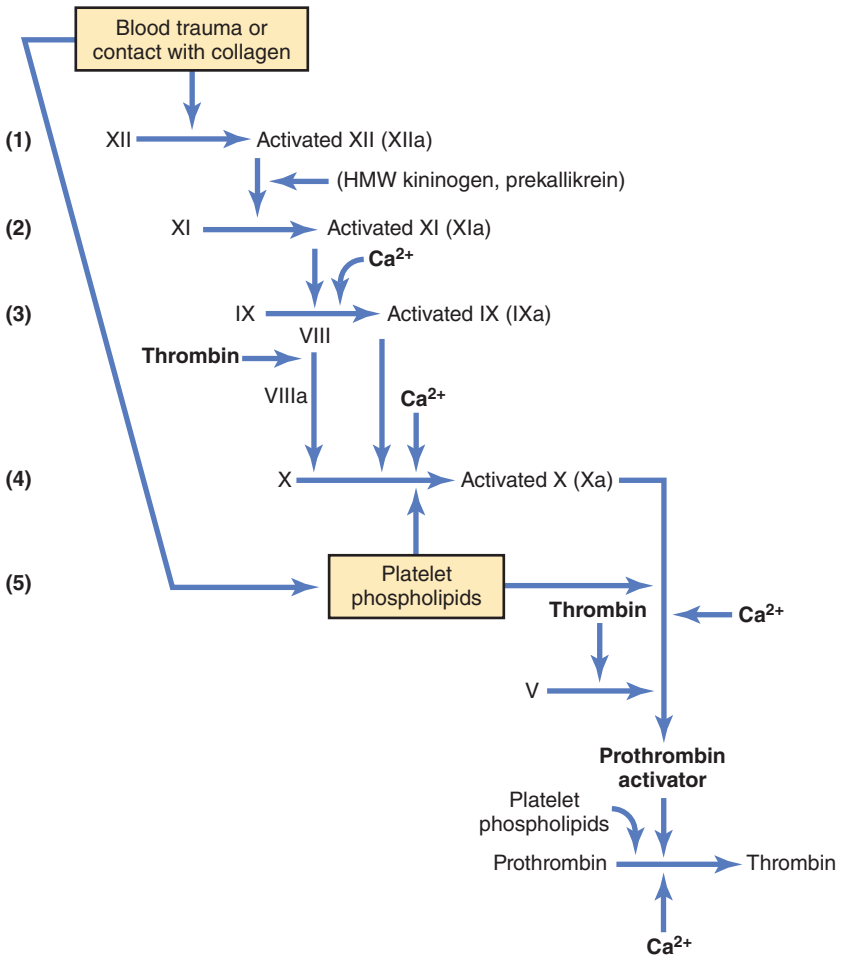

Figure 37.6 Intrinsic pathway for initiating blood clotting. *HMW*, High-molecular-weight.

the intrinsic clotting system; (2) a layer of *glycocalyx* on the endothelium; glycocalyx, a mucopolysaccharide adsorbed to the surfaces of the endothelial cells, repels clotting factors and platelets, thereby preventing activation of clotting; and (3) a protein bound with the endothelial membrane, *thrombomodulin*, which binds thrombin. Not only does the binding of thrombin with thrombomodulin slow the clotting process by removing thrombin, but the thrombomodulin-thrombin complex also activates a plasma protein, *protein C*, that acts as an anticoagulant by *inactivating* activated factors V and VIII.

When the endothelial wall is damaged, its smoothness and glycocalyx-thrombomodulin layer are lost, which activates both factor XII and the platelets, thus setting off the intrinsic pathway of clotting. If factor XII and platelets come into contact with the subendothelial collagen, the activation is even more powerful.

Intact endothelial cells also produce other substances such as *prostacyclin* and *nitric oxide* (NO) that inhibit platelet aggregation and initiation of blood clotting. Prostacyclin, also called *prostaglandin* I_2 (PGI_2), is a member of the eicosanoid family of lipids and is a vasodilator, as well as an inhibitor of platelet aggregation. As discussed in Chapter 17, NO is a powerful vasodilator released from healthy vascular endothelial cells throughout the body, and it is an important inhibitor of platelet aggregation. When endothelial cells are damaged, their production of prostacyclin and NO is greatly diminished.

Antithrombin Action of Fibrin and Antithrombin III. Among the most important *anticoagulants* in the blood are those that remove thrombin from the blood. The most powerful of these are the following: (1) the *fibrin fibers* that are formed during the process of clotting; and (2) an α globulin called *antithrombin III* or *antithrombin-heparin cofactor*.

While a clot is forming, about 85% to 90% of the thrombin formed from the prothrombin becomes adsorbed to the fibrin fibers as they develop. This adsorption helps prevent the spread of thrombin into the remaining blood and, therefore, prevents excessive spread of the clot.

The thrombin that does not adsorb to the fibrin fibers soon combines with antithrombin III. This further blocks the effect of thrombin on fibrinogen and then also inactivates thrombin during the next 12 to 20 minutes.

Heparin Is a Powerful Anticoagulant. Although heparin is another powerful anticoagulant, its blood concentration is normally low and it has significant anticoagulant effects only under special physiological conditions. However, heparin is used widely as a pharmacological agent

in medical practice in much higher concentrations to prevent intravascular clotting.

The heparin molecule is a highly negatively charged conjugated polysaccharide. By itself, it has little or no anticoagulant properties, but when it combines with antithrombin III, the effectiveness of antithrombin III for removing thrombin increases by 100-fold to 1000-fold and thus acts as an anticoagulant. Therefore, in the presence of excess heparin, the removal of free thrombin from the circulating blood by antithrombin III is almost instantaneous.

The complex of heparin and antithrombin III removes several other activated coagulation factors in addition to thrombin, further enhancing the effectiveness of anticoagulation. The others include activated factors IX through XII.

Heparin is produced by many different cells of the body, but the largest quantities are formed by the basophilic *mast cells* located in the pericapillary connective tissue throughout the body. These cells continually secrete small quantities of heparin that diffuse into the circulatory system. The *basophil cells* of the blood, which are functionally almost identical to the mast cells, release small quantities of heparin into the plasma.

Mast cells are abundant in tissue surrounding the capillaries of the lungs and, to a lesser extent, capillaries of the liver. It is easy to understand why large quantities of heparin might be needed in these areas because the capillaries of the lungs and liver receive many embolic clots that have formed in slowly flowing venous blood; sufficient production of heparin prevents further growth of the clots.

PLASMIN CAUSES LYSIS OF BLOOD CLOTS

The plasma proteins contain a euglobulin called *plasminogen (profibrinolysin)* that when activated, becomes a substance called *plasmin (fibrinolysin)*. Plasmin is a proteolytic enzyme that resembles trypsin, the most important proteolytic digestive enzyme of pancreatic secretion. Plasmin digests fibrin fibers and some other protein coagulants, such as fibrinogen, factor V, factor VIII, prothrombin, and factor XII. Therefore, whenever plasmin is formed, it can cause lysis of a clot by destroying many of the clotting factors, sometimes even causing hypocoagulability of the blood.

Activation of Plasminogen to Form Plasmin, Then Clot Lysis. When a clot is formed, a large amount of plasminogen is trapped in the clot, along with other plasma proteins. This will not become plasmin or cause lysis of the clot until it is activated. The injured tissues and vascular endothelium very slowly release a powerful activator called *tissue plasminogen activator* (t-PA); a few days later, after the clot has stopped the bleeding, t-PA eventually converts plasminogen to plasmin, which in turn removes the remaining unnecessary blood clot. In fact, many small blood vessels in which blood flow has been blocked by clots are reopened by this mechanism. *Thus, an especially important function of the plasmin system is to remove minute clots from millions of tiny peripheral vessels* that eventually would become occluded were there no way to clear them.

CONDITIONS THAT CAUSE EXCESSIVE BLEEDING IN HUMANS

Excessive bleeding can result from a deficiency of any of the many blood-clotting factors. Three types of bleeding tendencies that have been studied to the greatest extent are discussed here—bleeding caused by (1) vitamin K deficiency, (2) hemophilia, and (3) thrombocytopenia (platelet deficiency).

DECREASED PROTHROMBIN, FACTOR VII, FACTOR IX, AND FACTOR X CAUSED BY LIVER DISEASE AND VITAMIN K DEFICIENCY

With few exceptions, almost all the blood-clotting factors are formed by the liver. Therefore, diseases of the liver such as *hepatitis*, *cirrhosis*, and *acute yellow atrophy* (degeneration of the liver caused by toxins, infections, or other agents) can sometimes depress the clotting system so much that the patient develops a severe tendency to bleed.

Another cause of depressed formation of clotting factors by the liver is vitamin K deficiency. Vitamin K is an essential factor to a liver carboxylase that adds a carboxyl group to glutamic acid residues on five of the important clotting factors—*prothrombin*, *factor VII*, *factor IX*, *factor X*, and *protein C*. On adding the carboxyl group to glutamic acid residues on the immature clotting factors, vitamin K is oxidized and becomes inactive. Another enzyme, *vitamin K epoxide reductase complex 1* (VKORC1), reduces vitamin K back to its active form. In the absence of active vitamin K, subsequent insufficiency of these coagulation factors in the blood can lead to serious bleeding tendencies.

Vitamin K is continually synthesized in the intestinal tract by bacteria, so vitamin K deficiency seldom occurs in healthy persons as a result of the absence of vitamin K from the diet (except in neonates, before they establish their intestinal bacterial flora). However, in persons with gastrointestinal disease, vitamin K deficiency often occurs as a result of poor absorption of fats from the gastrointestinal tract because vitamin K is fat-soluble and is ordinarily absorbed into the blood along with the fats.

One of the most prevalent causes of vitamin K deficiency is failure of the liver to secrete bile into the gastrointestinal tract, which occurs as a result of liver disease or obstruction of the bile ducts. Lack of bile prevents adequate fat digestion and absorption and, therefore, depresses vitamin K absorption as well. Thus, liver disease often causes decreased production of prothrombin and some other clotting factors because of poor vitamin K absorption and because of the diseased liver cells.

Vitamin K is therefore injected into surgical patients with liver disease or with obstructed bile ducts before the surgical procedure is performed. Ordinarily, if vitamin K is given to a deficient patient 4 to 8 hours before the operation and the liver parenchymal cells are at least half-normal in function, sufficient clotting factors will be produced to prevent excessive bleeding during the operation.

HEMOPHILIA

Hemophilia is a bleeding disease that occurs almost exclusively in men. In 85% of cases, it is caused by an *abnormality or deficiency of factor VIII*; this type of hemophilia is called *hemophilia A* or *classic hemophilia*. About 1 of every 10,000 men in the United States has classic hemophilia. In the other 15% of patients with *hemophilia B*, the bleeding tendency is caused by deficiency of factor IX. Both these factors are transmitted genetically by way of the female (X) chromosome and are recessive in their inheritance. Therefore, a woman will rarely have hemophilia because at least one of her two X chromosomes will have the appropriate genes. If one of her X chromosomes is deficient, she will be a *hemophilia carrier;* her male offspring will have a 50% chance of inheriting the illness, and her female offspring will have a 50% chance of inheriting the carrier status.

Although female carriers have one normal allele and usually do not develop symptomatic hemophilia, some may experience a mild bleeding trait. It is also possible for female carriers to develop mild hemophilia due to loss of part or all of the normal X chromosome (as in *Turner syndrome*) or inactivation *(lyonization)* of the X-chromosomes. For a woman to inherit full-blown symptomatic hemophilia A or B, she must receive two deficient X-chromosomes, one from her carrier mother and the other from her father, who must have hemophilia. Most cases of hemophilia are inherited, but approximately one-third of hemophilia patients do not have a family history of the disease, which appears to be caused by novel mutation events.

The bleeding trait in hemophilia can have various degrees of severity, depending on the genetic deficiency. Bleeding usually does not occur except after trauma, but in some patients, the degree of trauma required to cause severe and prolonged bleeding may be so mild that it is hardly noticeable. For example, bleeding can often last for days after extraction of a tooth.

Factor VIII has two active components, a large component with a molecular weight in the millions and a smaller component with a molecular weight of about 230,000. The smaller component is most important in the intrinsic pathway for clotting, and it is deficiency of this part of factor VIII that causes classic hemophilia. Another bleeding disease with somewhat different characteristics, called *von Willebrand disease*, results from loss of the large component of factor VIII.

When a person with classic hemophilia experiences severe prolonged bleeding, almost the only therapy that is truly effective is injection of purified factor VIII or factor IX. Both these clotting factors are now available as recombinant proteins, although they are expensive and their half-lives are relatively short; therefore, these products are not readily available for many patients with hemophilia, especially in economically disadvantaged countries.

THROMBOCYTOPENIA

Thrombocytopenia means the presence of very low numbers of platelets in the circulating blood. People with thrombocytopenia have a tendency to bleed, as do hemophiliacs, except that the bleeding is usually from many small venules or capillaries, rather than from larger vessels, as in hemophilia. As a result, small punctate hemorrhages occur throughout all the body tissues. The skin of such a person displays many small *petechiae*, red or purplish blotches, giving the disease the name *thrombocytopenic purpura*. As noted, platelets are especially important for the repair of minute breaks in capillaries and other small vessels.

Platelet counts below 30,000/μL, compared with the normal value of 150,000 to 450,000/μL, increase the risk for excessive bleeding after surgery or injury. Spontaneous bleeding, however, will not ordinarily occur until the number of platelets in the blood falls below 30,000/μL. Levels as low as 10,000/μL are frequently lethal.

Even without determining specific platelet counts in the blood, sometimes one can suspect the existence of thrombocytopenia if the person's blood clot fails to retract. As noted earlier, clot retraction is normally dependent on release of multiple coagulation factors from the large numbers of platelets entrapped in the fibrin mesh of the clot.

The major causes of thrombocytopenia include the following: (1) decreased platelet production in the bone marrow due to infections or sepsis, nutrient deficiencies, or myelodysplastic disorders, which usually also reduce production of other cells (red blood cells [RBCs] and white blood cells); (2) peripheral platelet destruction by antibodies; (3) sequestration (pooling) of platelets in the spleen, especially in individuals with portal hypertension and excessively large spleens (splenomegaly); (4) consumption of platelets in thrombi; and (5) dilution of the blood from fluid resuscitation or massive transfusion.

Most people with thrombocytopenia have the disease known as *idiopathic thrombocytopenia*, which means thrombocytopenia of unknown cause. In most of these people, it has been discovered that, for unknown reasons, specific antibodies have formed and react against the platelets to destroy them. *Fresh whole blood transfusions* that contain large numbers of platelets can often provide relief from bleeding for 1 to 4 days in patients with thrombocytopenia. Also, *splenectomy* may be helpful in some cases because the spleen normally removes large numbers of platelets from the blood.

THROMBOEMBOLIC CONDITIONS

Thrombi and Emboli. An abnormal clot that develops in a blood vessel is called a *thrombus*. Once a clot has developed, continued flow of blood past the clot is likely to break it away from its attachment and cause the clot to flow with the blood; such freely flowing clots are known as *emboli*. Also, emboli that originate in large arteries or in the left side of the heart can flow peripherally and plug arteries or arterioles in the brain, kidneys, or elsewhere. Emboli that originate in the venous system or in the right side of the heart generally flow into the lungs to cause pulmonary arterial embolism.

Causes of Thromboembolic Conditions. Some of the major causes of thromboembolic conditions in people include the following: (1) a *roughened endothelial surface of a vessel*—as may be caused by arteriosclerosis, infection, or trauma—is likely to initiate the clotting process; (2) blood often clots *when it flows very slowly* through blood vessels, where small quantities of thrombin and other procoagulants are always being formed; and (3) *atrial fibrillation*, which may lead to blood flow stasis in the left atria appendage, platelet activation, and thrombus formation, especially if fibrillation is sustained for several days. After the thrombus has formed, it may become dislodged, leading to an embolism in the peripheral circulation or in the cerebral circulation, causing a stroke.

Use of Tissue Plasminogen Activator in Treating Intravascular Clots. Genetically engineered *tissue plasminogen activator* (t-PA) is available. When delivered through a catheter to an area with a thrombus, it is effective in activating plasminogen to plasmin, which in turn can dissolve some intravascular clots. For example, if used within the 1 or 2 hours after thrombotic occlusion of a coronary artery, the heart is often spared serious damage.

FEMORAL VENOUS THROMBOSIS AND MASSIVE PULMONARY EMBOLISM

Because clotting almost always occurs when blood flow is blocked for many hours in any vessel of the body, the immobility of patients confined to bed, plus the practice of propping the knees up with pillows, may cause intravascular clotting because of blood stasis in one or more of the leg veins for hours at a time. Then the clot grows, mainly in the direction of the slowly moving venous blood, sometimes growing the entire length of the leg veins and occasionally even up into the common iliac vein and inferior vena cava.

About 10% of the time, a large part of the clot disengages from its attachments to the vessel wall and flows freely with the venous blood through the right side of the heart and into the pulmonary arteries to cause massive blockage of the pulmonary arteries; this is called a *massive pulmonary embolism*. If the clot is large enough to occlude both pulmonary arteries at the same time, immediate death ensues. If only one pulmonary artery is blocked, death may not occur, or the embolism may lead to death a few hours to several days later because of further growth of the clot in the pulmonary vessels. However, t-PA therapy can be a lifesaver.

DISSEMINATED INTRAVASCULAR COAGULATION

Occasionally, the clotting mechanism becomes activated in widespread areas of the circulation, giving rise to the condition called *disseminated intravascular coagulation* (DIC) (**Fig. 37.7**). This condition often results from severe infection, septicemia, or the presence of large amounts of traumatized or dying tissue in the body that releases great quantities of tissue factor into the blood, initiating the coagulation cascade, as previously discussed. Frequently, the clots are small but numerous, and they plug a large share of the small peripheral blood vessels. This process occurs especially in patients with widespread *septicemia*, in which circulating bacteria or bacterial toxins—especially *endotoxins*—activate the clotting mechanisms. The plugging of small peripheral vessels greatly diminishes delivery of oxygen and other nutrients to the tissues, a situation that can lead to tissue injury and circulatory shock. It is partly for this reason that *septicemic shock* is lethal in 35% to 50% of patients.

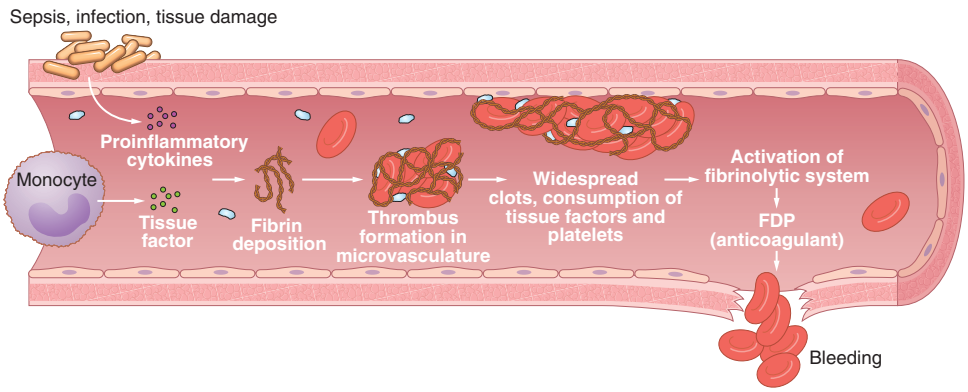

Figure 37.7 Disseminated intravascular coagulation (DIC). Tissue injury, cancer, sepsis, or severe infections cause release of proinflammatory cytokines and activation of tissue factor, which initiates the coagulation cascade. Widespread small clots may plug peripheral blood vessels and cause tissue injury. As DIC progresses, platelets and clotting factors are consumed, the fibrinolytic system is activated, and fibrin degradation products (FDP) may lead to bleeding under the skin (petechiae) and in deep tissues throughout the body.

A peculiar effect of DIC is that the patient, on occasion, begins to bleed. The reason for this bleeding is that so many of the clotting factors are consumed by the widespread clotting that too few procoagulants remain to allow normal hemostasis of the remaining blood.

Anticoagulants for Clinical Use

In some thromboembolic conditions, it is desirable to delay the coagulation process. Various anticoagulants have been developed for this purpose. The ones most clinically useful are *heparin* and the *coumarins*.

Heparin—Intravenous Anticoagulant

Commercial heparin is extracted from several different animal tissues and prepared in almost pure form. Synthetic heparin is also now available for medical applications. Injection of relatively small quantities of heparin, about 0.5 to 1 mg/kg of body weight, causes the blood-clotting time to increase from a normal of about 6 minutes to 30 or more minutes. Furthermore, this change in clotting time occurs almost instantaneously, thereby immediately preventing or slowing further development of a thromboembolic condition.

The action of heparin lasts about 1.5 to 4 hours. The injected heparin is destroyed by an enzyme in the blood known as *heparinase*.

Coumarins as Anticoagulants

When a coumarin, such as *warfarin*, is given to a patient, the amounts of active prothrombin and factors VII, IX, and X, all formed by the liver, begin to fall. Warfarin causes this effect by inhibiting the enzyme *VKORC1*. As discussed previously, this enzyme converts the inactive, oxidized form of vitamin K to its active, reduced form. By inhibiting VKORC1, warfarin decreases the available active form of vitamin K in the tissues. When adequate vitamin K is unavailable, the coagulation factors are no longer carboxylated and are biologically inactive. Over several days, the body stores of the active coagulation factors degrade and are replaced by inactive factors. Although the coagulation factors continue to be produced, they have greatly decreased coagulant activity.

After administration of an effective dose of warfarin, the coagulant activity of the blood decreases to about 50% of normal by the end of 12 hours and to about 20% of normal by the end of 24 hours. Thus, the coagulation process is not blocked immediately but must await the degradation of the active prothrombin and the other affected coagulation factors already present in the plasma. Normal coagulation usually returns 1 to 3 days after discontinuing coumarin therapy.

Prevention of Blood Coagulation Outside the Body

Although blood removed from the body and held in a glass test tube normally clots in about 6 minutes, blood collected in *siliconized containers* often does not clot for 1 hour or more. The reason for this delay is that coating surfaces of the containers with silicone prevents contact activation of platelets and factor XII, the two principal factors that initiate the intrinsic clotting mechanism. Conversely, untreated glass containers allow contact activation of the platelets and factor XII, with rapid development of clots.

Heparin can be used for preventing coagulation of blood outside the body, as well as in the body. Heparin is especially used in surgical procedures in which the blood must be passed through a heart-lung machine or artificial kidney machine and then back into the patient.

Various substances that *decrease the concentration of calcium ions* in the blood can also be used for preventing blood coagulation *outside* the body. For example, a soluble *oxalate* compound mixed in a very small quantity with a sample of blood causes precipitation of calcium oxalate from the plasma and thereby decreases the ionic calcium level so much that blood coagulation is blocked.

Any substance that deionizes the blood calcium will prevent coagulation. The negatively charged *citrate ion* is especially valuable for this purpose; it is mixed with blood usually in the form of *sodium*, *ammonium*, or *potassium citrate*. The citrate ion combines with calcium in the blood to produce a nonionized calcium compound, and the lack of *ionic* calcium prevents coagulation. Citrate anticoagulants have an important advantage over the oxalate anticoagulants because oxalate is toxic to the body, whereas moderate quantities of citrate can be injected intravenously. After injection, the citrate ion is removed from the blood within a few minutes by the liver and is polymerized into glucose or metabolized directly for energy. Consequently, 500 mL of blood that has been rendered noncoagulable by citrate can ordinarily be transfused into a recipient within a few minutes, without dire consequences. However, if the liver is damaged, or if large quantities of citrated blood or plasma are given too rapidly (within fractions of a minute), the citrate ion may not be removed quickly enough and the citrate can, under these conditions, greatly depress the level of calcium ion in the blood, which can result in tetany and convulsive death.

Blood Coagulation Tests

Bleeding Time

When a sharp-pointed knife is used to pierce the tip of the finger, bleeding ordinarily lasts for 1 to 6 minutes. This time depends largely on the depth of the wound and degree of hyperemia in the finger at the time of the test. Lack of any one of several of the clotting factors can prolong the bleeding time, but it is especially prolonged by lack of platelets.

Clotting Time

One method for determining blood-clotting time is to collect blood in a chemically clean glass test tube and then to tip the tube back and forth about every 30 seconds until the blood has clotted. By this method, the normal clotting time is 6 to 10 minutes. Procedures using multiple test tubes have also been devised for determining clotting time more accurately.

Unfortunately, the clotting time varies widely, depending on the method used for measuring it, so it is no longer used in many clinics. Instead, measurements of the clotting factors themselves are made, using sophisticated chemical procedures.

Prothrombin Time and International Normalized Ratio

The prothrombin time indicates the concentration of prothrombin in the blood. **Fig. 37.8** shows the relationship

of prothrombin concentration to prothrombin time. The method for determining prothrombin time is the following.

Blood removed from the patient is immediately oxalated so that none of the prothrombin can change into thrombin. Then, large excesses of calcium ion and tissue factor are quickly mixed with the oxalated blood. The excess calcium nullifies the effect of the oxalate, and the tissue factor activates the prothrombin to thrombin reaction by means of the extrinsic clotting pathway. The time required for coagulation to take place is known as the *prothrombin time*. The *shortness of the time* is determined mainly by the prothrombin concentration. The normal prothrombin time is about 12 seconds. In each laboratory, a curve relating prothrombin concentration to prothrombin time, such as that shown in **Fig. 37.8**, is drawn for the method used so that the prothrombin in the blood can be quantified.

The results obtained for prothrombin time may vary considerably, even in the same individual if there are differences in activity of the tissue factor and the analytical system used to perform the test. Tissue factor is isolated from human tissues, such as placental tissue, and different batches may have different activity. The *international normalized ratio* (INR) was devised as a way to standardize measurements of prothrombin time. For each batch of tissue factor, the manufacturer assigns an *international sensitivity index* (ISI), which indicates the activity of the tissue factor with a standardized sample. The ISI usually varies between 1.0 and 2.0. The INR is the ratio of the person's prothrombin time (PT) to a normal control sample raised to the power of the ISI:

$$\text{INR} = \left(\frac{\text{PT}_{\text{test}}}{\text{PT}_{\text{normal}}} \right)^{\text{ISI}}$$

The normal range for INR in a healthy person is 0.9 to 1.3. A high INR level (e.g., 4 or 5) indicates a high risk of bleeding, whereas a low INR (e.g., 0.5) suggests that there is a chance of having a clot. Patients undergoing warfarin therapy usually have an INR of 2.0 to 3.0.

Tests similar to that for prothrombin time and INR have been devised to determine the quantities of other blood-clotting factors. In each of these tests, excesses of calcium ions and all the other factors *in addition to the one being tested* are added to oxalated blood all at once. Then, the time required for coagulation is determined in the same manner as for prothrombin time. If the factor being tested is deficient, the coagulation time is prolonged. The time itself can then be used to quantitate the concentration of the factor.

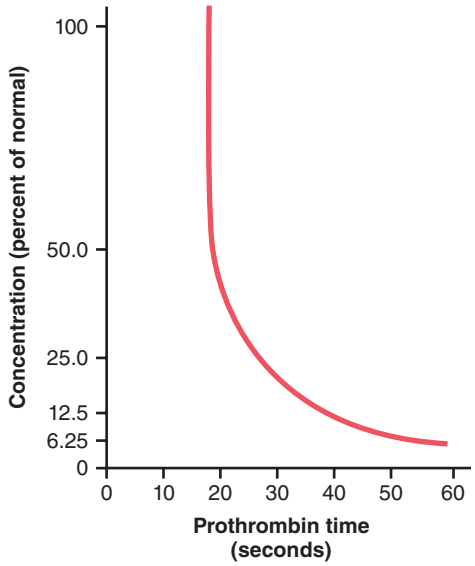

Figure 37.8 Relationship of prothrombin concentration in the blood to prothrombin time.

CHAPTER 38

Pulmonary Ventilation

The main functions of respiration are to provide oxygen to the tissues and remove carbon dioxide. The four major components of respiration are the following: (1) *pulmonary ventilation*, which means the inflow and outflow of air between the atmosphere and the lung alveoli; (2) *diffusion of oxygen* (O_2) *and carbon dioxide* (CO_2) *between the alveoli and the blood*; (3) *transport of oxygen and carbon dioxide in the blood and body fluids* to and from the body's tissue cells; and (4) *regulation of ventilation* and other facets of respiration. This chapter is a discussion of pulmonary ventilation; the subsequent five chapters cover other respiratory functions plus the physiology of special respiratory abnormalities.

MECHANICS OF PULMONARY VENTILATION

MUSCLES THAT CAUSE LUNG EXPANSION AND CONTRACTION

The lungs can be expanded and contracted in two ways: (1) by downward or upward movement of the diaphragm to lengthen or shorten the chest cavity; and (2) by elevation or depression of the ribs to increase or decrease the anteroposterior diameter of the chest cavity. **Fig. 38.1** shows these two methods.

Normal quiet breathing is accomplished almost entirely by movement of the diaphragm. During inspiration, contraction of the diaphragm pulls the lower surfaces of the lungs downward. Then, during expiration, the diaphragm simply relaxes, and the *elastic recoil* of the lungs, chest wall, and abdominal structures compresses the lungs and expels the air. During heavy breathing, however, the elastic forces are not powerful enough to cause the necessary rapid expiration, so extra force is achieved mainly by contraction of the *abdominal muscles*, which pushes the abdominal contents upward against the bottom of the diaphragm, thereby compressing the lungs.

The second method for expanding the lungs is to raise the rib cage. Raising the rib cage expands the lungs because, in the natural resting position, the ribs slant downward, as shown on the left side of **Fig. 38.1**, thus allowing the sternum to fall backward toward the vertebral column. When the rib cage is elevated, however, the ribs project almost directly forward, so the sternum also moves forward, away from the spine, making the anteroposterior thickness of the chest about 20% greater during maximum inspiration than during expiration. *Therefore, all the muscles that elevate the chest cage are classified as muscles of inspiration, and the muscles that depress the chest cage are classified as muscles of expiration.*

The most important muscles that raise the rib cage are the *external intercostals*, but others that help are the following: (1) *sternocleidomastoid* muscles, which lift upward on the sternum; (2) *anterior serrati*, which lift many of the ribs; and (3) *scaleni*, which lift the first two ribs.

The muscles that pull the rib cage downward during expiration are mainly the following: (1) the *abdominal recti*, which have the powerful effect of pulling downward on the lower ribs at the same time that they and other abdominal muscles also compress the abdominal contents upward against the diaphragm; and (2) the *internal intercostals*.

Fig. 38.1 also shows the mechanism whereby the external and internal intercostals act to cause inspiration and expiration. To the left, the ribs during expiration are angled downward, and the external intercostals are elongated forward and downward. As they contract, they pull the upper ribs forward in relation to the lower ribs, which causes leverage on the ribs to raise them upward, thereby causing inspiration. The internal intercostals function in the opposite manner, functioning as expiratory muscles because they angle between the ribs in the opposite direction and cause opposite leverage.

PRESSURES THAT CAUSE MOVEMENT OF AIR IN AND OUT OF THE LUNGS

See **Video 38.1**. The lung is an elastic structure that collapses like a balloon and expels all its air through the trachea whenever there is no force to keep it inflated. Also, there are no attachments between the lung and walls of the chest cage, except where it is suspended at its hilum from the *mediastinum*, the middle section of the chest cavity. Instead, the lung "floats" in the thoracic cavity, surrounded by a thin layer of *pleural fluid* that lubricates lung movement within the cavity. Furthermore, continual suction of excess fluid into lymphatic channels maintains a slight suction between the visceral surface of the lung

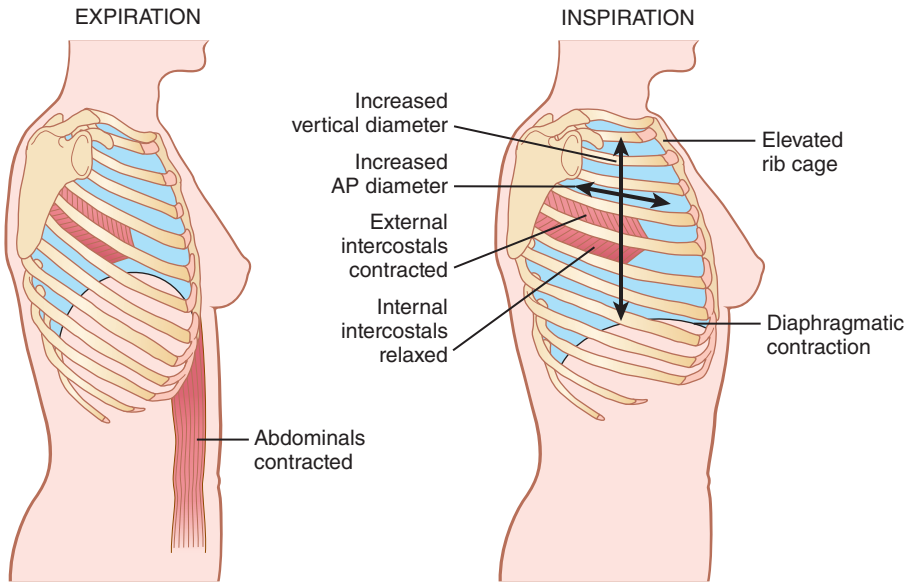

Figure 38.1 Contraction and expansion of the thoracic cage during expiration and inspiration, demonstrating diaphragmatic contraction, function of the intercostal muscles, and elevation and depression of the rib cage. *AP*, Anteroposterior.

pleura and the parietal pleural surface of the thoracic cavity. Therefore, the lungs are held to the thoracic wall as if glued there, except that they are well lubricated and can slide freely as the chest expands and contracts.

Pleural Pressure and Its Changes During Respiration. *Pleural pressure* is the pressure of the fluid in the thin space between the lung pleura and chest wall pleura. This pressure is normally a slight suction, which means a slightly *negative* pressure. The normal pleural pressure at the beginning of inspiration is about −5 centimeters of water (cm H_2O), which is the amount of suction required to hold the lungs open to their resting level. During normal inspiration, expansion of the chest cage pulls outward on the lungs with greater force and creates more negative pressure to an average of about −7.5 cm H_2O.

These relationships between pleural pressure and changing lung volume are demonstrated in **Fig. 38.2**, in which the lower panel shows the increasing negativity of the pleural pressure from −5 to −7.5 cm H_2O during inspiration, with the upper panel showing an increase in lung volume of 0.5 liter. Then, during expiration, the events are essentially reversed.

Alveolar Pressure—Air Pressure Inside the Lung Alveoli. When the glottis is open and no air is flowing into or out of the lungs, the pressures in all parts of the respiratory tree, all the way to the alveoli, are equal to atmospheric pressure, which is considered to be zero reference pressure in the airways—that is, 0 cm H_2O pressure. To cause inward flow of air into the alveoli during inspiration, the pressure in the alveoli must fall to a value slightly below atmospheric pressure (below 0). The second curve (labeled "alveolar pressure") of **Fig. 38.2** demonstrates that during normal inspiration, alveolar pressure decreases to about −1 cm H_2O. This slight negative pressure is enough to pull 0.5 liter of air into the lungs in the 2 seconds required for normal quiet inspiration.

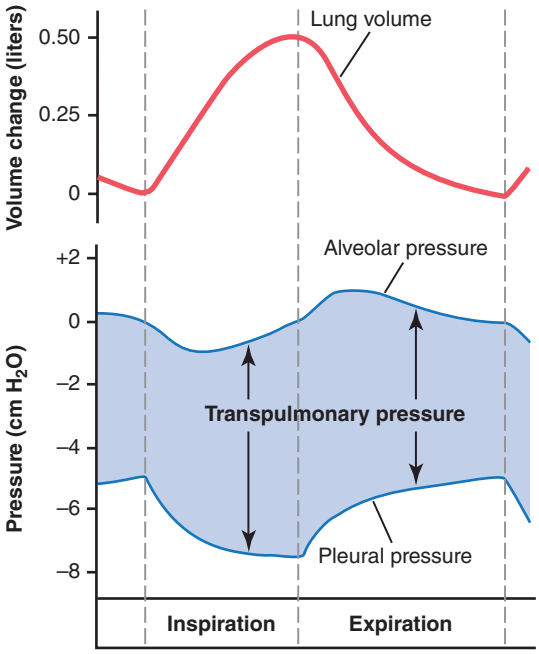

Figure 38.2 Changes in lung volume, alveolar pressure, pleural pressure, and transpulmonary pressure during normal breathing.

During expiration, alveolar pressure rises to about +1 cm H_2O, which forces the 0.5 liter of inspired air out of the lungs during the 2 to 3 seconds of expiration.

Transpulmonary Pressure—Difference Between Alveolar and Pleural Pressures. Note in **Fig. 38.2** that the *transpulmonary pressure* is the difference between alveolar pressure and pleural pressure; it is a measure of the elastic forces in the lungs that tend to collapse the lungs at each instant of respiration, called the *recoil pressure*.

Compliance of the Lungs

The extent to which the lungs will expand for each unit increase in transpulmonary pressure (if enough time is

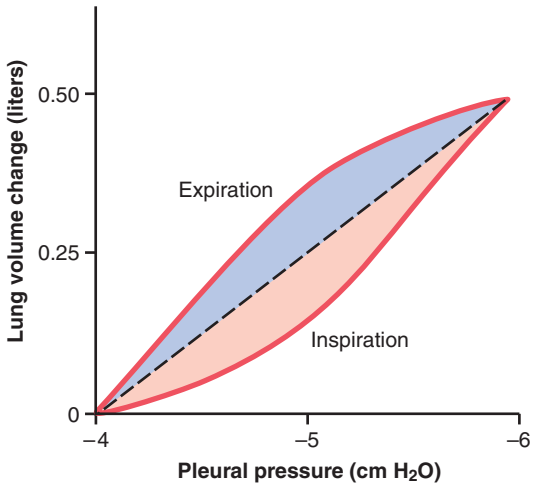

Figure 38.3 Compliance diagram in a healthy person. This diagram shows changes in lung volume during changes in transpulmonary pressure (alveolar pressure minus pleural pressure).

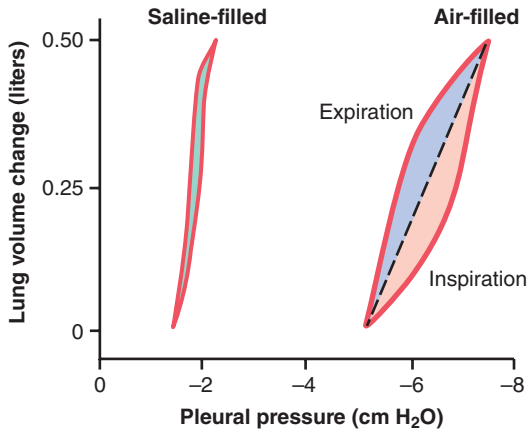

Figure 38.4 Comparison of the compliance diagrams of saline-filled and air-filled lungs when the alveolar pressure is maintained at atmospheric pressure (0 cm H_2O) and pleural pressure is changed to alter the transpulmonary pressure.

allowed to reach equilibrium) is called the *lung compliance*. The total compliance of both lungs together in the normal adult averages about 200 mL of air/cm H_2O transpulmonary pressure. That is, every time the transpulmonary pressure increases by 1 cm H_2O, the lung volume, after 10 to 20 seconds, will expand 200 mL.

Compliance Diagram of the Lungs. **Fig. 38.3** is a diagram relating lung volume changes to changes in pleural pressure, which, in turn, alters transpulmonary pressure. Note that the relationship is different for inspiration and expiration. Each curve is recorded by changing the pleural pressure in small steps and allowing the lung volume to come to a steady level between successive steps. The two curves are called, respectively, the *inspiratory compliance curve* and the *expiratory compliance curve*, and the entire diagram is called the *compliance diagram of the lungs*.

The characteristics of the compliance diagram are determined by the elastic forces of the lungs. These forces can be divided into two parts: (1) *elastic forces of the lung tissue;* and (2) *elastic forces caused by surface tension of the fluid that lines the inside walls of the alveoli* and other lung air spaces.

The elastic forces of the lung tissue are determined mainly by *elastin* and *collagen* fibers interwoven among the lung parenchyma. In deflated lungs, these fibers are in an elastically contracted and kinked state; then, when the lungs expand, the fibers become stretched and unkinked, thereby elongating and exerting even more elastic force.

The elastic forces caused by surface tension are much more complex. The significance of surface tension is shown in **Fig. 38.4**, which compares the compliance diagram of the lungs when filled with saline solution and when filled with air. When the lungs are filled with air, there is an interface between the alveolar fluid and the air in the alveoli. In lungs filled with saline solution, there is no air-fluid interface and, therefore, the surface tension effect is not present; only tissue elastic forces are operative in the lung filled with saline solution.

Note that transpleural pressures required to expand air-filled lungs are about three times as great as those required to expand lungs filled with saline solution. Thus, one can conclude that *the tissue elastic forces tending to cause collapse of the air-filled lung represent only about one-third of the total lung elasticity, whereas the fluid-air surface tension forces in the alveoli represent about two-thirds*.

The fluid-air surface tension elastic forces of the lungs also increase tremendously when the substance called *surfactant* is *not* present in the alveolar fluid.

Surfactant, Surface Tension, and Collapse of the Alveoli

Principle of Surface Tension. When water forms a surface with air, the water molecules on the surface of the water have an especially strong attraction for one another. As a result, the water surface is always attempting to contract. This is what holds raindrops together—a tight contractile membrane of water molecules around the entire surface of the raindrop. Now, let us apply these principles to the inner surfaces of the alveoli. Here, the water surface is also attempting to contract. This tends to force air out of the alveoli through the bronchi and, in doing so, causes the alveoli to try to collapse. The net effect is to cause an elastic contractile force of the entire lungs, which is called the *surface tension elastic force*.

Surfactant and Its Effect on Surface Tension. Surfactant is a *surface-active agent in water*, which means that it greatly reduces the surface tension of water. It is secreted by special surfactant-secreting epithelial cells called *type II alveolar epithelial cells*, which constitute about 10% of the surface area of the alveoli. These cells contain lipid inclusions that are secreted in the surfactant into the alveoli.

Surfactant is a complex mixture of several phospholipids, proteins, and ions. The most important components are the phospholipid *dipalmitoyl phosphatidylcholine, surfactant*

apoproteins, and *calcium ions*. The dipalmitoyl phosphatidylcholine and several less important phospholipids are responsible for reducing the surface tension. They perform this function by not dissolving uniformly in the fluid lining the alveolar surface. Instead, part of the molecule dissolves while the remainder spreads over the surface of the water in the alveoli. This surface has from one-twelfth to one-half the surface tension of a pure water surface.

Quantitatively, the surface tension of different water fluids is approximately the following: pure water, 72 dynes/cm; normal fluids lining the alveoli but without surfactant, 50 dynes/cm; normal fluids lining the alveoli and *with* normal amounts of surfactant included, between 5 and 30 dynes/cm.

Pressure in Occluded Alveoli Caused By Surface Tension. If the air passages leading from the alveoli of the lungs are blocked, the surface tension in the alveoli tends to collapse the alveoli. This collapse creates positive pressure in the alveoli, attempting to push the air out. The amount of pressure generated in this way in an alveolus can be calculated from the following formula:

$$\text{Pressure} = \frac{2 \times \text{Surface tension}}{\text{Radius of alveolus}}$$

For the average-sized alveolus with a radius of about 100 micrometers and lined with *normal surfactant*, this calculates to be about 4 cm H_2O pressure (3 mm Hg). If the alveoli were lined with pure water without any surfactant, the pressure would be calculated as about 18 cm H_2O pressure, or 4.5 times as great as normal. Thus, surfactant is of great importance in reducing alveolar surface tension and therefore also reducing the effort required by the respiratory muscles to expand the lungs.

Pressure Caused By Surface Tension Is Inversely Related to Alveolar Radius. Note from the preceding formula that the smaller the alveolus, the greater the alveolar pressure caused by the surface tension. Thus, when the alveoli have half the normal radius (50 instead of 100 micrometers), the pressures noted earlier are doubled. This phenomenon is especially significant in small premature infants, many of whom have alveoli with radii less than 25% that of an adult person. Furthermore, surfactant does not normally begin to be secreted into the alveoli until between the sixth and seventh months of gestation and, in some cases, even later. Therefore, many premature infants have little or no surfactant in the alveoli when they are born, and their lungs have an extreme tendency to collapse, sometimes as much as six to eight times that in a normal adult person, causing *respiratory distress syndrome of the newborn*. It is fatal if not treated with strong measures, especially properly applied continuous positive pressure breathing.

EFFECT OF THE THORACIC CAGE ON LUNG EXPANSIBILITY

Thus far, we have discussed the expansibility of the lungs alone, without considering the thoracic cage. The thoracic cage has its own elastic and viscous characteristics, and even if the lungs were not present in the thorax, muscular effort would still be required to expand the thoracic cage.

Compliance of Thorax and Lungs Together

The compliance of the entire pulmonary system (the lungs and thoracic cage together) is measured while expanding the lungs of a totally relaxed or paralyzed subject. To measure compliance, air is forced into the lungs a little at a time while recording lung pressures and volumes. To inflate this total pulmonary system, almost twice as much pressure is required compared with the same lungs after removal from the chest cage. Therefore, the compliance of the combined lung-thorax system is almost exactly half that of the lungs alone—110 mL/cm H_2O pressure for the combined system, compared with 200 mL/cm H_2O for the lungs alone. Furthermore, when the lungs are expanded to high volumes or compressed to low volumes, the limitations of the chest become extreme. When near these limits, the compliance of the combined lung-thorax system can be less than 20% of that of the lungs alone.

Work of Breathing

We have already pointed out that during normal quiet breathing, all respiratory muscle contraction occurs during inspiration; expiration is almost entirely a passive process caused by elastic recoil of the lungs and chest cage. Thus, under resting conditions, the respiratory muscles normally perform "work" to cause inspiration but not to cause expiration.

The work of inspiration can be divided into three fractions: (1) work required to expand the lungs against the lung and chest elastic forces, called *compliance work* or *elastic work*; (2) work required to overcome the viscosity of the lung and chest wall structures, called *tissue resistance work*; and (3) work required to overcome airway resistance to movement of air into the lungs, called *airway resistance work*.

Energy Required for Respiration. During normal quiet respiration, only 3% to 5% of the total energy expended by the body is required for pulmonary ventilation. However, during heavy exercise, the amount of energy required can increase as much as 50-fold, especially if the person has any degree of increased airway resistance or decreased pulmonary compliance. Therefore, one of the major limitations on the intensity of exercise that can be performed is the person's ability to provide enough muscle energy for the respiratory process alone.

PULMONARY VOLUMES AND CAPACITIES

Recording Changes in Pulmonary Volume—Spirometry

Pulmonary ventilation can be studied by recording the volume of air moved into and out of the lungs, a method called *spirometry*. A typical basic spirometer is shown in **Fig. 38.5**. It consists of a drum inverted over a chamber of water, with the drum counterbalanced by a weight. In the

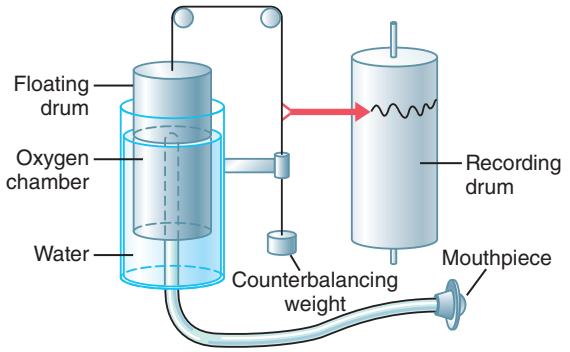

Figure 38.5 Spirometer.

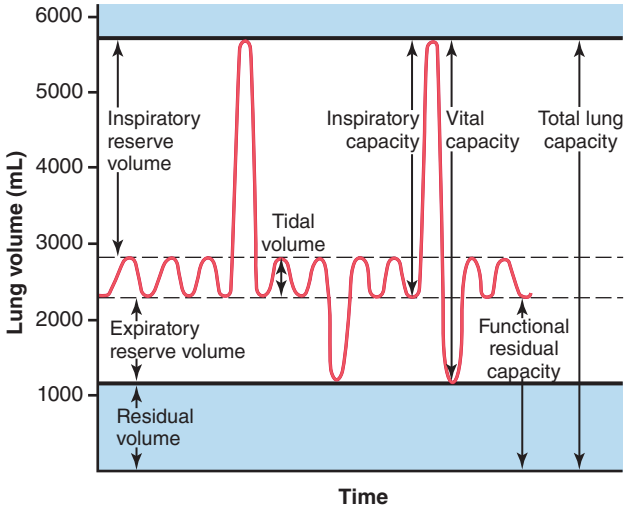

Figure 38.6 Respiratory excursions during normal breathing and during maximal inspiration and maximal expiration.

drum is a breathing gas, usually air or oxygen; a tube connects the mouth with the gas chamber. When the person breathes into and out of the chamber, the drum rises and falls, and an appropriate recording is made.

Fig. 38.6 shows a spirogram indicating changes in lung volume under different conditions of breathing. For ease in describing the events of pulmonary ventilation, the air in the lungs has been subdivided in this diagram into four *volumes* and four *capacities*, which are the averages for a *young adult man*. **Table 38.1** summarizes the average pulmonary volumes and capacities for young, healthy adult men and women.

Pulmonary Volumes

Fig. 38.6 lists four pulmonary lung volumes that, when added together, equal the maximum volume to which the lungs can be expanded. The lung volumes shown are for average adult men, but lung volumes vary considerably depending on physical fitness, age, height, sex, and other factors, such as the altitude at which a person resides. The significance of each of these lung volumes is the following:

1. The *tidal volume* is the volume of air inspired or expired with each normal breath; it amounts to about 500 mL.

Table 38.1 Average Pulmonary Volumes and Capacities for Healthy, Young Adult Men and Women

Pulmonary Volumes and Capacities	Men	Women
Volumes (mL)		
Tidal volume	500	400
Inspiratory reserve volume	3000	1900
Expiratory volume	1100	700
Residual volume	1200	1100
Capacities (mL)		
Inspiratory capacity	3500	2400
Functional residual capacity	2300	1800
Vital capacity	4600	3100
Total lung capacity	5800	4200

2. The *inspiratory reserve volume* is the extra volume of air that can be inspired over and above the normal tidal volume when the person inspires with full force; it is usually equal to about 3000 mL.
3. The *expiratory reserve volume* is the maximum extra volume of air that can be expired by forceful expiration after the end of a normal tidal expiration; this volume normally amounts to about 1100 mL.
4. The *residual volume* is the volume of air remaining in the lungs after the most forceful expiration; this volume averages about 1200 mL.

Pulmonary Capacities

In describing events in the pulmonary cycle, it is sometimes useful to consider two or more of the volumes together. Such combinations are called *pulmonary capacities*. To the right in **Fig. 38.6** are listed the important pulmonary capacities, which can be described as follows:

1. The *inspiratory capacity* equals the *tidal volume* plus the *inspiratory reserve volume*. This capacity is the amount of air (~3500 mL) that a person can breathe in, beginning at the normal expiratory level and distending the lungs to the maximum amount.
2. The *functional residual capacity* equals the *expiratory reserve volume* plus the *residual volume*. This capacity is the amount of air that remains in the lungs at the end of normal expiration (~2300 mL).
3. The *vital capacity* equals the *inspiratory reserve volume* plus the *tidal volume* plus the *expiratory reserve volume*. This capacity is the maximum amount of air a person can expel from the lungs after first filling the lungs to their maximum extent and then expiring to the maximum extent (~4600 mL).
4. The *total lung capacity* is the maximum volume to which the lungs can be expanded with the greatest possible effort (~5800 mL); it is equal to the *vital capacity* plus the *residual volume*.

Most pulmonary volumes and capacities are usually about 20% to 30% less in women than in men, and they are greater in large and athletic people than in small and asthenic people.

Abbreviations and Symbols Used in Pulmonary Function Studies

Spirometry is only one of many measurement procedures that pulmonary physicians use daily. Many of these procedures depend heavily on mathematical computations. To simplify these calculations, as well as the presentation of pulmonary function data, several abbreviations and symbols have become standardized. The more important of these are given in **Table 38.2**. Using these symbols, we present here a few simple algebraic equations showing some of the interrelationships among the pulmonary volumes and capacities; the student should think through and verify these interrelationships by reviewing **Fig. 38.6** again.

$$VC = IRV + V_T + ERV$$

$$VC = IC + ERV$$

$$TLC = VC + RV$$

$$TLC = IC + FRC$$

$$FRC = ERV + RV$$

Determination of Functional Residual Capacity, Residual Volume, and Total Lung Capacity—Helium Dilution Method

The functional residual capacity (FRC) is the volume of air that remains in the lungs at the end of each normal expiration and is important to lung function. Because its value changes markedly in some types of pulmonary disease, it is often desirable to measure this capacity. The spirometer cannot be used to measure the FRC directly because the air in the residual volume of the lungs cannot be expired into the spirometer, and this volume constitutes about half of the FRC. To measure FRC, the spirometer must be used in an indirect manner, usually by means of a helium dilution method, as follows.

A spirometer of known volume is filled with air mixed with helium at a known concentration. Before breathing from the spirometer, the person expires normally. At the end of this expiration, the remaining volume in the lungs is equal to the FRC. At this point, the subject immediately begins to breathe from the spirometer, and the gases of the spirometer mix with the gases of the lungs. As a result, the helium becomes diluted by the FRC gases, and the volume of the FRC can be calculated from the degree of dilution of the helium, using the following formula:

$$FRC = \left(\frac{Ci_{He}}{Cf_{He}} - 1\right) Vi_{Spir}$$

where *FRC* is functional residual capacity, Ci_{He} is the initial concentration of helium in the spirometer, Cf_{He} is the final concentration of helium in the spirometer, and Vi_{Spir} is the initial volume of the spirometer.

Once the FRC has been determined, the residual volume (RV) can be determined by subtracting expiratory reserve volume (ERV), as measured by normal spirometry, from the

Table 38.2 Abbreviations and Symbols for Pulmonary Function

Abbreviation	Function
V_T	Tidal volume
FRC	Functional residual capacity
ERV	Expiratory reserve volume
RV	Residual volume
IC	Inspiratory capacity
IRV	Inspiratory reserve volume
TLC	Total lung capacity
VC	Vital capacity
Raw	Resistance of the airways to flow of air into the lung
C	Compliance
V_D	Volume of dead space gas
V_A	Volume of alveolar gas
$\dot{V}_I$	Inspired volume of ventilation per minute
$\dot{V}_E$	Expired volume of ventilation per minute
$\dot{V}_S$	Shunt flow
$\dot{V}_A$	Alveolar ventilation per minute
$\dot{V}_{O_2}$	Rate of oxygen uptake per minute
$\dot{V}_{CO_2}$	Amount of carbon dioxide eliminated per minute
$\dot{V}_{CO}$	Rate of carbon monoxide uptake per minute
DLO_2	Diffusing capacity of the lungs for oxygen
DLCO	Diffusing capacity of the lungs for carbon monoxide
P_B	Atmospheric pressure
Palv	Alveolar pressure
Ppl	Pleural pressure
P_{O_2}	Partial pressure of oxygen
P_{CO_2}	Partial pressure of carbon dioxide
P_{N_2}	Partial pressure of nitrogen
Pa_{O_2}	Partial pressure of oxygen in arterial blood
Pa_{CO_2}	Partial pressure of carbon dioxide in arterial blood
P_{AO_2}	Partial pressure of oxygen in alveolar gas
P_{ACO_2}	Partial pressure of carbon dioxide in alveolar gas
P_{AH_2O}	Partial pressure of water in alveolar gas
R	Respiratory exchange ratio
$\dot{Q}$	Cardiac output
Ca_{O_2}	Concentration of oxygen in arterial blood
$C\bar{V}o_2$	Concentration of oxygen in mixed venous blood
So_2	Percentage saturation of hemoglobin with oxygen
Sa_{O_2}	Percentage saturation of hemoglobin with oxygen in arterial blood

FRC. Also, the total lung capacity (TLC) can be determined by adding the inspiratory capacity (IC) to the FRC. That is:

$$RV = FRC - ERV$$

and

$$TLC = FRC + IC$$

Minute Respiratory Volume Equals Respiratory Rate Times Tidal Volume

The *minute respiratory volume* is the total amount of new air moved into the respiratory passages each minute and is equal to the *tidal volume* times the *respiratory rate per minute*. The normal tidal volume is about 500 mL, and the normal respiratory rate is about 12 breaths/min. Therefore, the *minute respiratory volume averages about 6 L/min*. A person can live for a short period with a minute respiratory volume as low as 1.5 L/min and a respiratory rate of only 2 to 4 breaths/min.

The respiratory rate occasionally rises to 40 to 50 breaths/min, and the tidal volume can become as great as the vital capacity, about 4600 mL in a young man. This can give a minute respiratory volume greater than 200 L/min, or more than 30 times normal. Most people cannot sustain more than half to two-thirds of these values for longer than 1 minute.

ALVEOLAR VENTILATION

The ultimate importance of pulmonary ventilation is to renew the air in the gas exchange areas of the lungs continually, where air is in proximity to the pulmonary blood. These areas include the alveoli, alveolar sacs, alveolar ducts, and respiratory bronchioles. The rate at which new air reaches these areas is called *alveolar ventilation rate*.

Dead Space and Its Effect on Alveolar Ventilation

Some of the air a person breathes never reaches the gas exchange areas but simply fills respiratory passages, such as the nose, pharynx, and trachea, where gas exchange does not occur. This air is called *dead space air* because it is not useful for gas exchange.

On expiration, the air in the dead space is expired first, before any of the air from the alveoli reaches the atmosphere. Therefore, the dead space is very disadvantageous for removing the expiratory gases from the lungs.

Measurement of Dead Space Volume. A simple method for measuring dead space volume is demonstrated by the graph in **Fig. 38.7**. In making this measurement, the subject suddenly takes a deep breath of 100% O_2, which fills the entire dead space with pure O_2. Some oxygen also mixes with the alveolar air but does not completely replace this air. Then the person expires through a rapidly recording nitrogen meter, which makes the record shown in the figure. The first portion of the expired air comes from the dead space regions of the respiratory passageways, where the air has been completely replaced by O_2. Therefore, in the early part of the record, only O_2 appears, and the nitrogen concentration is 0. Then, when alveolar air begins to reach the nitrogen meter, the nitrogen concentration rises rapidly because alveolar air containing large amounts of nitrogen begins to mix with the dead space air. After still more air has been expired, all the dead space air has been washed from the passages and only alveolar air remains. Therefore, the recorded nitrogen concentration reaches a plateau level equal to its concentration in the alveoli, as shown at the right in the figure. The gray area represents the air that has no nitrogen in it and is a measure of the volume of dead space air. For exact quantification, the following equation is used:

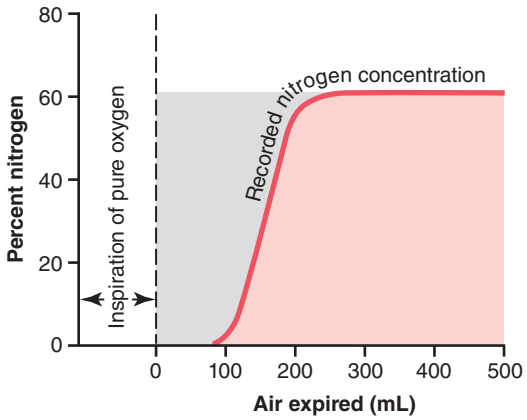

Figure 38.7 Record of the changes in nitrogen concentration in the expired air after a single previous inspiration of pure oxygen. This record can be used to calculate dead space, as discussed in the text.

$$V_D = \frac{\text{Gray area} \times V_E}{\text{Pink area} + \text{Gray area}}$$

where V_D is dead space air and V_E is the total volume of expired air.

Let us assume, for example, that the gray area on the graph is 30 square centimeters, the pink area is 70 square centimeters, and the total volume expired is 500 mL. The dead space would be

$$\frac{30}{30 + 70} \times 500 = 150 \text{ mL}$$

Normal Dead Space Volume. The normal dead space air in a healthy young man is about 150 mL, although dead space volume increases with increasing body size, height, and lung size. Women generally have smaller dead space volume than men, mainly due to anatomically smaller airway size. Dead space air increases slightly after around 50 to 60 years of age.

Anatomical Versus Physiological Dead Space. The method previously described for measuring the dead space measures the volume of all the space of the respiratory system other than the alveoli and their other closely related gas exchange areas; this space is called the *anatomic dead space*. On occasion, some of the alveoli are nonfunctional or only partially functional because of absent or poor blood flow through the adjacent pulmonary capillaries. Therefore, these alveoli must also be considered dead space.

When the alveolar dead space is included in the total measurement of dead space, this is called the *physiological dead space*, in contradistinction to the anatomical dead space. In a person with healthy lungs, the anatomical and physiological dead spaces are nearly equal because all alveoli are functional in normal lungs, but in a person with partially functional or nonfunctional alveoli in some parts of the lungs, the physiological dead space may be as much as 10 times the volume of the anatomical dead space, or 1 to 2 liters. These problems are discussed further in Chapter 40 in relation to pulmonary gaseous exchange and in Chapter 43 in relation to certain pulmonary diseases.

RATE OF ALVEOLAR VENTILATION

Alveolar ventilation per minute is the total volume of new air entering the alveoli and adjacent gas exchange areas each minute. It is equal to the respiratory rate times the amount of new air that enters these areas with each breath:

$$\dot{V}_A = \text{Freq} \times (V_T - V_D)$$

where $\dot{V}_A$ is the volume of alveolar ventilation per minute, *Freq* is the frequency of respiration per minute, V_T is the tidal volume, and V_D is the physiological dead space volume.

Thus, with a normal tidal volume of 500 mL, a normal dead space of 150 mL, and a respiratory rate of 12 breaths/min, alveolar ventilation equals 12 × (500 − 150), or 4200 mL/min.

Alveolar ventilation is one of the major factors determining the concentrations of oxygen and carbon dioxide in the alveoli. Therefore, almost all discussions of gaseous exchange in the following chapters on the respiratory system focus on alveolar ventilation.

Functions of Respiratory Passageways

Trachea, Bronchi, and Bronchioles

Fig. 38.8 highlights the respiratory passageways. The air is distributed to the lungs by way of the trachea, bronchi, and bronchioles.

One of the most important challenges in the respiratory passageways is to keep them open and allow easy passage of air to and from the alveoli. To keep the trachea from collapsing, multiple cartilage rings extend about five-sixths of the way around the trachea. In the walls of the bronchi, less extensive curved cartilage plates also maintain a reasonable amount of rigidity yet allow sufficient motion for the lungs to expand and contract. These plates become progressively less extensive in the later generations of bronchi and are gone in the bronchioles, which usually have diameters less than 1.5 millimeters. The bronchioles are not prevented from collapsing by the rigidity of their walls. Instead, they are kept expanded mainly by the same transpulmonary pressures that expand the alveoli. That is, as the alveoli enlarge, the bronchioles also enlarge, but not as much.

Muscular Wall of the Bronchi and Bronchioles. In all areas of the *trachea* and *bronchi* not occupied by cartilage plates, the walls are composed mainly of smooth muscle.

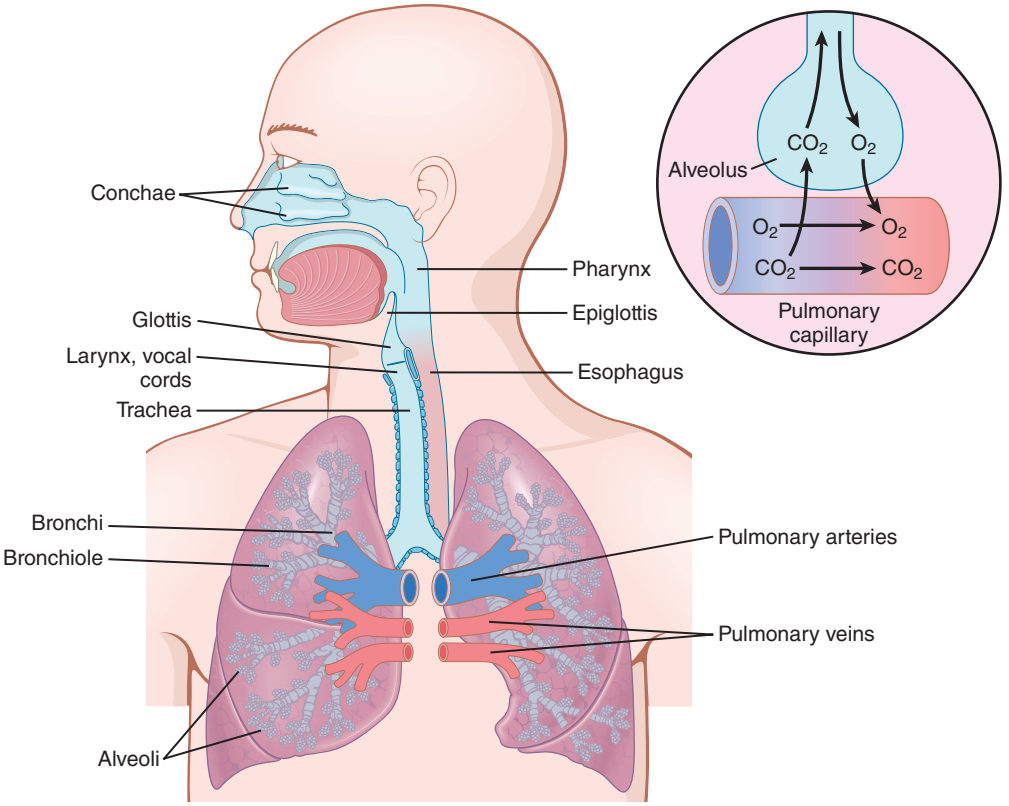

Figure 38.8 Respiratory passages.

Also, the walls of the *bronchioles* are almost entirely smooth muscle, with the exception of the most terminal bronchiole, called the *respiratory bronchiole*, which is mainly pulmonary epithelium and underlying fibrous tissue plus a few smooth muscle fibers. Many obstructive diseases of the lung result from narrowing of the smaller bronchi and larger bronchioles, often because of excessive contraction of the smooth muscle.

Resistance to Airflow in the Bronchial Tree. Under *normal respiratory conditions*, air flows through the respiratory passageways so easily that less than 1 cm H_2O pressure gradient from the alveoli to the atmosphere is sufficient to cause enough airflow for quiet breathing. The greatest amount of resistance to airflow occurs not in the tiny air passages of the terminal bronchioles but in some of the larger bronchioles and bronchi near the trachea. The reason for this high resistance is that there are relatively few of these larger bronchi in comparison with the approximately 65,000 parallel terminal bronchioles, through each of which only a minute amount of air must pass.

In some disease conditions, the smaller bronchioles play a far greater role in determining airflow resistance because of their small size and because they are easily occluded by the following: (1) muscle contraction in their walls; (2) edema in the walls; or (3) mucus collecting in the lumens of the bronchioles.

Nervous and Local Control of the Bronchiolar Musculature—Sympathetic Dilation of the Bronchioles. Direct control of the bronchioles by sympathetic nerve fibers is relatively weak because few of these fibers penetrate to the central portions of the lung. However, the bronchial tree is very much exposed to *norepinephrine* and *epinephrine* released into the blood by sympathetic stimulation of the adrenal gland medullae. Both these hormones, especially epinephrine because of its greater stimulation of *beta-adrenergic receptors*, cause dilation of the bronchial tree.

Parasympathetic Constriction of the Bronchioles. A few parasympathetic nerve fibers derived from the vagus nerves penetrate the lung parenchyma. These nerves secrete *acetylcholine* and, when activated, cause mild to moderate constriction of the bronchioles. When a disease process such as asthma has already caused some bronchiolar constriction, superimposed parasympathetic nervous stimulation often worsens the condition. When this situation occurs, administration of drugs that block the effects of acetylcholine, such as *atropine*, can sometimes relax the respiratory passages enough to relieve the obstruction.

Sometimes the parasympathetic nerves are also activated by reflexes that originate in the lungs. Most of these reflexes begin with irritation of the epithelial membrane of the respiratory passageways, initiated by noxious gases, dust, cigarette smoke, or bronchial infection. Also, a bronchiolar constrictor reflex often occurs when microemboli occlude small pulmonary arteries.

Local Secretory Factors May Cause Bronchiolar Constriction. Several substances formed in the lungs are often active in causing bronchiolar constriction. Two of the most important of these are *histamine* and *slow reactive substance of anaphylaxis*. Both these substances are released in the lung tissues by *mast cells* during allergic reactions, especially those caused by pollen in the air. Therefore, they play key roles in causing airway obstruction in allergic asthma; this is especially true of the slow reactive substance of anaphylaxis.

The same irritants that cause parasympathetic constrictor reflexes of the airways—smoke, dust, sulfur dioxide, and some of the acidic elements in smog—may also act directly on the lung tissues to initiate local, non-nervous reactions that cause obstructive constriction of the airways.

Mucus Lining the Respiratory Passageways and Cilia Action to Clear the Passageways

All the respiratory passages, from the nose to the terminal bronchioles, are kept moist by a layer of mucus that coats the entire surface. The mucus is secreted partly by individual *mucous goblet cells* in the epithelial lining of the passages and partly by small submucosal glands. In addition to keeping the surfaces moist, the mucus traps small particles out of the inspired air and keeps most of these particles from ever reaching the alveoli. The mucus and entrapped particles are removed from the passages in the following manner.

The entire surface of the respiratory passages, in the nose and the lower passages, down as far as the terminal bronchioles, is lined with ciliated epithelium, with about 200 cilia on each epithelial cell. These cilia beat continually at a rate of 10 to 20 times/sec by the mechanism explained in Chapter 2, and the direction of their "power stroke" is always toward the pharynx. That is, the cilia in the lungs beat upward, whereas those in the nose beat downward. This continual beating causes the coat of mucus to flow slowly, at a velocity of a few millimeters per minute, toward the pharynx. Then the mucus and its entrapped particles are swallowed or coughed and spit to the exterior.

Cough Reflex

The bronchi and trachea are so sensitive to light touch that slight amounts of foreign matter or other causes of irritation initiate the cough reflex. The larynx and carina (the point where the trachea divides into the bronchi) are especially sensitive, and the terminal bronchioles and even the alveoli are sensitive to corrosive chemical stimuli such as sulfur dioxide gas or chlorine gas. Afferent nerve impulses pass from the respiratory passages mainly through the vagus nerves to the medulla of the brain. There, an automatic sequence of events is triggered by the neuronal circuits of the medulla, causing the following effects.

1. Up to 2.5 liters of air are rapidly inspired.
2. The epiglottis closes, and the vocal cords shut tightly to entrap the air within the lungs.
3. The abdominal muscles contract forcefully, pushing against the diaphragm while other expiratory muscles, such as the internal intercostals, also contract forcefully. Consequently, the pressure in the lungs rises rapidly, to as much as 100 mm Hg or more.
4. The vocal cords and epiglottis suddenly open widely, so that air under this high pressure in the lungs *explodes* outward. Sometimes this air is expelled at velocities ranging from 75 to 100 miles/hr.

Importantly, the strong compression of the lungs collapses the bronchi and trachea by causing their noncartilaginous parts to invaginate inward, so the exploding air actually passes through *bronchial* and *tracheal slits*. The rapidly moving air usually carries with it foreign matter that is present in the bronchi or trachea.

Sneeze Reflex

The sneeze reflex is very much like the cough reflex, except that it applies to the nasal passageways instead of the lower respiratory passages. The initiating stimulus of the sneeze reflex is irritation in the nasal passageways; the afferent impulses pass in the fifth cranial nerve to the medulla, where the reflex is triggered. A series of reactions similar to those for the cough reflex takes place, but the uvula is depressed, so large amounts of air pass rapidly through the nose, thus helping clear the nasal passages of foreign matter.

Normal Respiratory Functions of the Nose

As air passes through the nose, three distinct normal respiratory functions are performed by the nasal cavities: (1) the air is *warmed* by the extensive surfaces of the conchae and septum (**Fig. 38.8**), a total area of about 160 square centimeters; (2) the air is *almost completely humidified*, even before it passes beyond the nose; and (3) the air is *partially filtered*. These functions together are called the *air-conditioning function* of the upper respiratory passageways. Ordinarily, the temperature of the inspired air rises to within 1°F of body temperature and to within 2% to 3% of full saturation with water vapor before it reaches the trachea. When a person breathes air through a tube directly into the trachea (as through a tracheostomy), the cooling and especially the drying effect in the lower lung can lead to serious lung crusting and infection.

Filtration Function of the Nose. The hairs at the entrance to the nostrils are important for filtering out large particles. Much more important, though, is the removal of particles by *turbulent precipitation*. That is, the air passing through the nasal passageways hits many obstructing vanes—the *conchae* (also called *turbinates*, because they cause turbulence of the air), the septum, and the pharyngeal wall. Each time air hits one of these obstructions, it changes its direction of movement. The particles suspended in the air, having far more mass and momentum than air, cannot change their direction of travel as rapidly as the air can. Therefore, they continue forward, striking the surfaces of the obstructions, and are entrapped in the mucous coating and transported by the cilia to the pharynx to be swallowed.

Size of Particles Entrapped in the Respiratory Passages. The nasal turbulence mechanism for removing particles from air is so effective that almost no particles larger than 6 micrometers in diameter enter the lungs through the nose. This size is smaller than red blood cells.

Of the remaining particles, many that are between 1 and 5 micrometers *settle* in the smaller bronchioles as a result of *gravitational precipitation*. For example, terminal bronchiolar disease is common in coal miners because of settled dust particles. Some of the still smaller particles (<1 micrometer in diameter) *diffuse* against the walls of the alveoli and adhere to the alveolar fluid. However, many particles smaller than 0.5 micrometer in diameter remain suspended in the alveolar air and are expelled by expiration. For example, the particles of cigarette smoke are about 0.3 micrometer. Almost none of these particles are precipitated in the respiratory passageways before they reach the alveoli. Unfortunately, up to one-third of them precipitate in the alveoli by the diffusion process, with the balance remaining suspended and expelled in the expired air.

Many of the particles that become entrapped in the alveoli are removed by *alveolar macrophages*, as explained in Chapter 34, and others are carried away by the lung lymphatics. An excess of particles can cause growth of fibrous tissue in the alveolar septa, leading to permanent debility.

Vocalization

Speech involves the respiratory system, as well as the following: (1) specific speech nervous control centers in the cerebral cortex, discussed in Chapter 58; (2) respiratory control centers of the brain; and (3) the articulation and resonance structures of mouth and nasal cavities. Speech is composed of two mechanical functions: (1) *phonation*, which is achieved by the larynx; and (2) *articulation*, which is achieved by the structures of the mouth.

Phonation. The larynx, shown in **Fig. 38.9A**, is especially adapted to act as a vibrator. The vibrating elements are the *vocal folds*, commonly called the *vocal cords*. The vocal cords protrude from the lateral walls of the larynx toward the center of the glottis; they are stretched and positioned by several specific muscles of the larynx itself.

Fig. 38.9B shows the vocal cords as they are seen when looking into the glottis with a laryngoscope. During normal breathing, the cords are wide open to allow easy passage of air. During phonation, the cords move together so that passage of air between them will cause vibration. The pitch of the vibration is determined mainly by the degree of stretch of the cords, but also by how tightly the cords are approximated to one another and by the mass of their edges.

Fig. 38.9A shows a dissected view of the vocal folds after removal of the mucous epithelial lining. Immediately inside each cord is a strong elastic ligament called the *vocal ligament*. This ligament is attached anteriorly to the large *thyroid cartilage*, which is the cartilage that projects forward from the anterior surface of the neck and is called the *Adam's apple*. Posteriorly, the vocal ligament is attached to the *vocal processes* of two *arytenoid cartilages*. The thyroid cartilage and the arytenoid cartilages articulate from below with a ring-shaped cartilage called the *cricoid cartilage* (not shown in **Fig. 38.9**).

The vocal cords can be stretched by forward rotation of the thyroid cartilage or posterior rotation of the arytenoid cartilages, activated by muscles stretching from the thyroid cartilage and arytenoid cartilages to the cricoid cartilage. Muscles located in the vocal cords lateral to the vocal ligaments, the thyroarytenoid muscles, can pull the arytenoid cartilages toward the thyroid cartilage and, therefore, loosen the vocal cords. Also, slips of these muscles *in* the vocal cords can change the *shapes and masses of the vocal cord edges*, sharpening them to emit high-pitched sounds and blunting them for the more bass sounds.

Several other sets of small laryngeal muscles lie between the arytenoid cartilages and cricoid cartilage and can rotate these cartilages inward or outward or pull their bases together or apart to give the various configurations of the vocal cords, shown in **Fig. 38.9B**.

Articulation and Resonance. The three major organs of articulation are the *lips*, *tongue*, and *soft palate*. They need not be discussed in detail here because we are all familiar with their movements during speech and other vocalizations.

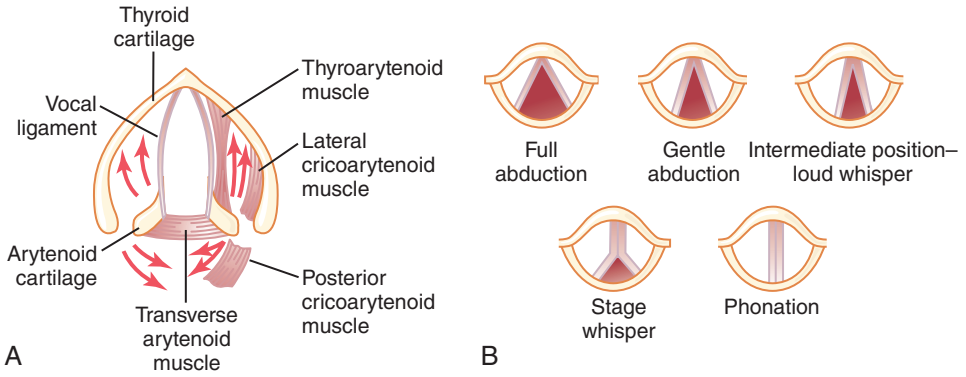

Figure 38.9 (A) Anatomy of the larynx. (B) Laryngeal function in phonation, showing the positions of the vocal cords during different types of phonation. (*Modified from Greene MC.* The Voice and Its Disorders. *4th ed. Philadelphia: JB Lippincott; 1980.*)

The resonators include the *mouth*, the *nose* and *associated nasal sinuses*, the *pharynx*, and even the *chest cavity*. Again, we are familiar with the resonating qualities of these structures. For example, the function of the nasal resonators is demonstrated by the change in voice quality when a person has a severe cold that blocks the air passages to these resonators.

CHAPTER 39

Pulmonary Circulation, Pulmonary Edema, and Pleural Fluid

The lung has two circulations, *a high-pressure, low-flow circulation* and *a low-pressure, high-flow circulation*. The *high-pressure, low-flow circulation* supplies systemic arterial blood to the trachea, bronchial tree (including the terminal bronchioles), supporting tissues of the lung, and outer coats (adventitia) of the pulmonary arteries and veins. The *bronchial arteries*, which are branches of the thoracic aorta, supply most of this systemic arterial blood at a pressure that is only slightly lower than the aortic pressure.

The *low-pressure, high-flow circulation* supplies venous blood from all parts of the body to the alveolar capillaries, where oxygen (O_2) is added and carbon dioxide (CO_2) is removed. The *pulmonary artery*, which receives blood from the right ventricle, and its arterial branches carry blood to the alveolar capillaries for gas exchange, and the pulmonary veins then return the blood to the left atrium to be pumped by the left ventricle though the systemic circulation.

In this chapter, we discuss the special aspects of the pulmonary circulation that are important for gas exchange in the lungs.

PHYSIOLOGICAL ANATOMY OF THE PULMONARY CIRCULATORY SYSTEM

Pulmonary Blood Vessels. The pulmonary artery extends only 5 centimeters beyond the apex of the right ventricle and then divides into right and left main branches that supply blood to the two respective lungs.

The pulmonary artery normally has a wall thickness one-third that of the aorta. The pulmonary arterial branches are short, and all the pulmonary arteries, even the smaller arteries and arterioles, have larger diameters than their counterpart systemic arteries. This feature, combined with the fact that the vessels are thin and distensible, gives the pulmonary arterial tree a *large compliance*, averaging almost 7 mL/mm Hg, which is similar to that of the entire systemic arterial tree. This large compliance allows the pulmonary arteries to accommodate the stroke volume output of the right ventricle.

The pulmonary veins, like the pulmonary arteries, are also short. They immediately empty their effluent blood into the left atrium.

Bronchial Blood Vessels. Blood also flows to the lungs through small bronchial arteries that originate from the systemic circulation, amounting to 1% to 2% of the total cardiac output. This bronchial arterial blood is *oxygenated* blood, in contrast to the partially deoxygenated blood in the pulmonary arteries. It supplies the supporting tissues of the lungs, including the connective tissue, septa, and large and small bronchi. After this bronchial and arterial blood passes through the supporting tissues, it empties into the pulmonary veins and *enters the left atrium*, rather than passing back to the right atrium. Therefore, the flow into the left atrium and left ventricular output are about 1% to 2% greater than that of the right ventricular output.

Lymphatics. Lymph vessels are present in all the supportive tissues of the lung, beginning in the connective tissue spaces that surround the terminal bronchioles, coursing to the hilum of the lung, and then emptying mainly into the *right thoracic lymph duct*. Particulate matter entering the alveoli is partly removed by these lymph vessels, and plasma protein leaking from the lung capillaries is also removed from the lung tissues, thereby helping to prevent pulmonary edema.

PRESSURES IN THE PULMONARY CIRCULATORY SYSTEM

Pressures in the Right Ventricle. The pressure pulse curves of the right ventricle and pulmonary artery are shown in the lower portion of **Fig. 39.1**. These curves are contrasted with the much higher aortic pressure curve shown in the upper portion of the figure. The normal systolic pressure in the right ventricle averages about 25 mm Hg, a value that is only one-fifth that for the left ventricle. Diastolic pressure in the right ventricle averages about 0 to 1 mm Hg,

Pressures in the Pulmonary Artery. During *systole*, the pressure in the pulmonary artery is essentially equal to the pressure in the right ventricle, as also shown in **Fig. 39.1**. However, after the pulmonary valve closes at the end of systole, the ventricular pressure falls precipitously, whereas the pulmonary arterial pressure falls more slowly as blood flows through the lungs.

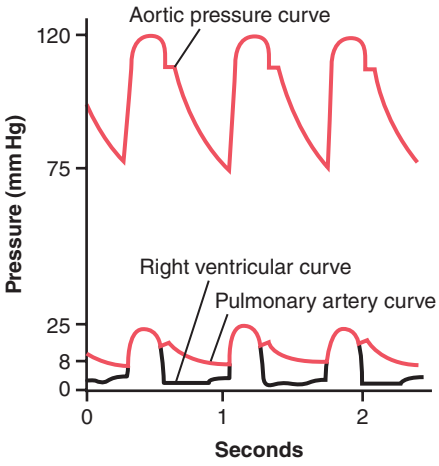

Figure 39.1 Pressure pulse contours in the right ventricle, pulmonary artery, and aorta.

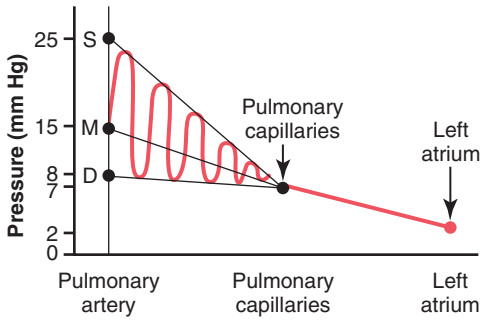

Figure 39.2 Pressures in the different vessels of the lungs. The *red curve* denotes arterial pulsations. *D*, Diastolic; *M*, mean; *S*, systolic.

As shown in **Fig. 39.2**, the *systolic pulmonary arterial pressure* normally averages about 25 mm Hg in the human being, the *diastolic pulmonary arterial pressure* is about 8 mm Hg, and the *mean pulmonary arterial pressure* is 15 mm Hg.

Pulmonary Capillary Pressure. The mean pulmonary capillary pressure, as diagrammed in **Fig. 39.2**, is about 7 mm Hg. The importance of this low capillary pressure is discussed in detail later in the chapter in relation to fluid exchange functions of the pulmonary capillaries.

Left Atrial and Pulmonary Venous Pressures. The mean pressure in the left atrium and major pulmonary veins averages about 2 mm Hg in the recumbent person, varying from as low as 1 mm Hg to as high as 5 mm Hg. It usually is not feasible to measure someone's left atrial pressure using a direct measuring device because it is difficult to pass a catheter through the heart chambers into the left atrium. However, the left atrial pressure can be estimated with moderate accuracy by measuring the so-called *pulmonary wedge pressure*. This is measured by inserting a catheter first through a peripheral vein to the right atrium, then through the right side of the heart and through the pulmonary artery into one of the small branches of the pulmonary artery, and finally pushing the catheter until it *wedges tightly in the small branch*.

The pressure measured through the catheter, called the *wedge pressure*, is about 5 mm Hg. Because all blood flow has been stopped in the small wedged artery, and because the blood vessels extending beyond this artery make a direct connection with the pulmonary capillaries, this wedge pressure is usually only 2 to 3 mm Hg higher than the left atrial pressure. When the left atrial pressure rises to high values, the pulmonary wedge pressure also rises. Therefore, wedge pressure measurements can be used to estimate changes in pulmonary capillary pressure and left atrial pressure in patients with congestive heart failure.

BLOOD VOLUME OF THE LUNGS

The blood volume of the lungs is about 450 mL, about 9% of the total blood volume of the entire circulatory system. Approximately 70 mL of this pulmonary blood volume is in the pulmonary capillaries; the remainder is divided about equally between the pulmonary arteries and veins.

Lungs Serve as a Blood Reservoir. Under various physiological and pathological conditions, the quantity of blood in the lungs can vary from as little as half-normal up to twice normal. For example, when a person blows out air so hard that high pressure is built up in the lungs, such as when blowing a trumpet, as much as 250 mL of blood can be expelled from the pulmonary circulatory system into the systemic circulation. Also, loss of blood from the systemic circulation by hemorrhage can be partly compensated for by the automatic shift of blood from the lungs into the systemic vessels.

Cardiac Pathology May Shift Blood From Systemic Circulation to Pulmonary Circulation. Failure of the left side of the heart, or increased resistance to blood flow through the mitral valve as a result of mitral stenosis or mitral regurgitation, causes blood to dam up in the pulmonary circulation, sometimes increasing the pulmonary blood volume as much as 100% and causing large increases in the pulmonary vascular pressures and, potentially, pulmonary edema as discussed later. Because the volume of the systemic circulation is about nine times that of the pulmonary system, a shift of blood from one system to the other affects the pulmonary system greatly but usually has only mild systemic circulatory effects.

BLOOD FLOW THROUGH THE LUNGS AND ITS DISTRIBUTION

Blood flow through the lungs is essentially equal to the cardiac output. Therefore, the factors that control cardiac output—mainly peripheral factors, as discussed in Chapter 20—also control pulmonary blood flow. Under most conditions, the pulmonary vessels act as distensible tubes that enlarge with increasing pressure and narrow with decreasing pressure. For adequate aeration of the blood to occur, the blood must be distributed to the segments of the lungs where the alveoli are best oxygenated. This distribution is achieved by the following mechanism.

Decreased Alveolar Oxygen Reduces Local Alveolar Blood Flow and Regulates Pulmonary Blood Flow Distribution. When the concentration of O_2 in the alveolar air decreases below normal, especially when it falls below 70% of normal (i.e., <73 mm Hg P_{O_2}), the adjacent blood vessels constrict (**Fig. 39.3**) and may increase vascular resistance more than 5-fold at extremely low O_2 levels. This effect is *opposite to the effect observed in systemic vessels*, which dilate rather than constrict in response to low O_2 levels.

Although the mechanisms that promote pulmonary vasoconstriction during hypoxia are not completely understood, low O_2 concentration may have the following effects:

- Inhibit oxygen-sensitive potassium ion channels in pulmonary vascular smooth muscle cell membranes. Inhibition of these channels leads to depolarization of the cell membrane, which then causes activation of voltage-gated calcium channels and influx of calcium ions. The rise of calcium concentration then causes constriction of small arteries and arterioles.
- Stimulate release of, or increase sensitivity to, vasoconstrictor substances such as endothelin or reactive oxygen species.
- Decrease release of a vasodilator, such as nitric oxide, from the lung tissue.

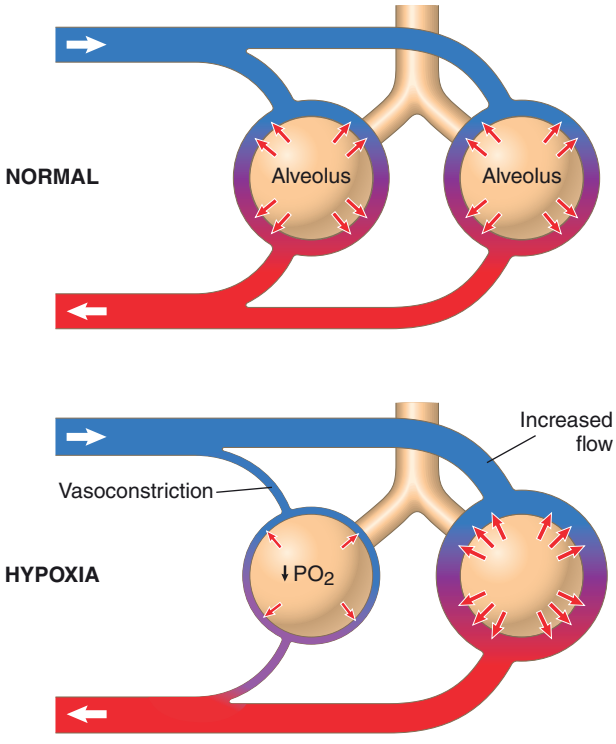

Figure 39.3 Regulation of blood flow in the lungs during local tissue hypoxia. Local tissue blood flow and alveolar ventilation are normally matched for optimal gas exchange *(top panel)*. Decreased P_{O_2} in tissue surrounding poorly ventilated alveoli causes vasoconstriction of adjacent arterioles and diverts blood flow to alveoli that are well ventilated *(bottom panel)*.

The increase in pulmonary vascular resistance as a result of low O_2 concentration has the important function of distributing blood flow to where it is most effective. That is, if some alveoli are poorly ventilated and have a low O_2 concentration, the local vessels constrict. This constriction causes the blood to flow through other areas of the lungs that are better aerated, thus providing an automatic control system for distributing blood flow to the pulmonary areas in proportion to their alveolar O_2 pressures.

EFFECT OF HYDROSTATIC PRESSURE GRADIENTS IN THE LUNGS ON REGIONAL PULMONARY BLOOD FLOW

In Chapter 15, we pointed out that the blood pressure in the foot of a standing person can be as much as 90 mm Hg greater than the pressure at the level of the heart. This difference is caused by *hydrostatic pressure*—that is, by the weight of the blood itself in the blood vessels. The same effect, but to a lesser degree, occurs in the lungs. In the upright adult, the lowest point in the lungs is normally about 30 cm below the highest point, which represents a pressure difference of 23 mm Hg, about 15 mm Hg of which is above the heart and 8 below. That is, the pulmonary arterial pressure in the uppermost portion of the lung of a standing person is about 15 mm Hg less than the pulmonary arterial pressure at the level of the heart, and the pressure in the lowest portion of the lungs is about 8 mm Hg higher.

Such pressure differences have profound effects on blood flow through the different areas of the lungs. This effect is demonstrated by the lower curve in **Fig. 39.4**, which depicts blood flow per unit of lung tissue at different levels of the lung in the upright person. Note that in the standing position at rest, blood flow at the bottom of the lung is about 5 times as great as in the top of the

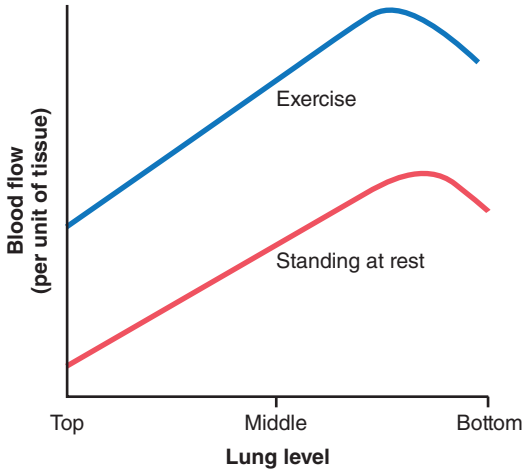

Figure 39.4 Blood flow at different levels in the lung of an upright person at rest *(red curve)* and during exercise *(blue curve)*. Note that when the person is at rest, the blood flow is very low at the top of the lungs; most of the flow is through the bottom of the lung.

lung. To help explain these differences, the lung is often described as being divided into three zones, as shown in **Fig. 39.5**. In each zone, the patterns of blood flow are quite different.

Zones 1, 2, and 3 of Pulmonary Blood Flow

The capillaries in the alveolar walls are distended by the blood pressure inside them but simultaneously are compressed by the alveolar air pressure on their outsides. Therefore, whenever the lung alveolar air pressure becomes greater than the capillary blood pressure, the capillaries close, and there is no blood flow. Under different normal and pathological lung conditions, one may find multiple zones of pulmonary blood flow. These zones are generally divided into three possible patterns, as follows:

- *Zone 1: No blood flow during all portions of the cardiac cycle* because the local alveolar capillary pressure in that area of the lung never rises higher than the alveolar air pressure during any part of the cardiac cycle
- *Zone 2: Intermittent blood flow* only during the peaks of pulmonary arterial pressure because the systolic pressure is then greater than the alveolar air pressure, but the diastolic pressure is less than the alveolar air pressure
- *Zone 3: Continuous blood flow* because the alveolar capillary pressure remains greater than alveolar air pressure during the entire cardiac cycle

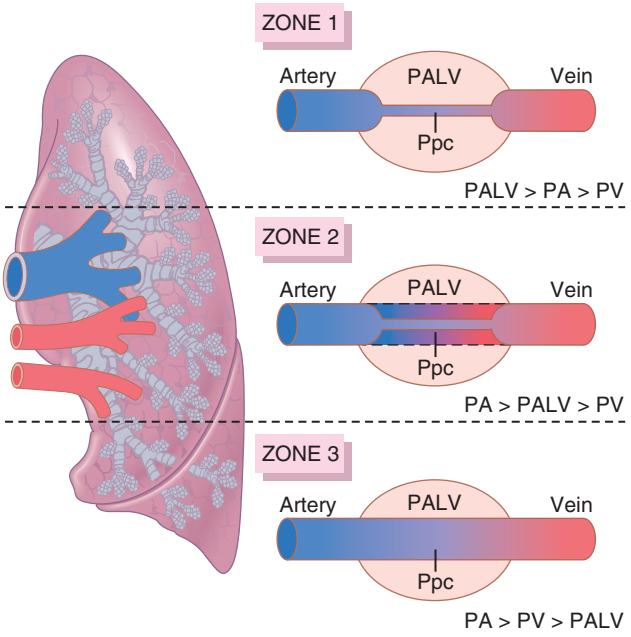

Figure 39.5 Mechanics of blood flow in the three blood flow zones of the lung: *zone 1, no flow*—alveolar air pressure (*PALV*) is greater than arterial pressure (PA) and venous pressure (PV); *zone 2, intermittent flow*—systolic arterial pressure rises higher than alveolar air pressure, but diastolic arterial pressure falls below alveolar air pressure; and *zone 3, continuous flow*—arterial pressure and pulmonary capillary pressure (*Ppc*) remain greater than alveolar air pressure at all times.

Normally, the lungs have only zones 2 and 3 blood flow—zone 2 (intermittent flow) in the apices and zone 3 (continuous flow) in all the lower areas. For example, when a person is in the upright position, the pulmonary arterial pressure at the lung apex is about 15 mm Hg less than the pressure at the level of the heart. Therefore, the apical systolic pressure is only 10 mm Hg (25 mm Hg at heart level minus 15 mm Hg hydrostatic pressure difference). This 10 mm Hg apical blood pressure is greater than the 0 alveolar air pressure, so blood flows through the pulmonary apical capillaries during cardiac systole. Conversely, during diastole, the 8 mm Hg diastolic pressure at the level of the heart is not sufficient to push the blood up the 15 mm Hg hydrostatic pressure gradient required to cause diastolic capillary flow. Therefore, blood flow through the apical part of the lung is intermittent, with flow during systole but cessation of flow during diastole; this is called *zone 2 blood flow*. Zone 2 blood flow begins in normal lungs about 10 cm above the midlevel of the heart and extends from there to the top of the lungs.

In the lower regions of the lungs, from about 10 cm above the level of the heart all the way to the bottom of the lungs, the pulmonary arterial pressure during both systole and diastole remains greater than the 0 alveolar air pressure. Therefore, continuous flow occurs through the alveolar capillaries, or zone 3 blood flow. Also, when a person is lying down, no part of the lung is more than a few centimeters above the level of the heart. In this case, blood flow in a normal person is entirely zone 3 blood flow, including the lung apices.

Zone 1 Blood Flow Occurs Only Under Abnormal Conditions. Zone 1 blood flow, which means no blood flow at any time during the cardiac cycle, occurs when the pulmonary systolic arterial pressure is too low or the alveolar pressure is too high to allow flow. For example, if an upright person is breathing against a positive air pressure so that the intraalveolar air pressure is at least 10 mm Hg greater than normal but the pulmonary systolic blood pressure is normal, one would expect zone 1 blood flow (no blood flow) in the lung apices. Another case in which zone 1 blood flow occurs is in an upright person whose pulmonary systolic arterial pressure is exceedingly low, as might occur after severe blood loss.

Exercise Normally Increases Blood Flow Through All Parts of the Lungs. Referring again to **Fig. 39.4**, one sees that the blood flow in all parts of the lung increases during exercise. A major reason for increased blood flow is that the pulmonary vascular pressures rise enough during exercise to convert the lung apices from a zone 2 pattern into a zone 3 pattern of flow.

The Pulmonary Circulation Normally Accommodates Increased Cardiac Output During Heavy Exercise Without Large Increases in Pulmonary Artery Pressure

During heavy exercise, blood flow through the lungs may increase 4-fold to 7-fold. This extra flow is accommodated

in the lungs in three ways: (1) by increasing the number of open capillaries, sometimes as much as 3-fold; (2) by distending all the capillaries and increasing the rate of flow through each capillary more than 2-fold; and (3) by increasing the pulmonary arterial pressure. Normally, the first two changes decrease pulmonary vascular resistance so much that the pulmonary arterial pressure rises very little, even during maximum exercise. This effect is shown in **Fig. 39.6**.

The ability of the lungs to accommodate greatly increased blood flow during exercise, without increasing the pulmonary arterial pressure, conserves the energy of the right side of the heart. This ability also prevents a major rise in pulmonary capillary pressure and the development of pulmonary edema.

Function of Pulmonary Circulation When Left Atrial Pressure Rises as a Result of Left-Sided Heart Failure

The left atrial pressure in a healthy person almost never rises above +6 mm Hg, even during the most strenuous exercise. These small changes in left atrial pressure have virtually no effect on pulmonary circulatory function because this merely expands the pulmonary venules and opens up more capillaries so that blood continues to flow with almost equal ease from the pulmonary arteries.

When the left side of the heart fails, however, blood begins to dam up in the left atrium. As a result, the left atrial pressure can rise on occasion from its normal value of 1 to 5 mm Hg to as high as 40 to 50 mm Hg. The initial rise in atrial pressure, up to about 7 mm Hg, has little effect on pulmonary circulatory function. However, when the left atrial pressure rises to greater than 7 or 8 mm Hg, further increases in left atrial pressure cause almost equally great increases in pulmonary arterial pressure, thus causing a concomitant increased load on the right heart. Any increase in left atrial pressure above 7 or 8 mm Hg increases capillary pressure almost equally as much. When the left atrial pressure rises above 30 mm Hg, causing similar increases in capillary pressure, pulmonary edema is likely to develop, as discussed later in the chapter.

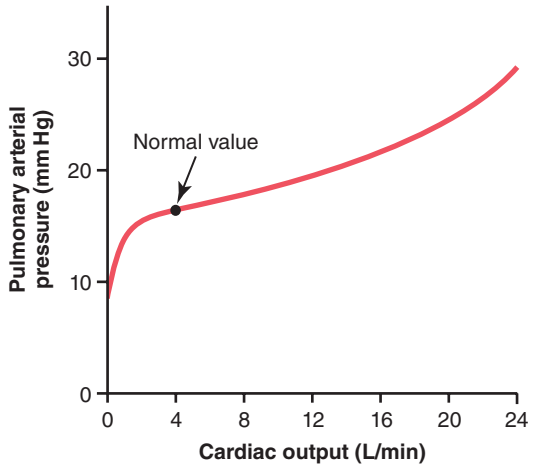

Figure 39.6 Effect on mean pulmonary arterial pressure caused by increasing the cardiac output during exercise.

PULMONARY CAPILLARY DYNAMICS

Exchange of gases between the alveolar air and pulmonary capillary blood is discussed in the next chapter. However, it is important to note here that the alveolar walls are lined with so many capillaries that, in most places, the capillaries almost touch one another side by side. Therefore, it is often said that the capillary blood flows in the alveolar walls as a "sheet of flow," rather than in individual capillaries.

Pulmonary Capillary Pressure. Although direct measurements of pulmonary capillary pressure have not been reported, indirect estimates have suggested that it normally averages about 7 mm Hg. This value is probably nearly correct because the mean left atrial pressure is about 2 mm Hg, and the mean pulmonary arterial pressure is only 15 mm Hg, so the mean pulmonary capillary pressure must lie somewhere between these two values.

Length of Time Blood Stays in the Pulmonary Capillaries. From histological studies of the total cross-sectional area of all the pulmonary capillaries, it can be calculated that when the cardiac output is normal, blood passes through the pulmonary capillaries in about 0.8 second. When the cardiac output increases, this time can shorten to as little as 0.3 second. The shortened time would be much greater were it not for the fact that additional capillaries, which normally are collapsed, open up to accommodate the increased blood flow. Thus, in only a fraction of a second, blood passing through the alveolar capillaries becomes oxygenated and loses its excess carbon dioxide.

Capillary Exchange of Fluid in the Lungs and Pulmonary Interstitial Fluid Dynamics

Although the dynamics of fluid exchange across the lung capillary membranes are qualitatively the same as for peripheral tissues, there are important quantitative differences, as follows:

1. The pulmonary capillary pressure is low, about 7 mm Hg, in comparison with a considerably higher functional capillary pressure in many peripheral tissues of about 17 to 25 mm Hg.
2. The interstitial fluid pressure in the lung is slightly more negative than that in peripheral subcutaneous tissue. This pressure has been measured in two ways—by a micropipette inserted into the pulmonary interstitium, giving a value of about −5 mm Hg, and by measuring the absorption pressure of fluid from the alveoli, giving a value of about −8 mm Hg.
3. The colloid osmotic pressure of the pulmonary interstitial fluid is about 14 mm Hg, in comparison with less than half this value in most peripheral tissues.

4. The alveolar walls are extremely thin, and the alveolar epithelium covering the alveolar surfaces is so weak that it can be ruptured by any positive pressure in the interstitial spaces greater than alveolar air pressure (>0 mm Hg), which allows dumping of fluid from the interstitial spaces into the alveoli. Now let us see how these quantitative differences affect pulmonary fluid dynamics.

Interrelationships Between Interstitial Fluid Pressure and Other Pressures in the Lung. Fig. 39.7 shows a pulmonary capillary, alveolus, and lymphatic capillary draining the interstitial space between the blood capillary and alveolus. Note the balance of forces at the blood capillary membrane, as follows:

	mm Hg
Forces tending to cause movement of fluid outward from the capillaries and into the pulmonary interstitium:	
• Capillary hydrostatic pressure	7
• Interstitial fluid colloid osmotic pressure	14
• Negative interstitial fluid hydrostatic pressure	8
TOTAL OUTWARD FORCE	29
Forces tending to cause absorption of fluid into the capillaries:	
• Plasma colloid osmotic pressure	28
TOTAL INWARD FORCE	28

Thus, the normal outward forces are slightly greater than the inward forces, providing a mean filtration pressure at the pulmonary capillary membrane that can be calculated as +29 − 28 mm Hg = +1 mm Hg.

This filtration pressure causes a slight continual flow of fluid from the pulmonary capillaries into the interstitial spaces and, except for a small amount that evaporates in the alveoli, this fluid is pumped back to the circulation through the pulmonary lymphatic system.

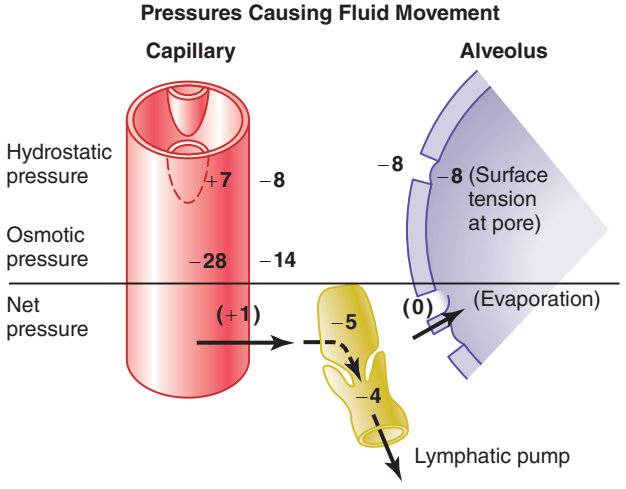

Figure 39.7 Hydrostatic and osmotic forces in mm Hg at the capillary *(left)* and alveolar membrane *(right)* of the lungs. Also shown is the tip end of a lymphatic vessel *(center)* that pumps fluid from the pulmonary interstitial spaces.

Negative Pulmonary Interstitial Pressure and Mechanism for Keeping Alveoli Dry. What keeps the alveoli from filling with fluid under normal conditions? The pulmonary capillaries and pulmonary lymphatic system normally maintain a slight *negative pressure* in the interstitial spaces; whenever extra fluid appears in the alveoli, it is sucked mechanically into the lung interstitium through the small openings between the alveolar epithelial cells. The excess fluid is then carried away through the pulmonary lymphatics. Thus, under normal conditions, the alveoli are kept "dry," except for a small amount of fluid that seeps from the epithelium onto the lining surfaces of the alveoli to keep them moist.

Pulmonary Edema

Pulmonary edema occurs in the same way that edema occurs elsewhere in the body. Any factor that increases fluid filtration out of the pulmonary capillaries or that impedes pulmonary lymphatic function and causes pulmonary interstitial fluid pressure to rise from the negative range into the positive range will tend to cause filling of the pulmonary interstitial spaces and alveoli with free fluid.

The most common causes of pulmonary edema are as follows:

1. Left-sided heart failure or mitral valve disease, with consequent great increases in pulmonary venous pressure and pulmonary capillary pressure, and flooding of the interstitial spaces and alveoli
2. Damage to the pulmonary blood capillary membranes caused by infections such as pneumonia or by breathing noxious substances such as chlorine gas or sulfur dioxide gas

Each of these mechanisms causes rapid leakage of plasma proteins and fluid out of the capillaries and into the lung interstitial spaces and alveoli.

Pulmonary Edema Safety Factor. Experimental studies have shown that pulmonary capillary pressure normally must rise to a value at least equal to the colloid osmotic pressure of the plasma inside the capillaries before significant pulmonary edema will occur. To give an example, Fig. 39.8 shows how different levels of left atrial pressure increase the rate of pulmonary edema formation. Remember that when the left atrial pressure rises to high values, pulmonary capillary pressure rises to a level 1 to 2 mm Hg greater than the left atrial pressure. In these experiments, as soon as the left atrial pressure rose above 23 mm Hg (causing the pulmonary capillary pressure to rise above 25 mm Hg), fluid began to accumulate in the lungs. This fluid accumulation increased even more rapidly with further increases in capillary pressure. The plasma colloid osmotic pressure during these experiments was equal to this 25 mm Hg critical pressure level. Therefore, in a person whose normal plasma colloid osmotic pressure is 28 mm Hg, one can predict that the pulmonary capillary pressure must rise from the normal level of 7 mm Hg to more than 28 mm Hg to cause substantial pulmonary edema, giving an *acute safety factor against pulmonary edema* of 21 mm Hg.

Pulmonary Edema Safety Factor in Chronic Conditions. When pulmonary capillary pressure remains elevated

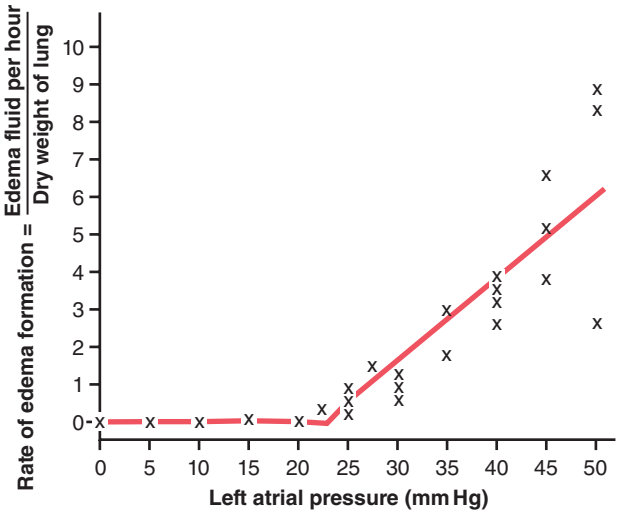

Figure 39.8 Rate of fluid loss into the lung tissues when the left atrial pressure (and pulmonary capillary pressure) is increased. *(From Guyton AC, Lindsey AW. Effect of elevated left atrial pressure and decreased plasma protein concentration on the development of pulmonary edema.* Circ Res. *1959;7:649.)*

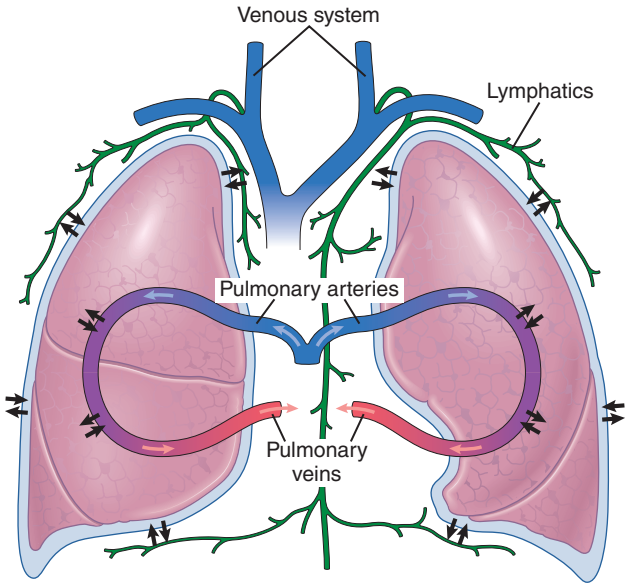

Figure 39.9 Dynamics of fluid exchange in the intrapleural space.

chronically (for at least 2 weeks), the lungs become even more resistant to pulmonary edema because the lymph vessels expand greatly, increasing their capability of carrying fluid away from the interstitial spaces perhaps as much as 10-fold. Therefore, in patients with chronic mitral stenosis, pulmonary capillary pressures of 40 to 45 mm Hg have been measured without the development of lethal pulmonary edema.

Rapidity of Death in Persons With Acute Pulmonary Edema. When pulmonary capillary pressure rises even slightly above the safety factor level, lethal pulmonary edema can occur within hours, or even within 20 to 30 minutes if capillary pressure rises 25 to 30 mm Hg above the safety factor level. Thus, in acute left-sided heart failure, in which pulmonary capillary pressure occasionally does rise to 50 mm Hg, death may ensue in less than 30 minutes as a result of acute pulmonary edema.

FLUID IN THE PLEURAL CAVITY

When the lungs expand and contract during normal breathing, they slide back and forth within the pleural cavity. To facilitate this movement, a thin layer of mucoid fluid lies between the parietal and visceral pleurae.

Fig. 39.9 shows the dynamics of fluid exchange in the pleural space. The pleural membrane is a porous, mesenchymal, serous membrane through which small amounts of interstitial fluid transude continually into the pleural space. These fluids carry tissue proteins with them, giving the pleural fluid a mucoid characteristic, which is what allows extremely easy slippage of the moving lungs.

The total amount of fluid in each pleural cavity is normally only a few milliliters. Whenever the quantity becomes more than barely enough to begin flowing in the pleural cavity, the excess fluid is pumped away by lymphatic vessels opening directly from the pleural cavity into the following: (1) the mediastinum; (2) the superior surface of the diaphragm; and (3) the lateral surfaces of the parietal pleura. Therefore, the *pleural space*—the space between the parietal and visceral pleurae—is called a *potential space* because it normally is so narrow that it is not obviously a physical space.

Negative Pressure in Pleural Fluid. A negative force is always required on the outside of the lungs to keep the lungs expanded. This force is provided by negative pressure in the normal pleural space. The basic cause of this negative pressure is pumping of fluid from the space by the lymphatics, which is also the basis of the negative pressure found in other tissue spaces of the body, such as the skin as discussed in Chapter 16.

Because the normal collapse tendency of the lungs is about −4 mm Hg, the pleural fluid pressure must always be at least as negative as −4 mm Hg to keep the lungs expanded. Actual measurements have shown that the pressure is usually about −7 mm Hg, which is a few millimeters of mercury more negative than the collapse pressure of the lungs. Thus, the negativity of the pleural fluid pressure keeps the normal lungs pulled against the parietal pleura of the chest cavity, except for an extremely thin layer of mucoid fluid that acts as a lubricant.

Pleural Effusion—Collection of Excess Free Fluid in the Pleural Space. Pleural effusion is analogous to edema fluid in the tissues and can be called *edema of the pleural cavity*. The causes of the effusion are the same as the causes of edema in other tissues (discussed in Chapter 25), including the following: (1) blockage of lymphatic drainage from the pleural cavity; (2) cardiac failure, which causes excessively high peripheral and pulmonary capillary pressures, leading to excessive transudation of fluid into the pleural cavity; (3) greatly reduced plasma colloid osmotic

pressure, thus allowing excessive transudation of fluid; and (4) infection or any other cause of inflammation of the surfaces of the pleural cavity, which increases permeability of the capillary membranes and allows rapid dumping of plasma proteins and fluid into the cavity.

CHAPTER 40

Principles of Gas Exchange; Diffusion of Oxygen and Carbon Dioxide Through Respiratory Membranes

After the alveoli are ventilated with fresh air, the next step in respiration is *diffusion* of oxygen (O_2) from the alveoli into the pulmonary blood and diffusion of carbon dioxide (CO_2) in the opposite direction, out of the blood into the alveoli. The process of diffusion is simply the random motion of molecules in all directions through the respiratory membrane and adjacent fluids. However, in respiratory physiology, we are concerned not only with the basic mechanism by which diffusion occurs but also with the *rate* at which it occurs, which is a much more complex issue, requiring a deeper understanding of the physics of diffusion and gas exchange across the respiratory membranes.

Physics of Gas Diffusion and Gas Partial Pressures

Molecular Basis of Gas Diffusion

All the gases of concern in respiratory physiology are simple molecules that are free to move among one another by diffusion. This is also true of gases dissolved in the fluids and tissues of the body.

This source of energy for diffusion is provided by the kinetic motion of the molecules. Except at absolute zero temperature, all molecules of all matter are continually undergoing motion. For free molecules that are not physically attached to others, this means linear movement at high velocity until they strike other molecules. They then bounce away in new directions and continue moving until they strike other molecules again. In this way, the molecules move rapidly and randomly among one another.

Net Diffusion of a Gas in One Direction Along a Concentration Gradient. If a gas chamber or solution has a high concentration of a particular gas at one end of the chamber and a low concentration at the other end, as shown in **Fig. 40.1**, net diffusion of the gas will occur from the high-concentration area toward the low-concentration area. The reason is obvious. There are far more molecules at end A of the chamber to diffuse toward end B than there are molecules to diffuse in the opposite direction. Therefore, the rates of diffusion in each of the two directions are proportionately different, as demonstrated by the lengths of the arrows in the figure.

Partial Pressures of Individual Gases in a Mixture of Gases

Pressure is caused by multiple impacts of moving molecules against a surface. Therefore, the pressure of a gas acting on the surfaces of the respiratory passages and alveoli is proportional to the summated force of impact of all the molecules of that gas striking the surface at any given instant. This means that *the pressure is directly proportional to the concentration of the gas molecules.*

In respiratory physiology, one deals with mixtures of gases, mainly *oxygen, nitrogen*, and *carbon dioxide.* The rate of diffusion of each of these gases is directly proportional to the pressure caused by that gas alone, which is called the *partial pressure* of that gas. The concept of partial pressure can be explained as follows.

Consider air, which has an approximate composition of 79% nitrogen and 21% oxygen. The total pressure of this mixture at sea level averages 760 mm Hg. It is clear from the preceding description of the molecular basis of pressure that each gas contributes to the total pressure in direct proportion to its concentration. Therefore, 79% of the 760 mm Hg is caused by nitrogen (600 mm Hg) and 21% by O_2 (160 mm Hg). Thus, the partial pressure of nitrogen in the mixture is 600 mm Hg, and the partial pressure of O_2 is 160 mm Hg; the total pressure is 760 mm Hg, the sum of the individual partial pressures. The partial pressures of individual gases in a mixture are designated by the symbols P_{O_2}, P_{CO_2}, P_{N_2}, P_{He}, and so forth.

Pressures of Gases Dissolved in Water and Tissues

Gases dissolved in water or in body tissues also exert pressure because the dissolved gas molecules are moving randomly and have kinetic energy. Furthermore, when the gas dissolved in fluid encounters a surface, such as the membrane of a cell, it exerts its own partial pressure in the same way as a gas in the gas phase. The partial pressures of the separate dissolved gases are designated the same as the partial pressures in the gas state—that is, P_{O_2}, P_{CO_2}, P_{N_2}, P_{He}, and so forth.

Factors That Determine Partial Pressure of a Gas Dissolved in a Fluid. The partial pressure of a gas in a solution is determined not only by its concentration but also by the *solubility coefficient* of the gas. That is, some types of molecules, especially CO_2, are physically or chemically attracted to water molecules, whereas other types of molecules are repelled. When molecules are attracted, far more of them can be dissolved without building up excess partial pressure within the solution. Conversely, in the case of molecules that are repelled, high partial pressure will develop with fewer dissolved molecules.

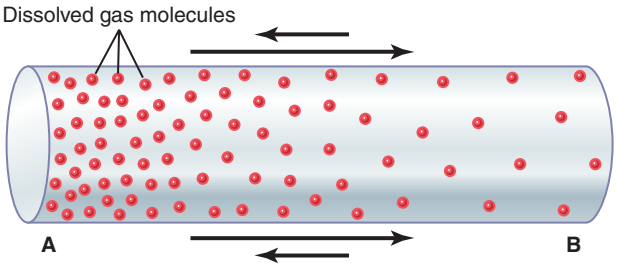

Figure 40.1 Diffusion of oxygen from one end of a chamber to the other. The difference between the lengths of the arrows represents *net diffusion*.

These relationships are expressed by the following formula, which is *Henry's law*:

$$\text{Partial pressure} = \frac{\text{Concentration of dissolved gas}}{\text{Solubility coefficient}}$$

When partial pressure is expressed in atmospheres (1 atmosphere [1 atm] pressure equals 760 mm Hg) and concentration is expressed in volume of gas dissolved in each volume of water, the solubility coefficients for important respiratory gases at body temperature are the following:

Oxygen:	0.024
Carbon dioxide:	0.57
Carbon monoxide:	0.018
Nitrogen:	0.012
Helium:	0.008

From this list, one can see that CO_2 is more than 20 times as soluble as O_2. Therefore, the partial pressure of CO_2 for a given concentration is less than one-twentieth (5%) of that exerted by O_2.

Diffusion of Gases Between Gas Phase in Alveoli and Dissolved Phase in Pulmonary Blood. The partial pressure of each gas in the alveolar respiratory gas mixture tends to force molecules of that gas into solution in the blood of the alveolar capillaries. Conversely, the molecules of the same gas that are already dissolved in the blood are bouncing randomly in the fluid of the blood, and some of these bouncing molecules escape back into the alveoli. The rate at which they escape is directly proportional to their partial pressure in the blood.

But, in which direction will *net diffusion* of the gas occur? The answer is that net diffusion is determined by the difference between the two partial pressures. If the partial pressure is greater in the gas phase in the alveoli, as is normally true for oxygen, then more molecules will diffuse into the blood than in the other direction. Alternatively, if the partial pressure of the gas is greater in the dissolved state in the blood, which is normally true for CO_2, then net diffusion will occur toward the gas phase in the alveoli.

Vapor Pressure of Water

When nonhumidified air is breathed into the respiratory passageways, water immediately evaporates from the surfaces of these passages and humidifies the air. This results from the fact that water molecules, like different dissolved gas molecules, are continually escaping from the water surface into the gas phase. The partial pressure that water molecules exert to escape through the surface is called the *vapor pressure* of the water. At normal body temperature, 37°C (98.6°F), this vapor pressure is 47 mm Hg. Therefore, once the gas mixture has become fully humidified—that is, once it is in equilibrium with the water—the partial pressure of the water vapor in the gas mixture is 47 mm Hg. This partial pressure, like the other partial pressures, is designated as P_{H_2O}.

The vapor pressure of water depends entirely on the temperature of the water. The higher the temperature, the greater the kinetic activity of the molecules and, therefore, the greater the likelihood that the water molecules will escape from the surface of the water into the gas phase. For example, the water vapor pressure at 0°C is 5 mm Hg, and at 100°C it is 760 mm Hg. The most important value to remember is the vapor pressure at normal body temperature, 47 mm Hg. This value appears in many of our subsequent discussions.

Pressure Difference Causes Net Diffusion of Gases Through Fluids

From the preceding discussion, it is clear that when the partial pressure of a gas is greater in one area than in another area, there will be net diffusion from the high-pressure area toward the low-pressure area. Returning to **Fig. 40.1**, one can readily see that the molecules in the area of high pressure, because of their greater number, have a greater chance of moving randomly into the area of low pressure than do molecules attempting to go in the other direction. However, some molecules do bounce randomly from the low-pressure area toward the high-pressure area. Therefore, the *net diffusion* of gas from the area of high pressure to the area of low pressure is equal to the number of molecules bouncing in this forward direction *minus* the number bouncing in the opposite direction, which is proportional to the gas partial pressure difference between the two areas, called simply the *pressure difference for causing diffusion*.

Quantifying Net Rate of Diffusion in Fluids. In addition to the pressure difference, several other factors affect the rate of gas diffusion in a fluid: (1) the solubility of the gas in the fluid; (2) the cross-sectional area of the fluid; (3) the distance through which the gas must diffuse; (4) the molecular weight of the gas; and (5) the temperature of the fluid. In the body, the temperature remains reasonably constant and usually need not be considered.

The greater the solubility of the gas, the greater the number of molecules available to diffuse for any given partial pressure difference. The greater the cross-sectional area of the diffusion pathway, the greater the total number of molecules that diffuse. Conversely, the greater the distance the molecules must diffuse, the longer it will take the molecules to diffuse the entire distance. Finally, the greater the velocity of kinetic movement of the molecules, which is inversely proportional to the square root of the molecular weight, the greater the rate of diffusion of the gas. All these factors can be expressed in a single formula, as follows:

$$D \propto \frac{\Delta P \times A \times S}{d \times \sqrt{MW}}$$

in which D is the diffusion rate, ΔP is the partial pressure difference between the two ends of the diffusion pathway, A is the cross-sectional area of the pathway, S is the solubility of the gas, d is the distance of diffusion, and MW is the molecular weight of the gas.

It is obvious from this formula that the characteristics of the gas determine two factors of the formula—solubility and molecular weight. Together, these two factors determine the *diffusion coefficient of the gas*, which is proportional to $S/\sqrt{MW}$; that is, the relative rates at which different gases at the same partial pressure levels will diffuse are proportional to their diffusion coefficients. Assuming that the diffusion coefficient for O_2 is 1, the *relative* diffusion coefficients for different gases of respiratory importance in the body fluids are as follows:

Oxygen:	1.0
Carbon dioxide:	20.3
Carbon monoxide:	0.81
Nitrogen:	0.53
Helium:	0.95

Diffusion of Gases Through Tissues

The gases that are of respiratory importance are all highly soluble in lipids and, consequently, are highly soluble in cell membranes. Because of this, the major limitation to movement of gases in tissues is the rate at which the gases can diffuse through the tissue water instead of through the cell membranes. Therefore, diffusion of gases through tissues, including through the respiratory membrane, is almost equal to the diffusion of gases in water, as given in the preceding list.

COMPOSITIONS OF ALVEOLAR AIR AND ATMOSPHERIC AIR ARE DIFFERENT

Alveolar air does not have the same concentrations of gases as atmospheric air (**Table 40.1**). There are several reasons for the differences. First, alveolar air is only partially replaced by atmospheric air with each breath. Second, O_2 is constantly being absorbed into the pulmonary blood from the alveolar air. Third, CO_2 is constantly diffusing from the pulmonary blood into the alveoli. And fourth, dry atmospheric air that enters the respiratory passages is humidified even before it reaches the alveoli.

Air Is Humidified in the Respiratory Passages

Table 40.1 shows that atmospheric air is composed almost entirely of nitrogen and O_2; it normally contains almost no CO_2 and little water vapor. However, as soon as the atmospheric air enters the respiratory passages, it is exposed to the fluids that cover the respiratory surfaces. Even before the air enters the alveoli, it becomes almost totally humidified.

Table 40.1 Partial Pressures (in mm Hg) and composition (in percentages) of Respiratory Gases as They Enter and Leave the Lungs[a]

	Atmospheric Air	Humidified Air	Alveolar Air	Expired Air
N_2	597	563.4	569	566
	(78.62)	(74.09)	(74.9)	(74.5)
O_2	159	149.3	104	120
	(20.84)	(19.67)	(13.6)	(15.7)

H_2O	3.7	47	47	47
	(0.50)	(6.20)	(6.2)	(6.2)
Total	760	760	760	760
	(100)	(100)	(100)	(100)

[a]At sea level.

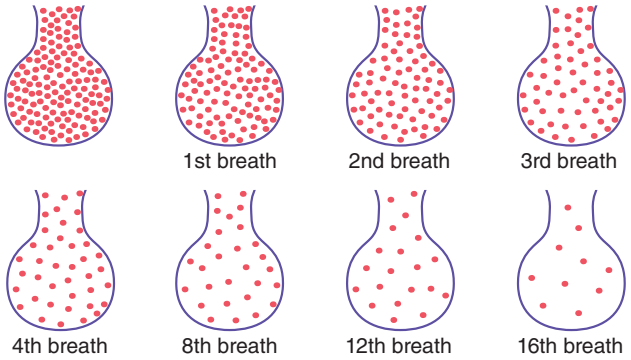

Figure 40.2 Expiration of a gas from an alveolus with successive breaths.

The partial pressure of water vapor at a normal body temperature of 37°C is 47 mm Hg, which is therefore the partial pressure of water vapor in the alveolar air. Because the total pressure in the alveoli cannot rise to more than the atmospheric pressure (760 mm Hg at sea level), this water vapor simply *dilutes* all the other gases in the inspired air. **Table 40.1** also shows that humidification of the air dilutes the oxygen partial pressure at sea level from an average of 159 mm Hg in atmospheric air to 149 mm Hg in the humidified air, and it dilutes the nitrogen partial pressure from 597 to 563 mm Hg.

Alveolar Air Is Slowly Renewed By Atmospheric Air

In Chapter 38, we pointed out that the average *functional residual capacity* of the lungs (the volume of air remaining in the lungs at the end of normal expiration) is about 2300 mL in men. Yet only 350 mL of new air is brought into the alveoli with each normal inspiration, and this same amount of old alveolar air is expired. Therefore, the volume of alveolar air replaced by new atmospheric air with each breath is only one-seventh of the total, so multiple breaths are required to exchange most of the alveolar air. **Fig. 40.2** illustrates this slow rate of renewal of the

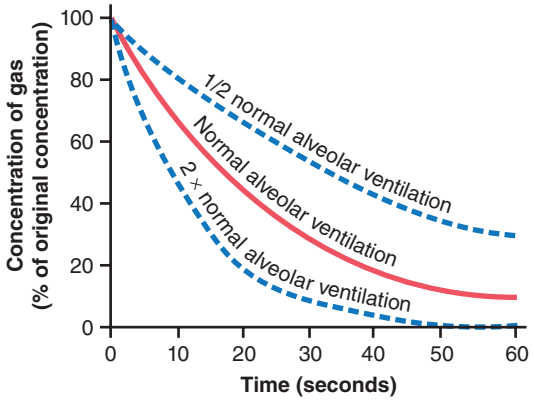

Figure 40.3 Rate of removal of excess gas from alveoli.

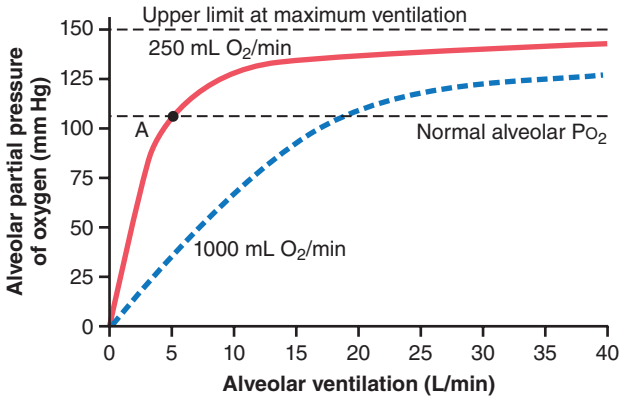

Figure 40.4 Effect of alveolar ventilation on the alveolar partial pressure of oxygen (P_{O_2}) at two rates of oxygen absorption from the alveoli—250 mL/min and 1000 mL/min. Point *A* is the normal operating point.

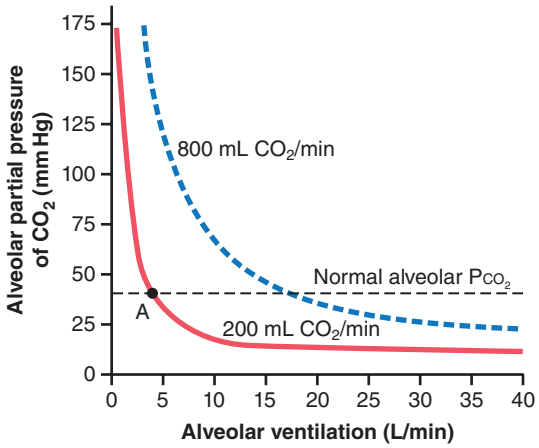

Figure 40.5 Effect of alveolar ventilation on the alveolar partial pressure of carbon dioxide (P_{CO_2}) at two rates of carbon dioxide excretion from the blood—800 mL/min and 200 mL/min. Point *A* is the normal operating point.

alveolar air. In the first alveolus of the figure, excess gas is present in the alveoli, but note that even after 16 breaths, the excess gas still has not been completely removed from the alveoli.

Fig. 40.3 demonstrates graphically the rate at which excess gas in the alveoli is normally removed, showing that with normal alveolar ventilation, about half the gas is removed in 17 seconds. When a person's rate of alveolar ventilation is only half-normal, half of the gas is removed in 34 seconds, and when the rate of ventilation is twice normal, half is removed in about 8 seconds.

Slow Replacement of Alveolar Air Helps Stabilize Respiratory Control. The slow replacement of alveolar air is of particular importance in preventing sudden changes in gas concentrations in the blood. This makes the respiratory control mechanism much more stable than it would be otherwise, and it helps prevent excessive increases and decreases in tissue O_2, CO_2, and pH when respiration is temporarily interrupted.

Oxygen Concentration and Partial Pressure in Alveoli

Oxygen is continually being absorbed from the alveoli into the blood of the lungs, and new O_2 is continually being breathed into the alveoli from the atmosphere. The more rapidly O_2 is absorbed, the lower its concentration in the alveoli becomes; conversely, the more rapidly new O_2 is breathed into the alveoli from the atmosphere, the higher its concentration becomes. Therefore, O_2 concentration in the alveoli, as well as its partial pressure, is controlled by the following: (1) the rate of absorption of O_2 into the blood; and (2) the rate of entry of new O_2 into the lungs by the ventilatory process.

Fig. 40.4 shows the effect of alveolar ventilation and rate of O_2 absorption into the blood on the alveolar P_{O_2}. One curve represents O_2 absorption at a rate of 250 mL/min, and the other curve represents a rate of 1000 mL/min. At a normal ventilatory rate of 4.2 L/min and an O_2 consumption of 250 mL/min, the normal operating point in **Fig. 40.4** is point A. The figure also shows that when 1000 mL of O_2 is being absorbed each minute, as during moderate exercise, the rate of alveolar ventilation must increase 4-fold to maintain the alveolar P_{O_2} at the normal value of 104 mm Hg.

Another effect shown in **Fig. 40.4** is that even an extreme increase in alveolar ventilation can never increase the alveolar P_{O_2} above 149 mm Hg as long as the person is breathing normal atmospheric air at sea level pressure, because 149 mm Hg is the maximum P_{O_2} in humidified air at this pressure. If the person breathes gases that contain partial pressures of O_2 higher than 149 mm Hg, the alveolar P_{O_2} can approach these higher pressures at high rates of ventilation.

CO_2 Concentration and Partial Pressure in Alveoli

Carbon dioxide is continually formed in the body and then carried in the blood to the alveoli; it is continually removed from the alveoli by ventilation. Therefore, CO_2 production by the tissues of the body and excretion from the alveoli are equal under steady-state conditions. **Fig. 40.5** shows the effects on the alveolar partial pressure of P_{CO_2} of both alveolar ventilation and two rates of CO_2

excretion, 200 and 800 mL/min. One curve represents a normal rate of CO_2 excretion of 200 mL/min. At the normal rate of alveolar ventilation of 4.2 L/min, the operating point for alveolar P_{CO_2} is at point A in **Fig. 40.5** (i.e., 40 mm Hg).

Two other facts are also evident from **Fig. 40.5**. First, *the alveolar P_{CO_2} increases directly in proportion to the rate of CO_2 production and excretion*, as represented by the 4-fold elevation of the curve (when 800 mL of CO_2 are excreted per minute). Second, *alveolar P_{CO_2} decreases in inverse proportion to alveolar ventilation*. Therefore, the concentrations and partial pressures of both O_2 and CO_2 in the alveoli are determined by the rates of absorption or excretion of the two gases and by the amount of alveolar ventilation.

Expired Air Is a Combination of Dead Space Air and Alveolar Air

The overall composition of expired air is determined by the following: (1) the amount of the expired air that is dead space air; and (2) the amount that is alveolar air. **Fig. 40.6** shows the progressive changes in O_2 and CO_2 partial pressures in the expired air during the course of expiration. The first portion of this air, the dead space air from the respiratory passageways, is typical humidified air, as shown in **Table 40.1**. Then, progressively more and more alveolar air becomes mixed with the dead space air until all the dead space air has finally been washed out, and nothing but alveolar air is expired at the end of expiration. Therefore, the method of collecting alveolar air for study is simply to collect a sample of the last portion of the expired air after forceful expiration has removed all the dead space air.

Normal expired air, containing both dead space air and alveolar air, has gas concentrations and partial pressures approximately as shown in **Table 40.1** (i.e., concentrations between those of alveolar air and humidified atmospheric air).

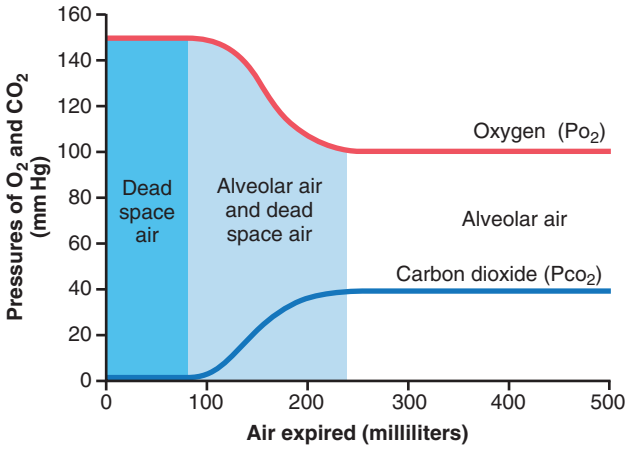

Figure 40.6 Oxygen and carbon dioxide partial pressures (P_{O_2} and P_{CO_2}) in the various portions of normal expired air.

DIFFUSION OF GASES THROUGH THE RESPIRATORY MEMBRANE

Respiratory Unit. **Fig. 40.7** shows the *respiratory unit* (also called *respiratory lobule*), which is composed of a *respiratory bronchiole, alveolar ducts, atria*, and *alveoli*. There are about 300 million alveoli in the two lungs, and each alveolus has an average diameter of about 0.2 millimeter. The alveolar walls are extremely thin, and between the alveoli is an almost solid network of interconnecting capillaries, shown in **Fig. 40.8**. Because of the extensiveness of the capillary plexus, the flow of blood in the alveolar wall has been described as a sheet of flowing blood. Thus, the alveolar gases are in very close proximity to the blood of the pulmonary capillaries. Furthermore, gas exchange between the alveolar air and pulmonary blood occurs through the membranes of all the terminal portions of the lungs, not merely in the alveoli. All these membranes are collectively known as the *respiratory membrane*, also called the *pulmonary membrane*.

Respiratory Membrane. **Fig. 40.9** shows the ultrastructure of the respiratory membrane drawn in cross section on the left and a red blood cell on the right. It also shows diffusion of O_2 from the alveolus into the red blood cell and diffusion of CO_2 in the opposite direction. Note the following different layers of the respiratory membrane:

1. A layer of fluid containing surfactant that lines the alveolus and reduces the surface tension of alveolar fluid

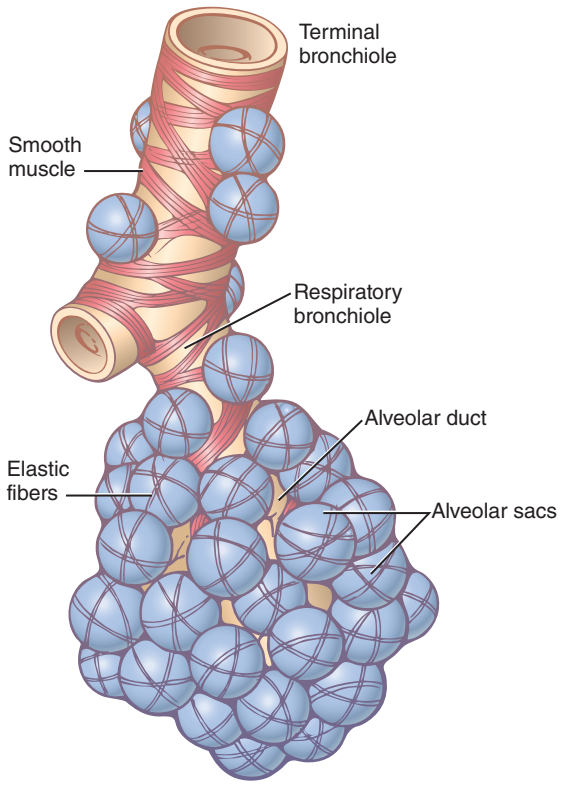

Figure 40.7 Respiratory unit.

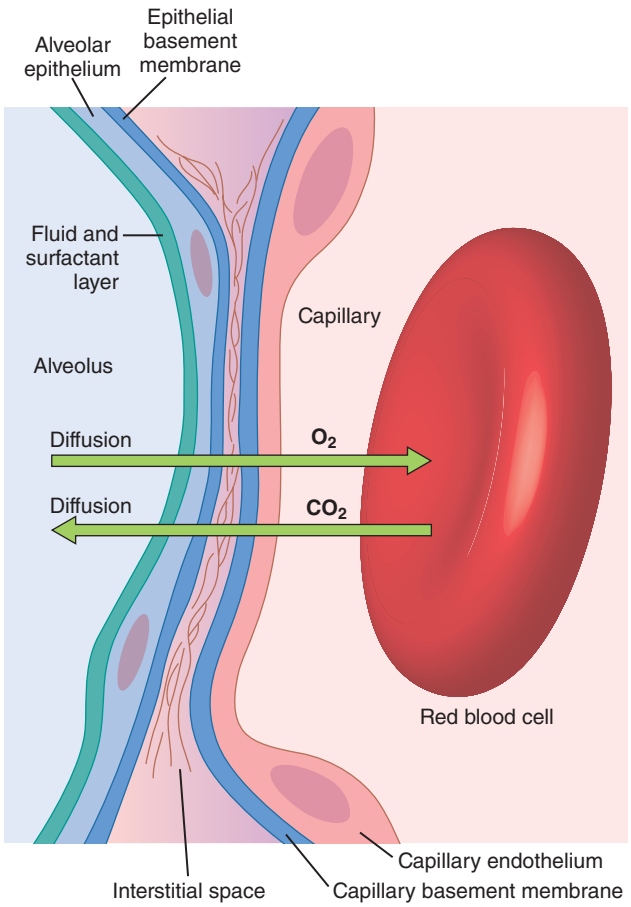

Figure 40.9 Ultrastructure of the alveolar respiratory membrane, shown in cross section.

2. The alveolar epithelium, composed of thin epithelial cells
3. An epithelial basement membrane
4. A thin interstitial space between the alveolar epithelium and capillary membrane
5. A capillary basement membrane that in many places fuses with the alveolar epithelial basement membrane
6. The capillary endothelial membrane

Despite the large number of layers, the overall thickness of the respiratory membrane in some areas is as little as 0.2 micrometer and averages about 0.6 micrometer, except where there are cell nuclei. The total surface area of the respiratory membrane is about 70 square meters in healthy men, which is equivalent to the floor area of a 25 × 30-foot room. The total quantity of blood in the capillaries of the lungs at any given instant is 60 to 140 mL. Now, imagine this small amount of blood spread over the entire surface of a 25 × 30-foot floor, and it is easy to understand the rapidity of the respiratory exchange of O_2 and CO_2.

The average diameter of the pulmonary capillaries is only about 5 micrometers, which means that red blood cells must squeeze through them. The red blood cell membrane usually touches the capillary wall, so O_2 and CO_2 need not pass through significant amounts of plasma as they diffuse between the alveolus and red blood cell. This also increases the rapidity of diffusion.

Factors Affecting Rate of Gas Diffusion Through the Respiratory Membrane

Referring to the earlier discussion of gas diffusion in water, one can apply the same principles to diffusion of gases through the respiratory membrane. Thus, the factors that determine how rapidly a gas will pass through the membrane are the following: (1) the *thickness of the membrane*; (2) the *surface area of the membrane*; (3) the *diffusion coefficient* of the gas in the substance of the membrane; and (4) the *partial pressure difference* of the gas between the two sides of the membrane.

The *thickness of the respiratory membrane* occasionally increases. For example, when there is edema fluid in the interstitial space of the membrane and in the alveoli, the respiratory gases must diffuse not only through the membrane but also through the edema fluid. Also, some pulmonary diseases cause fibrosis of the lungs, which can

increase the thickness of some portions of the respiratory membrane. Because the rate of diffusion through the membrane is inversely proportional to the thickness of the membrane, any factor that increases the thickness to more than two to three times normal can interfere significantly with normal respiratory exchange of gases.

The *surface area of the respiratory membrane* can be greatly decreased by many conditions. For example, removal of an entire lung decreases the total surface area to half-normal. Also, in *emphysema*, many of the alveoli coalesce, with dissolution of many alveolar walls. Therefore, the new alveolar chambers are much larger than the original alveoli, but the total surface area of the respiratory membrane is often decreased as much as 5-fold because of loss of the alveolar walls. When the total surface area is decreased to about one-third to one-fourth normal, exchange of gases through the membrane is substantially impeded *even under resting conditions*, and during strenuous exercise even the slightest decrease in surface area of the lungs can be a serious detriment to respiratory exchange of gases.

The *diffusion coefficient* for transfer of each gas through the respiratory membrane depends on the gas's *solubility* in the membrane and, inversely, on the *square root* of the gas's *molecular weight*. The rate of diffusion in the respiratory membrane is almost exactly the same as that in water, for reasons explained earlier. Therefore, for a given pressure difference, CO_2 diffuses about 20 times as rapidly as O_2. Oxygen diffuses about twice as rapidly as nitrogen.

The *pressure difference* across the respiratory membrane is the difference between the partial pressure of the gas in the alveoli and the partial pressure of the gas in the pulmonary capillary blood. Therefore, the difference between these two pressures is a measure of the *net tendency* for the gas molecules to move through the membrane.

When the partial pressure of a gas in the alveoli is greater than the pressure of the gas in the blood, as is true for O_2, net diffusion from the alveoli into the blood occurs. When the pressure of the gas in the blood is greater than the partial pressure in the alveoli, as is true for CO_2, net diffusion from the blood into the alveoli occurs.

Diffusing Capacity of the Respiratory Membrane

The ability of the respiratory membrane to exchange a gas between the alveoli and pulmonary blood is expressed in quantitative terms by the *respiratory membrane's diffusing capacity*, which is defined as the *volume of a gas that will diffuse through the membrane each minute for a partial pressure difference of 1 mm Hg*. All the factors discussed earlier that affect diffusion through the respiratory membrane can affect this diffusing capacity.

Lung Diffusing Capacity for Oxygen. In the average young men, the total *lung diffusing capacity for* O_2 under resting conditions averages *21 mL/min per mm Hg*. In functional terms, what does this mean? The mean O_2 pressure difference across the respiratory membrane during normal quiet breathing is about 11 mm Hg. Multiplying this pressure by the diffusing capacity (11 × 21) gives a total of about 230 mL of oxygen diffusing through the respiratory membrane each minute, which is equal to the rate at which the resting body uses O_2.

Increased Lung Diffusing Capacity for Oxygen During Exercise. During strenuous exercise or other conditions that greatly increase pulmonary blood flow and alveolar ventilation, the diffusing capacity for O_2 increases to about three times the diffusing capacity under resting conditions. This increase is caused by several factors, including the following: (1) opening up of many previously dormant pulmonary capillaries or extra dilation of already open capillaries, thereby increasing the surface area of the blood into which the O_2 can diffuse; and (2) a better match between the ventilation of the alveoli and perfusion of the alveolar capillaries with blood, called the *ventilation-perfusion ratio*, explained later in this chapter. Therefore, during exercise, oxygenation of the blood is increased not only by increased alveolar ventilation but also by greater diffusing capacity of the respiratory membrane for transporting O_2 into the blood.

Lung Diffusing Capacity for Carbon Dioxide. The total lung diffusing capacity for CO_2 has never been measured because CO_2 diffuses through the respiratory membrane so rapidly that the average difference of P_{CO_2} in the pulmonary blood and P_{CO_2} in the alveoli is less than 1 mm Hg. With currently available techniques, this difference is too small to be measured.

Nevertheless, measurements of diffusion of other gases have shown that the diffusing capacity varies directly with the diffusion coefficient of the particular gas. Because the diffusion coefficient of CO_2 is slightly more than 20 times that of O_2, one would expect a diffusing capacity for CO_2 under resting conditions of about 400 to 450 mL/min per mm Hg and during exercise of about 1200 to 1300 mL/min per mm Hg. **Fig. 40.10** compares the measured or calculated total lung diffusing capacities of carbon monoxide, O_2, and CO_2 at rest and during exercise, showing the extreme diffusing capacity of CO_2 and the effect of exercise on the diffusing capacity of each of these gases.

Carbon Monoxide Method for Measuring Lung Diffusing Capacity. The respiratory membrane O_2 diffusing capacity can be calculated from measurements of the following: (1) alveolar P_{O_2}; (2) P_{O_2} in the pulmonary capillary blood; and (3) the rate of O_2 uptake by the blood. However, measuring the P_{O_2} in the pulmonary capillary blood is so difficult and imprecise that it is not practical to measure oxygen diffusing capacity by such a direct procedure, except on an experimental basis.

To obviate the difficulties encountered in measuring oxygen diffusing capacity directly, physiologists usually measure carbon monoxide (CO) diffusing capacity instead and then calculate the O_2 diffusing capacity from this. The

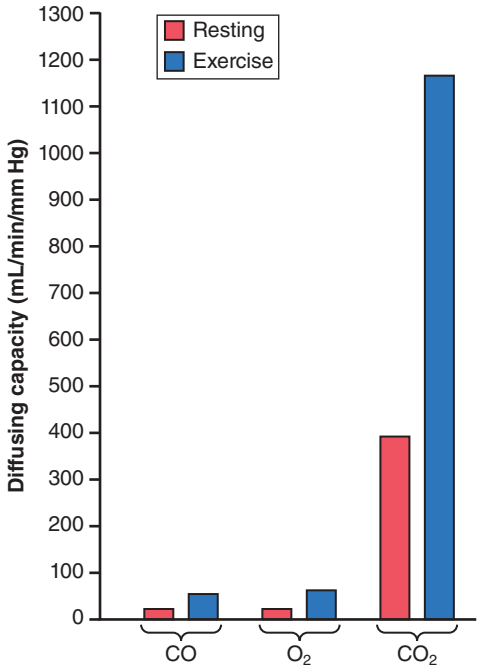

Figure 40.10 *Diffusing capacities* for carbon monoxide, oxygen, and carbon dioxide in the normal lungs under resting conditions and during exercise.

principle of the CO method is as follows. A small amount of CO is breathed into the alveoli, and the partial pressure of the CO in the alveoli is measured from appropriate alveolar air samples. The CO pressure in the blood is essentially zero because hemoglobin combines with this gas so rapidly that its pressure never has time to build up. Therefore, the pressure difference of CO across the respiratory membrane is equal to its partial pressure in the alveolar air sample. Then, by measuring the volume of CO absorbed in a short period and dividing this by the alveolar CO partial pressure, one can determine the CO diffusing capacity accurately.

To convert CO diffusing capacity to O_2 diffusing capacity, the value is multiplied by a factor of 1.23 because the diffusion coefficient for O_2 is 1.23 times that for CO. Thus, the average total lung diffusing capacity for CO in healthy young men at rest is about 17 mL/min per mm Hg, and the diffusing capacity for O_2 is 1.23 times this, or 21 mL/min per mm Hg.

Effect of Ventilation-Perfusion Ratio on Alveolar Gas Concentration

As we discussed previously, two factors determine the P_{O_2} and P_{CO_2} in the alveoli: (1) the rate of alveolar ventilation; and (2) the rate of transfer of O_2 and CO_2 through the respiratory membrane. For this discussion, we assumed that all the alveoli were ventilated equally and that blood flow through the alveolar capillaries was the same for each alveolus. However, in many lung diseases, some areas of the lungs are well ventilated but have almost no blood flow, whereas other areas may have excellent blood flow but little or no ventilation. In either of these conditions, gas exchange through the respiratory membrane is seriously impaired, and the person may suffer severe respiratory distress, despite normal *total* ventilation and normal *total* pulmonary blood flow, but with the ventilation and blood flow going to different parts of the lungs. Therefore, a highly quantitative concept has been developed to help us understand respiratory exchange when there is imbalance between alveolar ventilation and alveolar blood flow. This concept is called the *ventilation-perfusion ratio*.

In quantitative terms, the ventilation-perfusion ratio is expressed as $\dot{V}_A/\dot{Q}$. When $\dot{V}_A$ (alveolar ventilation) is normal for a given alveolus, and $\dot{Q}$ (blood flow) is also normal for the same alveolus, the ventilation-perfusion ratio ($\dot{V}_A/\dot{Q}$) is also said to be normal. When the ventilation ($\dot{V}_A$) is zero, yet there is still perfusion ($\dot{Q}$) of the alveolus, the $\dot{V}_A/\dot{Q}$ is zero. Or, at the other extreme, when there is adequate ventilation ($\dot{V}_A$) but zero perfusion ($\dot{Q}$), the ratio $\dot{V}_A/\dot{Q}$ is infinity. At a ratio of either zero or infinity, there is no exchange of gases through the respiratory membrane of the affected alveoli. Therefore, let us explain the respiratory consequences of these two extremes.

Alveolar Oxygen and Carbon Dioxide Partial Pressures When $\dot{V}_A/\dot{Q}$ Equals Zero. When $\dot{V}_A/\dot{Q}$ is equal to zero—that is, without any alveolar ventilation—the air in the alveolus comes to equilibrium with the blood O_2 and CO_2 because these gases diffuse between the blood and alveolar air. Because the blood that perfuses the capillaries is venous blood returning to the lungs from the systemic circulation, it is the gases in this blood with which the alveolar gases equilibrate. In Chapter 41, we describe how the normal venous blood ($\bar{V}$) has a P_{O_2} of 40 mm Hg and a P_{CO_2} of 45 mm Hg. Therefore, these are also the normal partial pressures of these two gases in alveoli that have blood flow but no ventilation.

Alveolar Oxygen and Carbon Dioxide Partial Pressures When $\dot{V}_A/\dot{Q}$ Equals Infinity. The effect on the alveolar gas partial pressures when $\dot{V}_A/\dot{Q}$ equals infinity is entirely different from the effect when $\dot{V}_A/\dot{Q}$ equals zero because now there is no capillary blood flow to carry O_2 away or to bring CO_2 to the alveoli. Therefore, instead of the alveolar gases coming to equilibrium with the venous blood, the alveolar air becomes equal to the humidified inspired air. That is, the air that is inspired loses no O_2 to the blood and gains no CO_2 from the blood. Furthermore, because normal inspired and humidified air has a P_{O_2} of 149 mm Hg and a P_{CO_2} of 0 mm Hg, these will be the partial pressures of these two gases in the alveoli.

Gas Exchange and Alveolar Partial Pressures When $\dot{V}_A/\dot{Q}$ Is Normal. When there is normal alveolar ventilation and normal alveolar capillary blood flow (normal alveolar perfusion), exchange of O_2 and CO_2 through the respiratory membrane is nearly optimal, and alveolar P_{O_2} is normally at a level of 104 mm Hg, which lies between that of the inspired air (149 mm Hg) and that of venous blood (40 mm Hg). Likewise, alveolar P_{CO_2} is normally 40 mm Hg, in contrast to 45 mm Hg in venous blood and 0 mm Hg in inspired air. Thus, under normal conditions, the alveolar air P_{O_2} averages 104 mm Hg and the P_{CO_2} averages 40 mm Hg.

P_{O_2}-P_{CO_2}, $\dot{V}_A/\dot{Q}$ Diagram

The concepts presented in the preceding sections are shown in graphic form in **Fig. 40.11**, called the P_{O_2}-P_{CO_2}, $\dot{V}_A/\dot{Q}$ diagram. The curve in the diagram represents all possible P_{O_2} and P_{CO_2} combinations between the limits of

$\dot{V}_A/\dot{Q}$ equals zero and $\dot{V}_A/\dot{Q}$ equals infinity when the gas pressures in the venous blood are normal and the person is breathing air at sea level pressure. Thus, $\bar{V}$ is the point on the plot of P_{O_2} and P_{CO_2} when $\dot{V}_A/\dot{Q}$ equals zero. At this point, the P_{O_2} is 40 mm Hg, and the P_{CO_2} is 45 mm Hg, which are the values in normal venous blood.

At the other end of the curve, when $\dot{V}_A/\dot{Q}$ equals infinity, point I represents inspired air, showing P_{O_2} to be 149 mm Hg while P_{CO_2} is zero. Also plotted on the curve is the point that represents normal alveolar air when $\dot{V}_A/\dot{Q}$ is normal. At this point, P_{O_2} is 104 mm Hg, and P_{CO_2} is 40 mm Hg.

Concept of Physiological Shunt (When $\dot{V}_A/\dot{Q}$ Is Below Normal)

Whenever $\dot{V}_A/\dot{Q}$ is below normal, there is inadequate ventilation to provide the O_2 needed to fully oxygenate the blood flowing through the alveolar capillaries. Therefore, a certain fraction of the venous blood passing through the pulmonary capillaries does not become oxygenated. This fraction is called *shunted blood*. Also, some additional blood flows through bronchial vessels rather than through alveolar capillaries, normally about 2% of the cardiac output; this, too, is unoxygenated, shunted blood.

The total amount of shunted blood per minute is called the *physiological shunt*. This physiological shunt is measured in clinical pulmonary function laboratories by analyzing the concentration of O_2 in both mixed venous blood and arterial blood, along with simultaneous measurement of cardiac output. From these values, the physiological shunt can be calculated by the following equation:

$$\frac{\dot{Q}_{PS}}{\dot{Q}_T} = \frac{Ci_{O_2} - Ca_{O_2}}{Ci_{O_2} - C\bar{v}_{O_2}}$$

in which $\dot{Q}_{PS}$ is the physiological shunt blood flow per minute, $\dot{Q}_T$ is cardiac output per minute, Ci_{O_2} is the concentration of oxygen in the arterial blood if there is an "ideal" ventilation-perfusion ratio, Ca_{O_2} is the measured concentration of oxygen in the arterial blood, and $C\bar{v}_{O_2}$ is the measured concentration of oxygen in the mixed venous blood.

The greater the physiological shunt, the greater the *amount of blood that fails to be oxygenated* as it passes through the lungs.

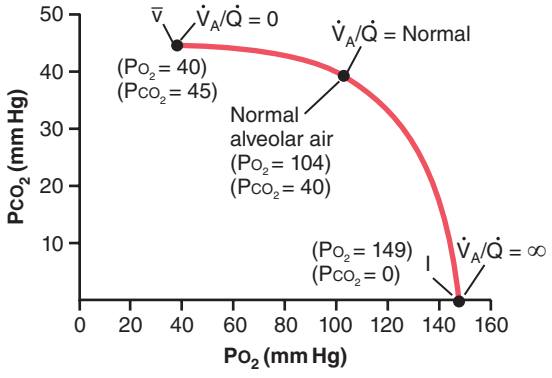

Figure 40.11 Normal partial pressure of oxygen (P_{O_2})–partial pressure of carbon dioxide (P_{CO_2}) ventilation-perfusion ($\dot{V}_A/\dot{Q}$) ratio diagram.

Concept of Physiological Dead Space When $\dot{V}_A/\dot{Q}$ Is Greater Than Normal

When ventilation of some of the alveoli is great but alveolar blood flow is low, there is far more available oxygen in the alveoli than can be transported away from the alveoli by the flowing blood. Thus, the ventilation of these alveoli is said to be *wasted*. The ventilation of the anatomical dead space areas of the respiratory passageways is also wasted. The sum of these two types of wasted ventilation is called the *physiological dead space*. This space is measured in the clinical pulmonary function laboratory by making appropriate blood and expiratory gas measurements and by using the following equation, called the *Bohr equation:*

$$\frac{\dot{V}_{D_{phys}}}{\dot{V}_T} = \frac{Pa_{CO_2} - P\bar{e}_{CO_2}}{Pa_{CO_2}}$$

in which $\dot{V}_{Dphys}$ is the physiological dead space, $\dot{V}_T$ is the tidal volume, Pa_{CO_2} is the partial pressure of CO_2 in the arterial blood, and $P\bar{e}_{CO_2}$ is the average partial pressure of CO_2 in the entire expired air.

When the physiological dead space is great, much of the *work of ventilation* is wasted effort because so much of the ventilating air never reaches the blood.

Abnormalities of Ventilation-Perfusion Ratio

Abnormal $\dot{V}_A/\dot{Q}$ in Upper and Lower Normal Lung. In a healthy person in the upright position, pulmonary capillary blood flow and alveolar ventilation are both considerably less in the upper part of the lung than in the lower part; however, the decrease of blood flow is considerably greater than the decrease in ventilation. Therefore, at the top of the lung, $\dot{V}_A/\dot{Q}$ is as much as 2.5 times as great as the ideal value, which causes a moderate degree of *physiological dead space* in this area of the lung.

At the other extreme, at the bottom of the lung, there is slightly too little ventilation in relation to blood flow, with $\dot{V}_A/\dot{Q}$ as low as 0.6 times the ideal value. In this area, a small fraction of the blood fails to become normally oxygenated, and this represents a *physiological shunt*.

In both extremes, inequalities of ventilation and perfusion slightly decrease the lung's effectiveness for exchanging O_2 and CO_2. However, during exercise, blood flow to the upper part of the lung increases markedly, so far less physiological dead space occurs, and the effectiveness of gas exchange now approaches optimum.

Abnormal $\dot{V}_A/\dot{Q}$ in Chronic Obstructive Lung Disease. Most people who smoke for many years develop various degrees of bronchial obstruction; in many of them, this condition eventually becomes so severe that serious alveolar air trapping develops, with resultant *emphysema*. The emphysema, in turn, causes many of the alveolar walls to be destroyed. Thus, two abnormalities occur in smokers to cause abnormal $\dot{V}_A/\dot{Q}$. First, because many of the small bronchioles are obstructed, the alveoli beyond the obstructions are unventilated, causing a $\dot{V}_A/\dot{Q}$ that approaches zero. Second, in the areas of the lung where the alveolar walls have mainly been destroyed but there is still alveolar ventilation, most of the ventilation is wasted because of inadequate blood flow to transport the blood gases.

Thus, in chronic obstructive lung disease, some areas of the lung exhibit *serious physiological shunt*, and other areas

exhibit *serious physiological dead space*. Both conditions tremendously decrease the effectiveness of the lungs as gas exchange organs, sometimes reducing their effectiveness to as little as one-tenth normal. In fact, this condition is the most prevalent cause of pulmonary disability today.

Transport of Oxygen and Carbon Dioxide in Blood and Tissue Fluids

Once *oxygen* (O_2) has diffused from the alveoli into the pulmonary blood, it is transported to the tissue capillaries almost entirely in combination with hemoglobin. The presence of hemoglobin in the red blood cells allows the blood to transport 30 to 100 times as much O_2 as could be transported in the form of dissolved O_2 in the water of the blood.

In the body's tissue cells, O_2 reacts with various foodstuffs to form large quantities of *carbon dioxide* (CO_2). This CO_2 enters the tissue capillaries and is transported back to the lungs. Carbon dioxide, like O_2, also combines with chemical substances in the blood that increase CO_2 transport 15- to 20-fold.

This chapter presents the physical and chemical principles of O_2 and CO_2 transport in the blood and tissue fluids qualitatively and quantitatively.

TRANSPORT OF OXYGEN FROM THE LUNGS TO THE BODY TISSUES

In Chapter 40, we pointed out that gases can move from one point to another by diffusion, and that the cause of this movement is always a partial pressure difference from the first point to the next. Thus, O_2 diffuses from the alveoli into the pulmonary capillary blood because the oxygen partial pressure (P_{O_2}) in the alveoli is greater than the P_{O_2} in the pulmonary capillary blood. In the other tissues of the body, a higher P_{O_2} in the capillary blood than in the tissues causes O_2 to diffuse into the surrounding cells.

Conversely, when O_2 is metabolized in the cells to form CO_2, the intracellular CO_2 partial pressure (P_{CO_2}) rises, causing CO_2 to diffuse into the tissue capillaries. After blood flows to the lungs, the CO_2 diffuses out of the blood into the alveoli because the P_{CO_2} in the pulmonary capillary blood is greater than that in the alveoli. Thus, the transport of O_2 and CO_2 by the blood depends on both diffusion and the flow of blood. We now consider quantitatively the factors responsible for these effects.

DIFFUSION OF OXYGEN FROM ALVEOLI TO PULMONARY CAPILLARY BLOOD

The top part of **Fig. 41.1** shows a pulmonary alveolus adjacent to a pulmonary capillary and diffusion of O_2 between alveolar air and pulmonary blood. The P_{O_2} of the gaseous O_2 in the alveolus averages 104 mm Hg, whereas the P_{O_2} of the venous blood entering the pulmonary capillary at its arterial end averages only 40 mm Hg because a large amount of O_2 was removed from this blood as it passed through the peripheral tissues. Therefore, the *initial* pressure difference that causes O_2 to diffuse into the pulmonary capillary is 104 − 40 mm Hg, or 64 mm Hg. In the graph at the bottom of the figure, the curve shows the rapid rise in blood P_{O_2} as the blood passes through the capillary; the blood P_{O_2} rises almost to the P_{O_2} of the alveolar air (104 mm Hg) by the time the blood has moved a third of the distance through the capillary.

Uptake of Oxygen By the Pulmonary Blood During Exercise. During strenuous exercise, a person's body may require as much as 20 times the normal amount of oxygen. Also, because of increased cardiac output during exercise, the time that the blood remains in the pulmonary capillary may be reduced to less than one-half normal. Yet, because of the great *safety factor* for diffusion of O_2 through the pulmonary membrane, the blood still becomes *almost saturated* with O_2 by the time it leaves the pulmonary capillaries. This can be explained as follows.

First, in Chapter 40, we pointed out that the diffusing capacity for O_2 increases almost 3-fold during exercise. This results mainly from increased surface area of capillaries participating in the diffusion and also from a more nearly ideal ventilation-perfusion ratio in the upper part of the lungs.

Second, note in the curve of **Fig. 41.1** that under nonexercising conditions, the blood becomes almost saturated with O_2 by the time it has passed through one-third of the pulmonary capillary, and little additional O_2 normally enters the blood during the latter two-thirds of its transit. That is, the blood normally stays in the lung capillaries about three times as long as needed to cause full oxygenation. Therefore, during exercise, even with a shortened time of exposure in the capillaries, the blood can still become almost fully oxygenated.

TRANSPORT OF OXYGEN IN ARTERIAL BLOOD

About 98% of the blood that enters the left atrium from the lungs has just passed through the alveolar capillaries

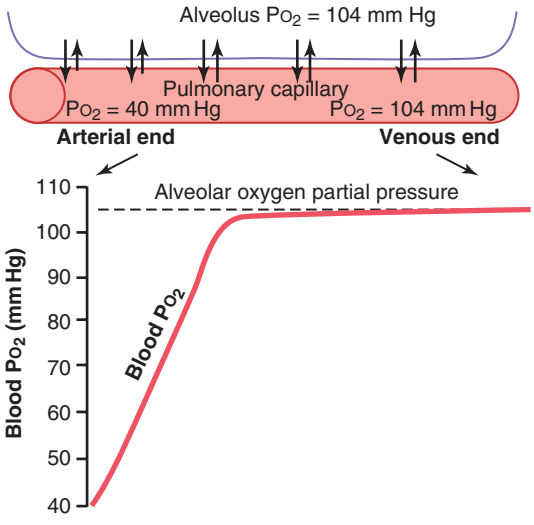

Figure 41.1 Uptake of oxygen by the pulmonary capillary blood. *(Data from Milhorn Jr. HT, Pulley Jr PE. A theoretical study of pulmonary capillary gas exchange and venous admixture.* Biophys J. *1968;8:337.)*

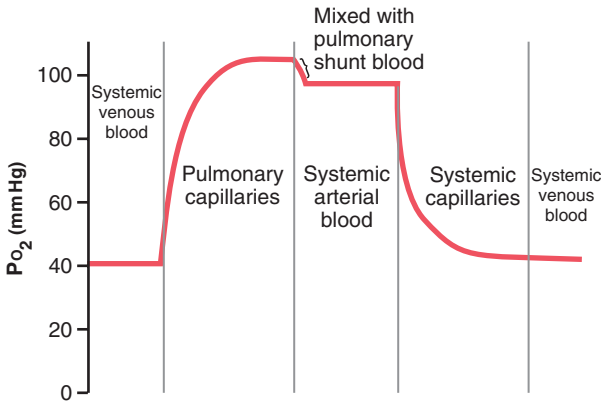

Figure 41.2 Changes in P_{O_2} in the pulmonary capillary blood, systemic arterial blood, and systemic capillary blood demonstrating the effect of venous admixture.

and has become oxygenated up to a P_{O_2} of about 104 mm Hg. Another 2% of the blood has passed from the aorta through the bronchial circulation, which supplies mainly the deep tissues of the lungs and is not exposed to lung air. This blood flow is called *shunt flow*, meaning that blood is shunted past the gas exchange areas. On leaving the lungs, the P_{O_2} of the shunt blood is approximately that of normal systemic venous blood—about 40 mm Hg. When this blood combines in the pulmonary veins with the oxygenated blood from the alveolar capillaries, this so-called *venous admixture of blood* causes the P_{O_2} of the blood entering the left heart and pumped into the aorta to fall to about 95 mm Hg. These changes in blood P_{O_2} at different points in the circulatory system are shown in **Fig. 41.2**.

DIFFUSION OF OXYGEN FROM THE PERIPHERAL CAPILLARIES INTO THE TISSUE FLUIDS

When the arterial blood reaches the peripheral tissues, its P_{O_2} in the capillaries is still 95 mm Hg. As shown in

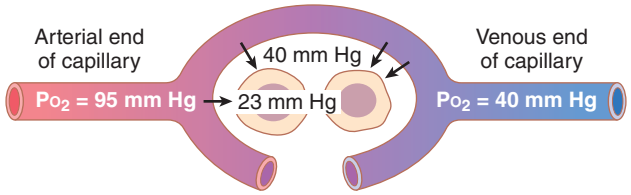

Figure 41.3 Diffusion of oxygen from a peripheral tissue capillary to the cells. (P_{O_2} in interstitial fluid = 40 mm Hg; in tissue cells, P_{O_2} = 23 mm Hg.)

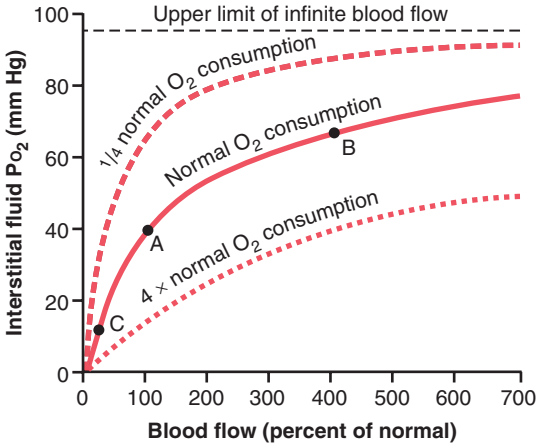

Figure 41.4 Effect of blood flow and rate of oxygen consumption on *tissue* P_{O_2}.

Fig. 41.3, the P_{O_2} in the *interstitial fluid* that surrounds the tissue cells averages only 40 mm Hg. Thus, there is a large initial pressure difference that causes O_2 to diffuse rapidly from the capillary blood into the tissues—so rapidly that the capillary P_{O_2} falls almost to equal the 40-mm Hg pressure in the interstitium. Therefore, the P_{O_2} of the blood leaving the tissue capillaries and entering the systemic veins is also about 40 mm Hg.

Increasing Blood Flow Raises Interstitial Fluid P_{O_2}. If blood flow through a particular tissue is increased, greater quantities of O_2 are transported into the tissue, and the tissue P_{O_2} becomes correspondingly higher. This effect is shown in **Fig. 41.4**. Note that an increase in flow to 400% of normal increases the P_{O_2} from 40 mm Hg (at point A in the figure) to 66 mm Hg (at point B). However, the upper limit to which the P_{O_2} can rise, even with maximal blood flow, is 95 mm Hg because this is the O_2 pressure in the arterial blood. Conversely, if blood flow through the tissue decreases, the tissue P_{O_2} also decreases, as shown at point C.

Increasing Tissue Metabolism Decreases Interstitial Fluid P_{O_2}. If the cells use more than normal O_2 for metabolism, the interstitial fluid P_{O_2} is reduced. **Fig. 41.4** also demonstrates this effect, showing reduced interstitial fluid P_{O_2} when the cellular oxygen consumption is increased and increased P_{O_2} when consumption is decreased.

In summary, tissue P_{O_2} is determined by a balance between (1) the rate of O_2 transport to the tissues in the blood, and (2) the rate at which the O_2 is used by the tissues.

DIFFUSION OF OXYGEN FROM PERIPHERAL CAPILLARIES TO TISSUE CELLS

Oxygen is always being used by the cells. Therefore, the intracellular P_{O_2} in peripheral tissues remains lower than the P_{O_2} in peripheral capillaries. Also, in some cases, there is considerable physical distance between the capillaries and cells. Therefore, the normal intracellular P_{O_2} ranges from as low as 5 mm Hg to as high as 40 mm Hg, averaging (by direct measurement in experimental animals) 23 mm Hg. Because only 1 to 3 mm Hg of O_2 pressure is normally required for full support of the chemical processes that use oxygen in the cell, even this low intracellular P_{O_2} of 23 mm Hg is more than adequate and provides a large safety factor.

DIFFUSION OF CO_2 FROM PERIPHERAL TISSUE CELLS INTO CAPILLARIES AND FROM PULMONARY CAPILLARIES INTO ALVEOLI

When O_2 is used by the cells, virtually all of it becomes CO_2, and this transformation increases intracellular P_{CO_2}; because of this elevated tissue cell P_{CO_2}, CO_2 diffuses from the cells into the capillaries and is then carried by the blood to the lungs. In the lungs, it diffuses from the pulmonary capillaries into the alveoli and is expired.

Thus, at each point in the gas transport chain, CO_2 diffuses in the direction exactly opposite to the diffusion of O_2. Yet, there is one major difference between diffusion of CO_2 and of O_2—*CO_2 can diffuse about 20 times as rapidly as O_2*. Therefore, the pressure differences required to cause CO_2 diffusion are, in each case, far less than the pressure differences required to cause O_2 diffusion. The CO_2 pressures are approximately the following:

1. Intracellular P_{CO_2}, 46 mm Hg; interstitial P_{CO_2}, 45 mm Hg. Thus, there is only a 1 mm Hg pressure differential, as shown in **Fig. 41.5**.
2. P_{CO_2} of the arterial blood entering the tissues, 40 mm Hg; P_{CO_2} of the venous blood leaving the tissues, 45 mm Hg. Thus, as shown in **Fig. 41.5**, the tissue capillary blood comes almost exactly to equilibrium with the interstitial P_{CO_2} of 45 mm Hg.
3. P_{CO_2} of the blood entering the pulmonary capillaries at the arterial end, 45 mm Hg; P_{CO_2} of the alveolar air, 40 mm Hg. Thus, only a 5 mm Hg pressure difference causes all the required CO_2 diffusion out of the pulmonary capillaries into the alveoli. Furthermore, as shown in **Fig. 41.6**, the P_{CO_2} of the pulmonary capillary blood falls to almost exactly equal the alveolar P_{CO_2} of 40 mm Hg before it has passed more than about one-third of the distance through the capillaries. This is the same effect that was observed earlier for O_2 diffusion, except that it is in the opposite direction.

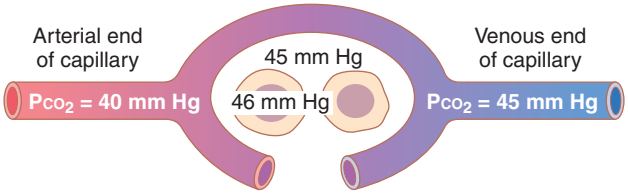

Figure 41.5 Uptake of carbon dioxide by the blood in the tissue capillaries. (P_{CO_2} in tissue cells = 46 mm Hg; in interstitial fluid, P_{CO_2} = 45 mm Hg.)

Effect of Tissue Metabolism and Tissue Blood Flow Rate on Interstitial P_{CO_2}. Tissue capillary blood flow and tissue metabolism affect the P_{CO_2} in ways exactly opposite to their effect on tissue P_{O_2}. **Fig. 41.7** shows these effects, as follows:

1. A decrease in blood flow from normal (point A) to one-quarter normal (point B) increases peripheral tissue P_{CO_2} from the normal value of 45 mm Hg to

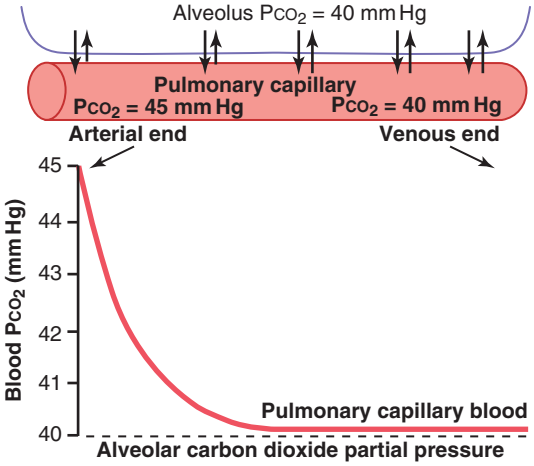

Figure 41.6 Diffusion of carbon dioxide from the pulmonary blood into the alveolus. *(Data from Milhorn Jr HT, Pulley Jr PE. A theoretical study of pulmonary capillary gas exchange and venous admixture.* Biophys J. *1968;8:337.)*

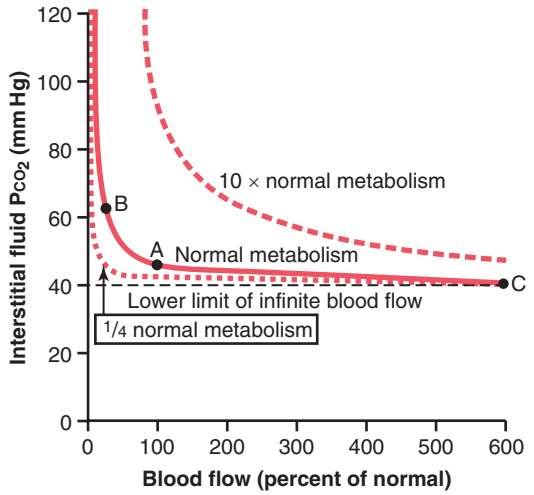

Figure 41.7 Effect of blood flow and metabolic rate on peripheral tissue P_{CO_2}.

an elevated level of 60 mm Hg. Conversely, increasing the blood flow to six times normal (point C) decreases the interstitial P_{CO_2} from the normal value of 45 to 41 mm Hg, almost equal to the P_{CO_2} in the arterial blood (40 mm Hg) entering the tissue capillaries.

2. Note also that a 10-fold increase in tissue metabolic rate greatly elevates the interstitial fluid P_{CO_2} at all rates of blood flow, whereas decreasing the metabolism to one-quarter normal causes the interstitial fluid P_{CO_2} to fall to about 41 mm Hg, closely approaching that of the arterial blood, 40 mm Hg.

ROLE OF HEMOGLOBIN IN OXYGEN TRANSPORT

Normally, about 97% of the oxygen transported from the lungs to the tissues is carried in chemical combination with hemoglobin in the red blood cells. The remaining 3% is transported in the dissolved state in the water of the plasma and blood cells. Thus, *under normal conditions*, oxygen is carried to the tissues almost entirely by hemoglobin.

Reversible Combination of O_2 With Hemoglobin

The chemistry of hemoglobin is presented in Chapter 33, where we point out that the O_2 molecule combines loosely and reversibly with the heme portion of hemoglobin. When P_{O_2} is high, as in the pulmonary capillaries, O_2 binds with hemoglobin. When P_{O_2} is low, as in the tissue capillaries, O_2 is released from hemoglobin. This is the basis for almost all O_2 transport from the lungs to the tissues.

Oxygen-Hemoglobin Dissociation Curve. **Fig. 41.8** shows the O_2-hemoglobin dissociation curve, which demonstrates a progressive increase in the percentage of hemoglobin bound with O_2 as blood P_{O_2} increases, called the *percent saturation of hemoglobin*. Because the blood leaving the lungs and entering the systemic arteries usually has a P_{O_2} of about 95 mm Hg, the *usual O_2 saturation of systemic arterial blood averages 97%*, as shown by the oxygen-hemoglobin dissociation curve. Conversely, in normal venous blood returning from the peripheral tissues, the P_{O_2} is about 40 mm Hg, and *the saturation of hemoglobin averages 75%*.

Maximum Amount of Oxygen That Can Combine With Hemoglobin of the Blood. The blood of a normal person contains about 15 grams of hemoglobin in each 100 mL of blood, and each gram of hemoglobin can bind with a maximum of 1.34 mL of O_2 (1.39 mL when the hemoglobin is chemically pure, but impurities such as methemoglobin reduce the amount of O_2 bound). Therefore, 15 times 1.34 equals 20.1, which means that, on average, 15 grams of hemoglobin in 100 mL of blood can combine with about 20 mL of O_2 if the hemoglobin is 100% saturated. This is usually expressed as *20 volume percent*. The O_2-hemoglobin dissociation curve for the normal person can also be expressed in terms of volume percent of O_2, as shown by the far right scale in **Fig. 41.8**, instead of percent saturation of hemoglobin.

Amount of Oxygen Released From Hemoglobin When Systemic Arterial Blood Flows Through Tissues. The total quantity of O_2 *bound with hemoglobin* in normal systemic arterial blood, which is 97% saturated, is about 19.4 mL/100 mL of blood, as shown in **Fig. 41.9**. On passing through the tissue capillaries, this amount is reduced, on average, to 14.4 mL (P_{O_2} of 40 mm Hg, 75% saturated hemoglobin). Thus, *under normal conditions, about 5 mL of O_2 are transported from the lungs to the tissues by each 100 mL of blood flow*.

Transport of Oxygen Is Markedly Increased During Strenuous Exercise. During heavy exercise, the muscle cells use O_2 at a rapid rate, which in extreme cases can cause the muscle interstitial fluid P_{O_2} to fall from the normal 40 mm Hg to as low as 15 mm Hg. At this low pressure, only 4.4 mL of O_2 remains bound with the hemoglobin in each 100 mL of blood, as shown in **Fig. 41.9**. Thus, 19.4 − 4.4 mL, or 15 mL, is the quantity of O_2 that is actually delivered to the tissues by each

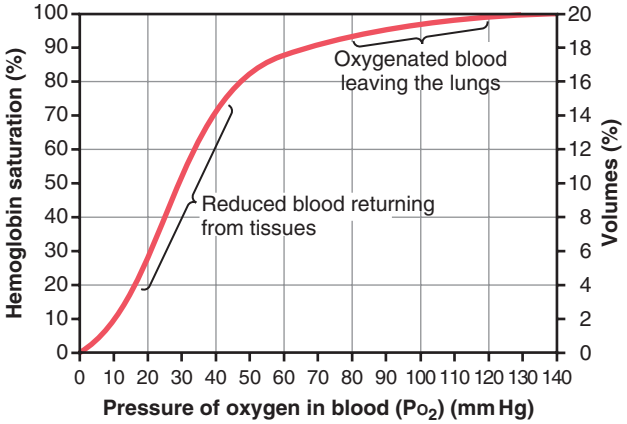

Figure 41.8 Oxygen-hemoglobin dissociation curve.

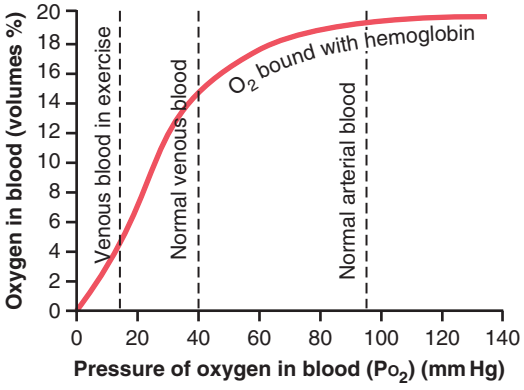

Figure 41.9 Effect of blood PO_2 on the quantity of oxygen bound with hemoglobin in each 100 mL of blood.

100 mL of blood flow, meaning that three times as much O_2 as normal is delivered in each volume of blood that passes through the tissues. Keep in mind that the cardiac output can increase to six to seven times normal in well-trained marathon runners. Thus, multiplying the increase in cardiac output (six- to 7-fold) by the increase in O_2 transport in each volume of blood (3-fold) gives about a 20-fold increase in O_2 transport to the tissues. We will see later in the chapter that several other factors facilitate delivery of O_2 into muscles during exercise, so muscle tissue P_{O_2} often falls just slightly below normal, even during very strenuous exercise.

Utilization Coefficient Is the Percentage of the Blood That Gives Up Its O_2 as It Passes Through the Tissue Capillaries. The normal value for the utilization coefficient is about 25%, as is evident from the preceding discussion—that is, 25% of the oxygenated hemoglobin gives its O_2 to the tissues. During strenuous exercise, the utilization coefficient in the entire body can increase to 75% to 85%. In local tissues where blood flow is extremely slow or the metabolic rate is very high, utilization coefficients approaching 100% have been recorded—that is, essentially all the O_2 is given to the tissues.

Hemoglobin "Buffers" Tissue P_{O_2}

Although hemoglobin is necessary for transporting O_2 to the tissues, it also serves as a tissue oxygen buffer system, another function essential to life. That is, the hemoglobin in blood is mainly responsible for stabilizing P_{O_2} in the tissues, which can be explained as follows.

Hemoglobin Helps Maintain Nearly Constant P_{O_2} in the Tissues. Under basal conditions, the tissues require about 5 mL of O_2 from each 100 mL of blood passing through the tissue capillaries. Referring to the O_2-hemoglobin dissociation curve in **Fig. 41.9**, note that for the normal 5 mL of O_2 to be released per 100 mL of blood flow, the P_{O_2} must fall to about 40 mm Hg. Therefore, the tissue P_{O_2} normally cannot rise above this 40 mm Hg level because, if it did, the amount of O_2 needed by the tissues would not be released from the hemoglobin. In this way, the hemoglobin normally sets an upper limit on the P_{O_2} in the tissues at about 40 mm Hg.

Conversely, during heavy exercise, extra amounts of O_2 (as much as 20 times normal) must be delivered from the hemoglobin to the tissues. However, this delivery of extra O_2 can be achieved with little further decrease in tissue P_{O_2} because of (1) the steep slope of the dissociation curve, and (2) the increase in tissue blood flow caused by the decreased P_{O_2}. That is, a very small fall in P_{O_2} causes large amounts of extra O_2 to be released from hemoglobin. Thus, hemoglobin in the blood automatically delivers O_2 to the tissues at a pressure that is held rather tightly between about 15 and 40 mm Hg.

When Atmospheric Oxygen Concentration Changes Markedly, the Buffer Effect of Hemoglobin Still Maintains Almost Constant Tissue P_{O_2}. The normal P_{O_2} in alveoli is about 104 mm Hg, but as one ascends a mountain or ascends in an airplane, the P_{O_2} can easily fall to less than half this amount. Alternatively, when one enters areas of compressed air, such as deep in the sea or in pressurized chambers, the P_{O_2} may rise to 10 times this level. Even so, the tissue P_{O_2} changes little.

The oxygen-hemoglobin dissociation curve in **Fig. 41.8** shows that when the alveolar P_{O_2} decreases to as low as 60 mm Hg, the arterial hemoglobin is still 89% saturated with O_2—only 8% below the normal saturation of 97%. Furthermore, the tissues still remove about 5 mL of O_2 from each 100 mL of blood passing through the tissues. To remove this O_2, the P_{O_2} of the venous blood falls to 35 mm Hg—only 5 mm Hg below the normal value of 40 mm Hg. Thus, the tissue P_{O_2} hardly changes, despite the marked fall in alveolar P_{O_2} from 104 to 60 mm Hg.

Conversely, when the alveolar P_{O_2} rises as high as 500 mm Hg, the maximum O_2 saturation of hemoglobin can never rise above 100%, which is only 3% above the normal level of 97%. Only a small amount of additional O_2 dissolves in the fluid of the blood, as will be discussed subsequently. Then, when the blood passes through the tissue capillaries and loses several milliliters of O_2 to the tissues, this reduces the P_{O_2} of the capillary blood to a value only a few milliliters higher than the normal 40 mm Hg. Consequently, the level of alveolar O_2 may vary greatly—from 60 to more than 500 mm Hg P_{O_2}—and still the P_{O_2} in the peripheral tissues does not vary more than a few milliliters from normal, *demonstrating beautifully the tissue "oxygen buffer" function of the blood hemoglobin system.*

Factors That Shift the Oxygen-Hemoglobin Dissociation Curve and Their Importance for Oxygen Transport

The O_2-hemoglobin dissociation curves of **Figs. 41.8** and **41.9** are for normal average blood. However, several factors can displace the dissociation curve in one direction or the other, as shown in **Fig. 41.10**. This figure shows that when the blood becomes slightly acidic, with the pH decreasing from the normal value of 7.4 to 7.2, the O_2-hemoglobin dissociation curve shifts, on average, about 15% to the right. Conversely, an increase in pH from the normal 7.4 to 7.6 shifts the curve a similar amount to the left.

In addition to pH changes, several other factors are known to shift the curve. Three of these, which shift the curve to the *right*, are the following: (1) increased CO_2 concentration; (2) increased blood temperature; and (3) increased 2,3-biphosphoglycerate (BPG), a metabolically important phosphate compound present in the blood in different concentrations under different metabolic conditions.

Increased Delivery of Oxygen to Tissues When CO_2 and H^+ Shift the Oxygen-Hemoglobin Dissociation Curve—the Bohr Effect

A shift of the oxygen-hemoglobin dissociation curve to the right in response to increases in blood CO_2 and H^+ levels

enhances the release of O_2 from the blood in the tissues and enhances oxygenation of the blood in the lungs. This is called the *Bohr effect*, which can be explained as follows. As the blood passes through the tissues, CO_2 diffuses from tissue cells into the blood. This diffusion increases the blood P_{CO_2}, which in turn raises blood H_2CO_3 (carbonic acid) and H^+ concentration. These effects shift the O_2-hemoglobin dissociation curve to the right and downward, as shown in **Fig. 41.10**, forcing O_2 away from the hemoglobin and therefore delivering increased amounts of O_2 to the tissues.

Exactly the opposite effects occur in the lungs, where CO_2 diffuses from the blood into alveoli. This diffusion reduces blood P_{CO_2} and H^+ concentration, shifting the O_2-hemoglobin dissociation curve to the left and upward. Therefore, the quantity of O_2 that binds with the hemoglobin at any given alveolar P_{O_2} becomes considerably increased, thus allowing greater O_2 transport to the tissues.

Effect of BPG to Cause Rightward Shift of the Oxygen-Hemoglobin Dissociation Curve

The normal BPG in the blood always keeps the O_2-hemoglobin dissociation curve shifted slightly to the right. In hypoxic conditions that last longer than a few hours, the quantity of BPG in the blood increases considerably, thus shifting the O_2-hemoglobin dissociation curve even farther to the right. This shift causes O_2 to be released to the tissues at as much as 10 mm Hg higher tissue O_2 pressure than would be the case without this increased BPG. Therefore, under some conditions, the BPG mechanism can be important for adaptation to hypoxia, especially to hypoxia caused by poor tissue blood flow.

Rightward Shift of the Oxygen-Hemoglobin Dissociation Curve During Exercise

During exercise, several factors shift the dissociation curve considerably to the right, thus delivering extra amounts of O_2 to the active, exercising muscle fibers. The exercising muscles, in turn, release large quantities of CO_2; this and several other acids released by the muscles increase the H^+ concentration in the muscle capillary blood. In addition, the temperature of the muscle often rises 2° to 3°C, which can increase O_2 delivery to the muscle fibers even more. All these factors act together to shift the oxygen-hemoglobin dissociation curve *of the muscle capillary blood* considerably to the right. This rightward shift of the curve forces O_2 to be released from blood hemoglobin to the muscle at P_{O_2} levels as great as 40 mm Hg, even when 70% of the O_2 has already been removed from the hemoglobin. Then, in the lungs, the shift occurs in the opposite direction, allowing extra amounts of O_2 to be picked up from alveoli.

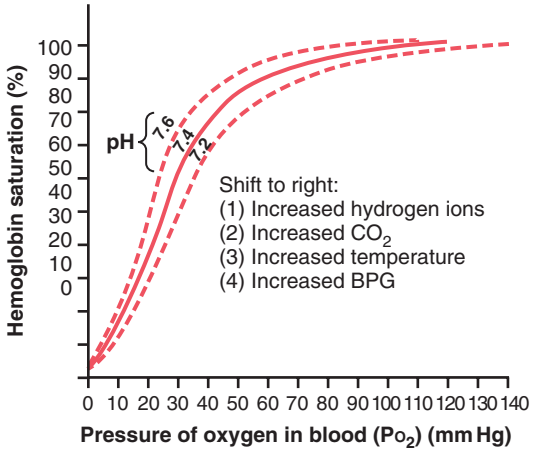

Figure 41.10 Shift of the oxygen-hemoglobin dissociation curve to the right caused by an increase in H^+ concentration (decrease in pH). *BPG*, 2,3-Biphosphoglycerate.

METABOLIC USE OF OXYGEN BY CELLS

Effect of Intracellular P_{O_2} on Oxygen Usage Rate. Only a minute level of O_2 pressure is required in the cells for normal intracellular chemical reactions to take place. The reason for this phenomenon is that the respiratory enzyme systems of the cell, discussed in Chapter 68, have been configured so that when the cellular P_{O_2} is more than 1 mm Hg, O_2 availability is no longer a limiting factor in the rates of the chemical reactions. Instead, the main limiting factor is the *concentration of adenosine diphosphate* (ADP) in the cells. This effect is illustrated in **Fig. 41.11**, which shows the relationship between intracellular P_{O_2} and the O_2 usage rate at different concentrations of ADP. Note that whenever the intracellular P_{O_2} is above 1 mm Hg, O_2 usage rate becomes constant for any given concentration of ADP in the cell. However, when the ADP concentration is altered, the rate of O_2 usage changes in proportion to the change in ADP concentration.

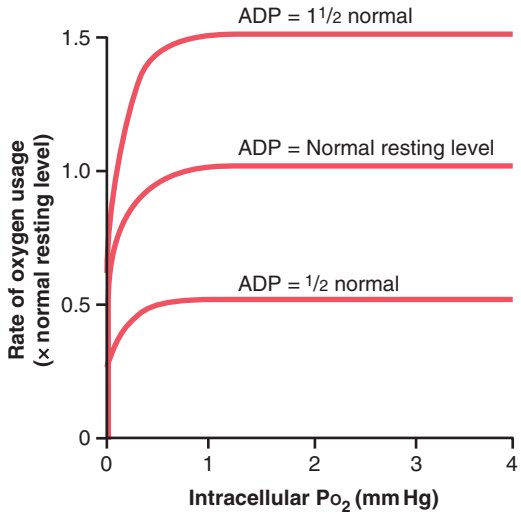

Figure 41.11 Effect of intracellular adenosine diphosphate (ADP) and P_{O_2} on rate of oxygen usage by the cells. Note that as long as the intracellular P_{O_2} remains above 1 mm Hg, the controlling factor for the rate of oxygen usage is the intracellular concentration of ADP.

As explained in Chapter 2, when adenosine triphosphate (ATP) is used in the cells to provide energy, it is converted into ADP. The increasing concentration of ADP increases metabolic usage of O_2 as it combines with the various cell nutrients, releasing energy that reconverts the ADP back to ATP. *Under normal operating conditions, the rate of O_2 usage by the cells is controlled ultimately by the rate of energy expenditure within the cells—that is, by the rate at which ADP is formed from ATP.*

Effect of Diffusion Distance From the Capillary to the Cell on Oxygen Usage. Tissue cells are seldom more than 50 micrometers away from a capillary, and O_2 normally can diffuse readily enough from the capillary to the cell to supply all the required amounts of O_2 for metabolism. However, occasionally, cells are located farther from the capillaries, and the rate of O_2 diffusion to these cells can become so low that intracellular P_{O_2} falls below the critical level required to maintain maximal intracellular metabolism. Thus, under these conditions, O_2 usage by the cells is *diffusion-limited* and is no longer determined by the amount of ADP formed in the cells. However, this situation almost never occurs, except in pathological states.

Effect of Blood Flow on Metabolic Use of Oxygen. The total amount of O_2 available each minute for use in any given tissue is determined by (1) the quantity of O_2 that can be transported to the tissue in each 100 mL of blood, and (2) the rate of blood flow. If blood flow rate falls to zero, the amount of available O_2 also falls to zero. Thus, there are times when blood flow rate through a tissue can be so low that tissue P_{O_2} falls below the critical 1 mm Hg required for intracellular metabolism. Under these conditions, the rate of tissue usage of O_2 is *blood flow–limited*. Neither diffusion-limited nor blood flow–limited oxygen states can continue for long, however, because the cells receive less O_2 than is required to continue life of the cells.

Transport of Oxygen in the Dissolved State

At the normal arterial P_{O_2} of 95 mm Hg, about 0.29 mL of O_2 is dissolved in every 100 mL of water in the blood, and when the P_{O_2} of the blood falls to the normal 40 mm Hg in the tissue capillaries, only 0.12 mL of O_2 remains dissolved. In other words, 0.17 mL of O_2 is normally transported in the dissolved state to the tissues by each 100 mL of arterial blood flow. This value compares with almost 5 mL of O_2 transported by the red blood cell hemoglobin. Therefore, the amount of O_2 transported to the tissues in the dissolved state is normally slight, only about 3% of the total, as compared with 97% transported by the hemoglobin.

During strenuous exercise, when hemoglobin release of O_2 to the tissues increases by another 3-fold, the relative quantity of O_2 transported in the dissolved state falls to as little as 1.5%. However, if a person breathes O_2 at very high alveolar P_{O_2} levels, the amount transported in the dissolved state can become much greater, sometimes so much so that a serious excess of O_2 occurs in the tissues, and so-called *O_2 poisoning* ensues. This condition often leads to brain convulsions and even death, as discussed in detail in Chapter 45 in relation to the high-pressure breathing of O_2 among deep-sea divers.

Combination of Hemoglobin With Carbon Monoxide—Displacement of O_2

Carbon monoxide (CO) combines with hemoglobin at the same point on the hemoglobin molecule as O_2; it can therefore displace O_2 from the hemoglobin and decrease the O_2 carrying capacity of blood. Furthermore, it binds with about 250 times as much tenacity as O_2, which is demonstrated by the CO-hemoglobin dissociation curve in **Fig. 41.12**. This curve is almost identical to the O_2-hemoglobin dissociation curve except that the CO partial pressures, shown on the abscissa, are at a level 1⁄250 of those for the O_2-hemoglobin dissociation curve of **Fig. 41.8**. Therefore, a CO partial pressure of only 0.4 mm Hg in the alveoli, 1⁄250 that of normal alveolar O_2 (100 mm Hg P_{O_2}), allows the CO to compete equally with the O_2 for combination with the hemoglobin and causes 50% of the hemoglobin in the blood to become bound with CO instead of with O_2. Therefore, a CO pressure of only 0.6 mm Hg (a volume concentration < one part/1000 in air) can be lethal.

Even though the O_2 content of blood is greatly reduced in CO poisoning, the P_{O_2} of the blood may be normal. This situation makes exposure to CO especially dangerous because the blood is bright red, and there are no obvious signs of hypoxemia, such as a bluish color of the fingertips or lips (*cyanosis*). Also, P_{O_2} is not reduced, and the feedback mechanism that usually stimulates an increased respiration rate in response to lack of O_2 (usually reflected by a low P_{O_2}) is absent. Because the brain is one of the first organs affected by lack of oxygen, the person may become disoriented and unconscious before becoming aware of the danger.

A patient severely poisoned with CO can be treated by administering pure O_2 because O_2 at high alveolar pressure can displace CO rapidly from its combination with hemoglobin. The patient can also benefit from simultaneous administration of 5% CO_2 because this strongly stimulates the respiratory center, which increases alveolar ventilation and reduces alveolar CO. With intensive O_2 and CO_2 therapy, CO can be removed from the blood as much as 10 times as rapidly as without therapy.

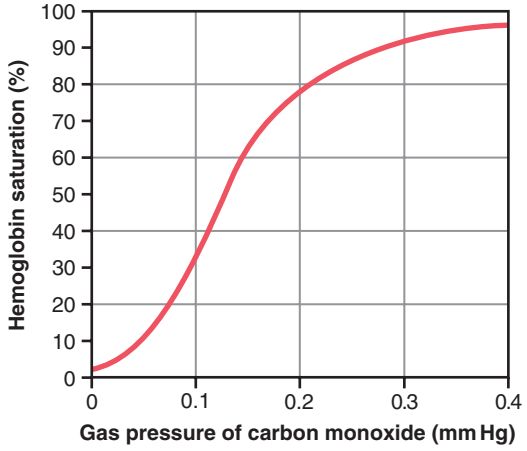

Figure 41.12 Carbon monoxide–hemoglobin dissociation curve. Note the extremely low carbon monoxide pressures at which carbon monoxide combines with hemoglobin.

TRANSPORT OF CO_2 IN BLOOD

Transport of CO_2 by the blood is not nearly as challenging as transport of O_2 is because even in the most abnormal conditions, CO_2 can usually be transported in far greater quantities than can O_2. However, the amount of CO_2 in the blood is closely associated with the acid–base balance of the body fluids, which is discussed in Chapter 31. Under normal resting conditions, *an average of 4 mL of CO_2 are transported from the tissues to the lungs in each 100 mL of blood.*

CHEMICAL FORMS IN WHICH CO_2 IS TRANSPORTED

To begin the process of CO_2 transport, CO_2 diffuses out of the tissue cells in the dissolved molecular CO_2 form. On entering the tissue capillaries, the CO_2 initiates a host of almost instantaneous physical and chemical reactions, shown in **Fig. 41.13**, which are essential for CO_2 transport.

Transpot of CO_2 in a Dissolved State

A small portion of the CO_2 is transported in the dissolved state to the lungs. Recall that the P_{CO_2} of venous blood is 45 mm Hg and that of arterial blood is 40 mm Hg. The amount of CO_2 dissolved in the fluid of the blood at 45 mm Hg is about 2.7 mL/100 mL (2.7 volume percent). The amount dissolved at 40 mm Hg is about 2.4 mL, or a difference of 0.3 mL. Therefore, only about 0.3 mL of CO_2 is transported in the dissolved form by each 100 mL of blood flow. This is about 7% of all the CO_2 normally transported.

Transport of CO_2 in the Form of Bicarbonate Ion

Carbonic Anhydrase Catalyzes the Reaction of CO_2 With Water in Red Blood Cells. The dissolved CO_2 in the blood reacts with water to form *carbonic acid*. This reaction would occur much too slowly to be of importance were it not for the fact that there is an enzyme called *carbonic anhydrase* inside the red blood cells, which catalyzes the reaction between CO_2 and water and accelerates its reaction rate by about 5000-fold. Therefore, instead of requiring many seconds or minutes to occur, as is true in the plasma, the reaction occurs so rapidly in red blood cells that it reaches almost complete equilibrium within a small fraction of a second. This rapid reaction allows tremendous amounts of CO_2 to react with red blood cell water, even before the blood leaves the tissue capillaries.

Dissociation of Carbonic Acid Into Bicarbonate and Hydrogen Ions. In another fraction of a second, the carbonic acid formed in red cells (H_2CO_3) dissociates into H^+ and *bicarbonate ions* (H^+ and HCO_3^-). Most of the H^+ ions then combine with hemoglobin in the red blood cells because the hemoglobin protein is a powerful acid–base buffer. In turn, many of the HCO_3^- ions diffuse from the red blood cells into the plasma while chloride ions diffuse into the red blood cells to take their place. This diffusion is made possible by the presence of a special *bicarbonate-chloride carrier protein* in the red blood cell membrane that shuttles these two ions in opposite directions at rapid velocities. Thus, the chloride content of venous red blood cells is greater than that of arterial red blood cells, a phenomenon called the *chloride shift*.

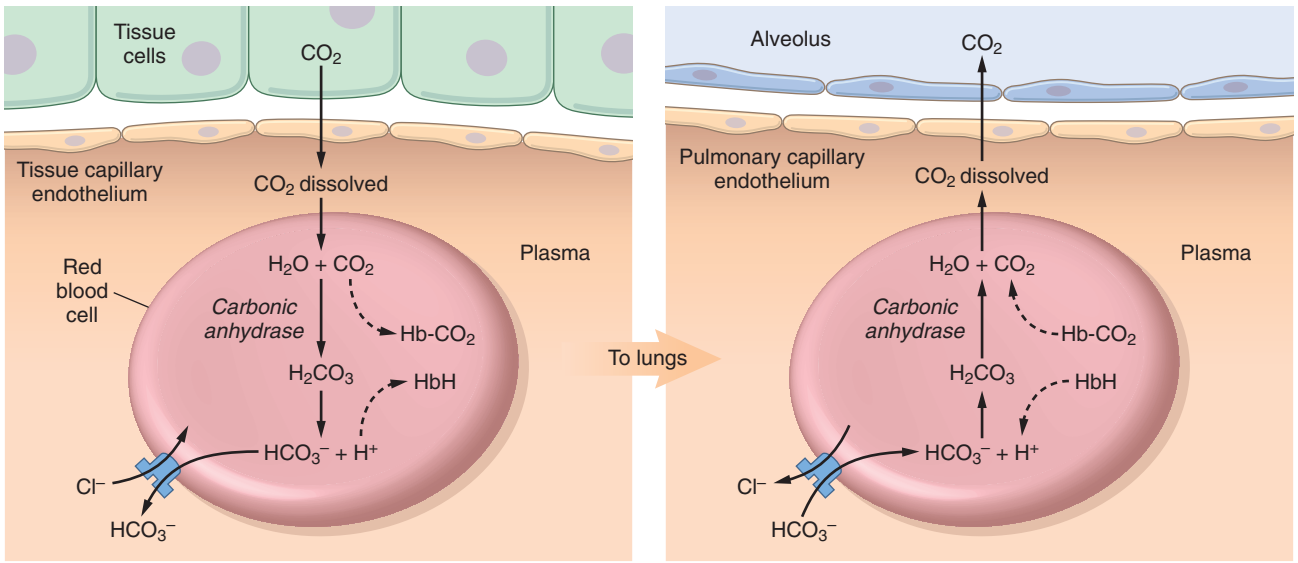

Figure 41.13 Transport of carbon dioxide in the blood from the tissues to the lungs. *Hb*, Hemoglobin.

The reversible combination of CO_2 with water in red blood cells under the influence of carbonic anhydrase accounts for about 70% of the CO_2 transported from the tissues to the lungs. Thus, this means of transporting CO_2 is the most important. Indeed, when a carbonic anhydrase inhibitor (e.g., acetazolamide) is administered to an animal to block the action of carbonic anhydrase in the red blood cells, CO_2 transport from the tissues becomes so poor that the tissue P_{CO_2} may rise to 80 mm Hg instead of the normal 45 mm Hg.

Transport of CO_2 in Combination With Hemoglobin and Plasma Proteins—Carbaminohemoglobin. In addition to reacting with water, CO_2 reacts directly with amine radicals of the hemoglobin molecule to form the compound *carbaminohemoglobin* (CO_2Hgb). This combination of CO_2 and hemoglobin is a reversible reaction that occurs with a loose bond, so the CO_2 is easily released into the alveoli, where the P_{CO_2} is lower than in the pulmonary capillaries.

A small amount of CO_2 also reacts in the same way with the plasma proteins in tissue capillaries. This reaction is much less significant for the transport of CO_2 because the quantity of these proteins in the blood is only one-fourth as great as the quantity of hemoglobin.

The quantity of CO_2 that can be carried from the peripheral tissues to the lungs by carbamino combination with hemoglobin and plasma proteins is about 30% of the total quantity transported—that is, normally about 1.5 mL of CO_2 in each 100 mL of blood. However, because this reaction is much slower than the reaction of CO_2 with water inside the red blood cells, it is doubtful that under normal conditions this carbamino mechanism transports more than 20% of the total CO_2.

CARBON DIOXIDE DISSOCIATION CURVE

The curve shown in **Fig. 41.14**, the *CO_2 dissociation curve*, depicts the dependence of total blood CO_2 in all its forms on P_{CO_2}. Note that the normal blood P_{CO_2} is within the narrow range of 40 mm Hg in arterial blood and 45 mm Hg in venous blood. Note also that the normal concentration of CO_2 in the blood in all its different forms is about 50 volume percent, but only 4 volume percent of this is exchanged during normal transport of CO_2 from the tissues to the lungs. That is, the concentration rises to about 52 volume percent as the blood passes through the tissues and falls to about 48 volume percent as it passes through the lungs.

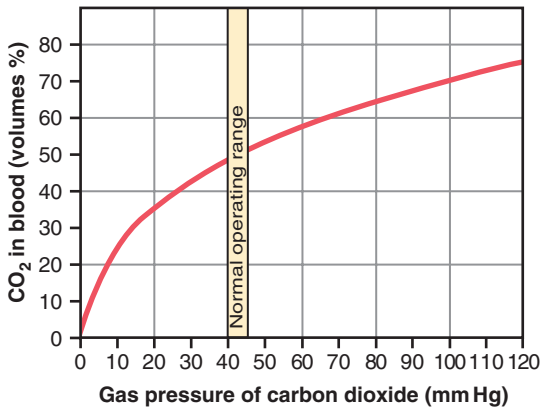

Figure 41.14 Carbon dioxide dissociation curve.

When Oxygen Binds With Hemoglobin, CO_2 Is Released (the Haldane Effect) to Increase CO_2 Transport

Earlier in the chapter, we noted that an increase in CO_2 in the blood causes O_2 to be displaced from the hemoglobin (the Bohr effect), which is an important factor in increasing O_2 transport. The reverse is also true—binding of O_2 with hemoglobin tends to displace CO_2 from the blood. This effect, called the *Haldane effect*, is quantitatively far more important in promoting CO_2 transport than the Bohr effect in promoting O_2 transport.

The Haldane effect results from the simple fact that the combination of O_2 with hemoglobin in the lungs causes the hemoglobin to become a stronger acid. This displaces CO_2 from the blood and into the alveoli in two ways. First, the more highly acidic hemoglobin has less tendency to combine with CO_2 to form carbaminohemoglobin, thus displacing much of the CO_2 that is present in the carbamino form from the blood. Second, the increased acidity of the hemoglobin also causes it to release an excess of H^+, and these ions bind with HCO_3^- to form carbonic acid, which then dissociates into water and CO_2, and the CO_2 is released from the blood into the alveoli and, finally, into the air.

Fig. 41.15 demonstrates quantitatively the significance of the Haldane effect on the transport of CO_2 from the tissues to the lungs. This figure shows small portions of two CO_2 dissociation curves: (1) when the P_{O_2} is 100 mm Hg, which is the case in the blood capillaries of the lungs; and (2) when the P_{O_2} is 40 mm Hg, which is the case in the tissue capillaries. Point A shows

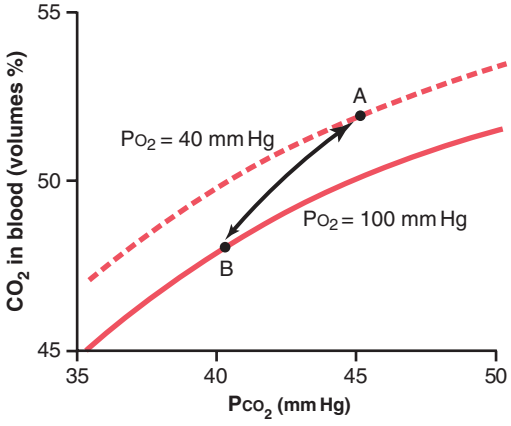

Figure 41.15 Portions of the carbon dioxide dissociation curve when the P_{O_2} is 100 or 40 mm Hg. The *arrow* represents the Haldane effect on the transport of carbon dioxide.

that the normal P_{CO_2} of 45 mm Hg in the tissues causes 52 volume percent of CO_2 to combine with the blood. On entering the lungs, the P_{CO_2} falls to 40 mm Hg, and the P_{O_2} rises to 100 mm Hg. If the CO_2 dissociation curve did not shift because of the Haldane effect, the CO_2 content of the blood would fall only to 50 volume percent, which would be a loss of only 2 volume percent of CO_2. However, the increase in P_{O_2} in the lungs lowers the CO_2 dissociation curve from the top curve to the lower curve of the figure, so the CO_2 content falls to 48 volume percent (point B). This represents an additional 2 volume percent loss of CO_2. Thus, *the Haldane effect approximately doubles the amount of CO_2 released from the blood in the lungs and approximately doubles the amount of CO_2 picked up by the blood from the tissues*.

Change in Blood Acidity During Co_2 Transport

The carbonic acid formed when CO_2 enters the blood in peripheral tissues decreases blood pH. However, reaction of this acid with the acid–base buffers of the blood prevents the H^+ concentration from rising very much (and the pH from falling very much). Ordinarily, arterial blood has a pH of about 7.41, and as the blood acquires CO_2 in the tissue capillaries, the pH falls to a venous value of about 7.37, a pH change of only 0.04 unit. The reverse occurs when CO_2 is released from the blood in the lungs, with the pH rising to the arterial value of 7.41 once again. During heavy exercise or other conditions of high metabolic activity, or when blood flow through the tissues is sluggish, the decrease in pH in the tissue blood (and in the tissues themselves) can be as much as 0.50, about 12 times normal, thus causing significant tissue acidosis.

RESPIRATORY EXCHANGE RATIO

The discerning reader will have noted that normal transport of O_2 from the lungs to the tissues by each 100 mL of blood is about 5 mL, whereas normal transport of CO_2 from the tissues to the lungs is about 4 mL. Thus, under normal resting conditions, only about 82% as much CO_2 is expired from the lungs as O_2 is taken up by the lungs. The ratio of CO_2 output to O_2 uptake is called the *respiratory exchange ratio* (R). That is:

$$R = \frac{\text{Rate of carbon dioxide output}}{\text{Rate of oxygen uptake}}$$

The value for R changes under different metabolic conditions. When a person is using carbohydrates exclusively for body metabolism, R rises to 1.00. Conversely, when a person is using fats exclusively for metabolic energy, the R level falls to as low as 0.7. The reason for this difference is that when O_2 is metabolized with carbohydrates, one molecule of CO_2 is formed for each molecule of O_2 consumed; when O_2 reacts with fats, a large share of the O_2 combines with hydrogen atoms from the fats to form water instead of CO_2. In other words, when fats are metabolized, the *respiratory quotient of the chemical reactions* in the tissues is about 0.70 instead of 1.00. (The tissue respiratory quotient is discussed in Chapter 72.) For a person on a normal diet consuming average amounts of carbohydrates, fats, and proteins, the average value for R is considered to be 0.825.

CHAPTER 42

Regulation of Respiration

We normally breathe almost without conscious effort from birth until death. Our breathing is automatically adjusted to accommodate eating and swallowing, talking, coughing, sneezing, sleeping, and to respond appropriately to physiological challenges (e.g., strenuous exercise) or changing environmental conditions (e.g., high altitude). The nervous system normally coordinates these complex breathing adjustments and alters the rate of alveolar ventilation to meet the demands of the body so that the partial pressures of oxygen (P_{O_2}) and carbon dioxide (P_{CO_2}) in the arterial blood are hardly altered, even during heavy exercise and most other types of respiratory stress. In this chapter we describe the function of this complex neurogenic system for regulation of respiration.

RESPIRATORY CENTER

The *respiratory center* is composed of several groups of neurons located *bilaterally* in the *medulla oblongata* and pons of the brain stem, as shown in **Fig. 42.1**. It is divided into three major collections of neurons: (1) a *dorsal respiratory group*, located in the dorsal portion of the medulla, which mainly causes inspiration; (2) a *ventral respiratory group*, located in the ventrolateral part of the medulla, which contains inspiratory and expiratory neurons; and (3) the *pneumotaxic center*, located dorsally in the superior portion of the pons, which mainly controls rate and depth of breathing.

The respiratory center generates and maintains the rhythm of respiration, and adjusts respiration in response to physiological changes. These adjustments are influenced by signals from peripheral chemoreceptors and mechanoreceptors, hormonal changes, and from other regions of the brain, including the cerebral cortex and hypothalamus, all of which contribute to regulation of the rate and depth of respiration.

DORSAL RESPIRATORY GROUP OF NEURONS CONTROLS INSPIRATION AND RESPIRATORY RHYTHM

The dorsal respiratory group of neurons plays a fundamental role in the control of respiration and extends most of the length of the medulla. Most of its neurons are located in the *nucleus of the tractus solitarius* (NTS), although additional neurons in the adjacent reticular substance of the medulla also play important roles in respiratory control. The NTS is the sensory termination of the vagal and the glossopharyngeal nerves, which transmit sensory signals into the respiratory center from the following: (1) peripheral chemoreceptors; (2) baroreceptors; (3) receptors in the liver, pancreas, and multiple parts of the gastrointestinal tract; and (4) several types of receptors in the lungs.

Rhythmical Inspiratory Discharges From the Dorsal and Ventral Respiratory Groups. Despite extensive investigation, the mechanisms responsible for generation of the basic respiratory rhythm remain somewhat controversial. However, the dorsal respiratory group of neurons appears to be at least partly responsible for the basic rhythm of respiration. Even when all the peripheral nerves entering the medulla have been sectioned, and the brain stem has been transected above and below the medulla, this group of neurons still emits repetitive bursts of *inspiratory neuronal action potentials*. In primitive animals, neural networks have been found in which activity of one set of neurons excites a second set, which in turn inhibits the first. Then, after a period of time, the mechanism repeats itself, continuing throughout the life of the animal. In humans, similar networks of neurons are present within the medulla, including neurons of the dorsal respiratory group and adjacent areas of the medulla that together contribute to the basic rhythm of respiration.

A small region of the rostral ventral respiratory group, the *pre-Bötzinger complex*, contains spontaneously firing neurons that project to the dorsal respiratory group and the ventral respiratory group and contribute to the basic rhythm of respiration. Neurons with voltage-dependent pacemaker-like properties have been identified in the pre-Bötzinger complex, and respiratory rhythm generation is eliminated by removal of this region of the medulla. For these reasons, the pre-Bötzinger complex has been suggested to be a key component of the so-called respiratory *central pattern generator* and may be responsible for the activity of the dorsal respiratory group inspiratory neurons to produce the ramping activity, discussed next.

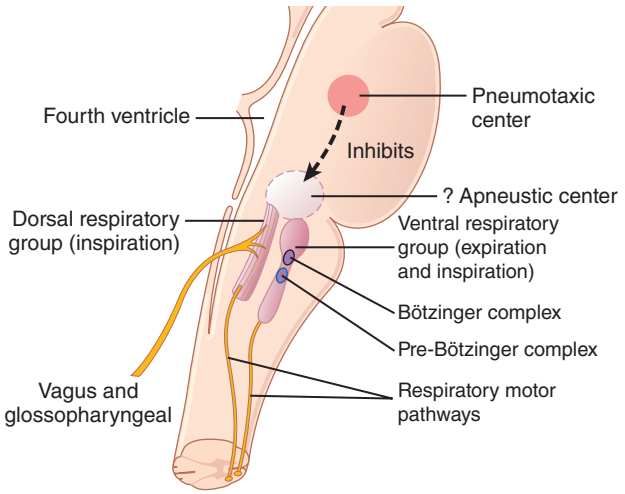

Figure 42.1 Organization of the respiratory center.

Inspiratory "Ramp" Signal. The nervous signal that is transmitted to the inspiratory muscles, mainly the diaphragm, is not an instantaneous burst of action potentials. Instead, it begins weakly and increases steadily in a ramp manner for about 2 seconds in normal respiration. It then ceases abruptly for approximately the next 3 seconds, which turns off the excitation of the diaphragm and allows elastic recoil of the lungs and chest wall to cause expiration. Next, the inspiratory signal begins again for another cycle; this cycle repeats again and again, with expiration occurring in between. Thus, the inspiratory signal is a *ramp signal*. The obvious advantage of the ramp is that it causes a steady increase in the volume of the lungs during inspiration, rather than inspiratory gasps.

Two qualities of the inspiratory ramp are controlled, as follows:

1. The *rate of increase of the ramp signal* is controlled so that during heavy respiration, the ramp increases rapidly and therefore fills the lungs rapidly.
2. The *limiting point at which the ramp suddenly ceases* is controlled and is the usual method for regulating the rate of respiration. That is, the earlier the ramp ceases, the shorter the duration of inspiration. This method also shortens the duration of expiration. Thus, the frequency of respiration is increased.

PNEUMOTAXIC CENTER LIMITS DURATION OF INSPIRATION AND INCREASES RESPIRATORY RATE

A *pneumotaxic center*, located dorsally in the *nucleus parabrachialis* of the upper pons, transmits signals to the inspiratory area. The primary effect of this center is to control the "switch-off" point of the inspiratory ramp, thereby controlling the duration of the filling phase of the lung cycle. When the pneumotaxic signal is strong, inspiration might last for as little as 0.5 second, thus filling the lungs only slightly; when the pneumotaxic signal is weak, inspiration might continue for 5 or more seconds, thus filling the lungs with much greater amounts of air.

The function of the pneumotaxic center is primarily to limit inspiration, which has a secondary effect of increasing the rate of breathing because limiting inspiration also shortens expiration and the entire period of each respiration. A strong pneumotaxic signal can increase the rate of breathing to 30 to 40 breaths/min, whereas a weak pneumotaxic signal may reduce the rate to only 3 to 5 breaths/min.

VENTRAL RESPIRATORY GROUP OF NEURONS—FUNCTIONS IN INSPIRATION AND EXPIRATION

Located in each side of the medulla, about 5 millimeters anterior and lateral to the dorsal respiratory group of neurons, is the *ventral respiratory group of neurons*, found in the *nucleus ambiguus* rostrally and the *nucleus retroambiguus* caudally. The function of this neuronal group differs from that of the dorsal respiratory group in several important ways:

1. The ventral respiratory group of neurons has an important function for inspiration and expiration. Although most of the ventral respiratory group neurons remain *inactive* during normal quiet respiration (*eupnea*), repetitive inspiratory signals from the pre-Bötzinger complex, as well as the dorsal respiratory group, are transmitted to the diaphragm during normal quiet breathing.
2. Signals from the *Bötzinger complex*, a group of neurons located rostral to the pre-Bötzinger complex, *inhibit* inspiration and contribute to switching from inspiration to expiration. After inspiration is inhibited, expiration normally results from passive elastic recoil of the lungs and thoracic cage. However, active expiration appears to have a distinct central pattern generator located in the region of the *retrotrapezoid nucleus*, which lies in the rostral medulla. Retrotrapezoid nucleus neurons are also a major nodal point for respiratory control of P_{CO_2} and H^+, responding vigorously to local increases in P_{CO_2} and H^+ and receiving chemosensory input from the carotid bodies.
3. The ventral respiratory group of neurons is especially important in providing the powerful expiratory signals to the abdominal muscles during very heavy expiration. Thus, this area operates more or less as an overdrive mechanism when high levels of pulmonary ventilation are required, especially during heavy exercise.

LUNG INFLATION SIGNALS LIMIT INSPIRATION—THE HERING-BREUER INFLATION REFLEX

In addition to the central nervous system respiratory control mechanisms operating entirely within the brain

stem, sensory nerve signals from the lungs also help control respiration. The muscular portions of the walls of the bronchi and bronchioles throughout the lungs contain *stretch receptors* that transmit signals through the *vagi* into the dorsal respiratory group of neurons when the lungs become overstretched. These signals affect inspiration in much the same way as signals from the pneumotaxic center; that is, when the lungs become overinflated, the stretch receptors activate a feedback response that "switches off" the inspiratory ramp and stops further inspiration. This mechanism is called the *Hering-Breuer inflation reflex*. This reflex also increases the rate of respiration, as is true for signals from the pneumotaxic center.

In humans, the Hering-Breuer reflex probably is not activated until the tidal volume increases to more than three times normal (>~1.5 L/breath). Therefore, this reflex appears to be mainly a protective mechanism for preventing excess lung inflation rather than an important factor in normal control of ventilation.

CONTROL OF OVERALL RESPIRATORY CENTER ACTIVITY

Up to this point, we have discussed mainly the basic mechanisms for causing inspiration and expiration, but it is also important to know how the intensity of the respiratory control signals is increased or decreased to match the ventilatory needs of the body. For example, during heavy exercise, the rates of O_2 usage and CO_2 formation are often increased to as much as 20 times normal, requiring commensurate increases in pulmonary ventilation. The major purpose of the rest of this chapter is to discuss this control of ventilation in accord with the respiratory needs of the body.

CHEMICAL CONTROL OF RESPIRATION

The ultimate goal of respiration is to maintain proper concentrations of O_2, CO_2, and H^+ in the tissues. Control of respiratory activity is therefore highly responsive to changes in each of these substances.

Excess CO_2 or excess H^+ in the blood mainly act directly on the respiratory center of the medulla, causing greatly increased strength of inspiratory and the expiratory motor signals to the respiratory muscles. Oxygen, in contrast, does not have a major *direct* effect on the respiratory center of the brain in controlling respiration. Instead, it acts almost entirely on peripheral *chemoreceptors* located in the *carotid* and *aortic bodies*, and these chemoreceptors in turn transmit appropriate nervous signals to the respiratory center for control of respiration.

DIRECT CONTROL OF RESPIRATORY CENTER ACTIVITY BY CO_2 AND H^+

Chemosensitive Area of the Respiratory Center Beneath the Medulla's Ventral Surface. We have mainly discussed three areas of the respiratory center—the dorsal respiratory group of neurons, the ventral respiratory group, and the pneumotaxic center. Although neurons throughout the brain stem appear to be *chemosensitive* and are involved in the detection of CO_2 and H^+, neurons in the *ventrolateral medulla* and *retrotrapezoid nucleus* are especially important. The retrotrapezoid nuclei are located bilaterally, lying only 0.2 millimeter beneath the ventral surface of the rostral part of the medulla. This area is highly sensitive to changes in either blood P_{CO_2} or H^+ concentration, and it in turn excites the other portions of the respiratory center.

Excitation of the Chemosensitive Neurons By H^+. The sensor neurons in the chemosensitive area are especially excited by H^+; in fact, H^+ may be the primary direct stimulus for these neurons. However, H^+ ions do not easily cross the blood–brain barrier. For this reason, changes in H^+ concentration in the blood have considerably less effect in stimulating the chemosensitive neurons than changes in blood CO_2, even though CO_2 is believed to stimulate these neurons secondarily by changing the H^+ concentration, as explained in the following section.

CO_2 Indirectly Stimulates the Chemosensitive Neurons. Although CO_2 has little direct effect in stimulating the neurons in the chemosensitive area, it does have a potent indirect effect. It has this effect by reacting with water of the tissues to form carbonic acid, which dissociates into H^+ and HCO_3^-; the H^+ then has a potent direct stimulatory effect on respiration. These reactions are shown in **Fig. 42.2**.

Why does blood CO_2 have a more potent effect in stimulating the chemosensitive neurons than blood H^+? The answer is that the blood–brain barrier is not very permeable to H^+, but CO_2 passes through this barrier almost as if the barrier did not exist. Consequently, whenever the blood

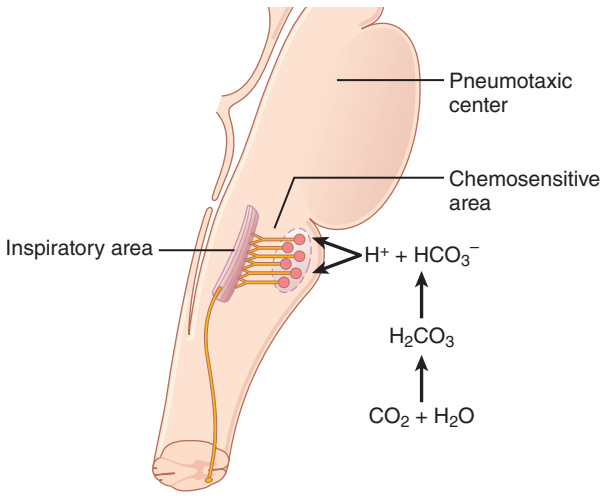

Figure 42.2 Stimulation of the *brain stem inspiratory* area by signals from the *chemosensitive area* located bilaterally in the medulla, lying only a fraction of a millimeter beneath the ventral medullary surface. Note also that H^+ stimulates the chemosensitive area, but carbon dioxide in the fluid gives rise to most of the H^+.

P_{CO_2} increases, so does the P_{CO_2} of the medulla interstitial fluid and the cerebrospinal fluid. In both these fluids, CO_2 immediately reacts with water to form new H^+. Thus, paradoxically, more H^+ is released into the respiratory chemosensitive sensory area of the medulla when the blood CO_2 concentration increases than when the blood H^+ concentration increases. For this reason, respiratory center activity is increased very strongly by changes in blood CO_2, a fact that we subsequently discuss quantitatively.

Attenuated Stimulatory Effect of CO_2 After 1 to 2 Days. Excitation of the respiratory center by CO_2 is great the first few hours after the blood CO_2 increases, but then it gradually declines over the next 1 to 2 days, decreasing to about one-fifth the initial effect. Part of this decline results from renal readjustment of the H^+ concentration in the circulating blood back toward normal after the CO_2 increases the H^+ concentration. The kidneys achieve this readjustment by increasing the blood HCO_3^-, which binds with H^+ in the blood and cerebrospinal fluid to reduce their concentrations. But, even more importantly, over a period of hours, the HCO_3^- also slowly diffuses through the blood–brain and blood–cerebrospinal fluid barriers and combines directly with H^+ adjacent to the respiratory neurons as well, thus reducing the H^+ back to near normal. A change in blood CO_2 concentration therefore has a potent *acute* effect on controlling respiratory drive but only a weak *chronic* effect after a few days' adaptation.

Quantitative Effects of Blood P_{CO_2} and H^+ Concentration on Alveolar Ventilation. **Fig. 42.3** shows quantitatively the approximate effects of blood P_{CO_2} (red curve) and blood pH (blue curve) on alveolar ventilation. Note especially the marked increase in ventilation caused by an increase in P_{CO_2} *in the normal range* between 35 and 75 mm Hg, which demonstrates the tremendous effect that CO_2 changes have in controlling respiration. By contrast, the change in respiration in the normal blood pH range, which is between 7.3 and 7.5, is less than 10% as great.

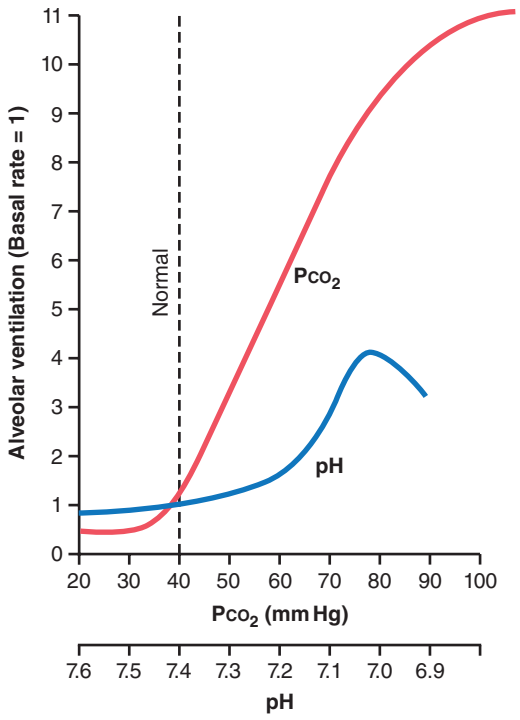

Figure 42.3 Effects of increased arterial blood P_{CO_2} (*red curve*) and decreased arterial pH (increased H^+ concentration, *blue curve*) on the rate of alveolar ventilation.

Changes in O_2 Have Little Direct Effect on Control of the Brain Respiratory Center. Changes in O_2 concentration have virtually no *direct* effect on the respiratory center itself to alter respiratory drive—although O_2 changes do have an indirect effect, acting through the peripheral chemoreceptors, as explained in the next section.

We learned in Chapter 41 that the hemoglobin-oxygen buffer system delivers almost exactly normal amounts of O_2 to the tissues, even when the pulmonary P_{O_2} changes from a value as low as 60 mm Hg up to a value as high as 1000 mm Hg. Therefore, except under special conditions, adequate delivery of O_2 can occur despite changes in lung ventilation ranging from slightly below half-normal to as high as 20 or more times normal. This is not true for CO_2 because both the blood and tissue P_{CO_2} change inversely with the rate of pulmonary ventilation; thus, the processes of animal evolution have made CO_2 the major controller of respiration, not O_2.

Yet, for those special conditions in which the tissues get into trouble for lack of O_2, the body has a special mechanism for respiratory control located in the peripheral chemoreceptors, outside the brain respiratory center. This mechanism responds when the blood O_2 falls too low, mainly below a P_{O_2} of 70 mm Hg, as explained in the next section.

PERIPHERAL CHEMORECEPTOR SYSTEM—ROLE OF OXYGEN IN RESPIRATORY CONTROL

In addition to control of respiratory activity by the brain respiratory center, another mechanism, the *peripheral chemoreceptor system*, is available for controlling respiration (**Fig. 42.4**). Special nervous *chemoreceptors* are located in several areas outside the brain. They are especially important for detecting changes in O_2 in the blood, although they also respond to a lesser extent to changes in CO_2 and H^+ concentrations. The chemoreceptors transmit nervous signals to the respiratory center in the brain to help regulate respiratory activity.

Most of the chemoreceptors are in the *carotid bodies*. However, a few are also in the *aortic bodies*, shown in the lower part of **Fig. 42.4**, and a very few are located elsewhere in association with other arteries of the thoracic and abdominal regions.

The *carotid bodies* are located bilaterally in the bifurcations of the common carotid arteries. Their afferent nerve fibers pass through Hering nerves to the *glossopharyngeal nerves* and then to the dorsal respiratory area of the

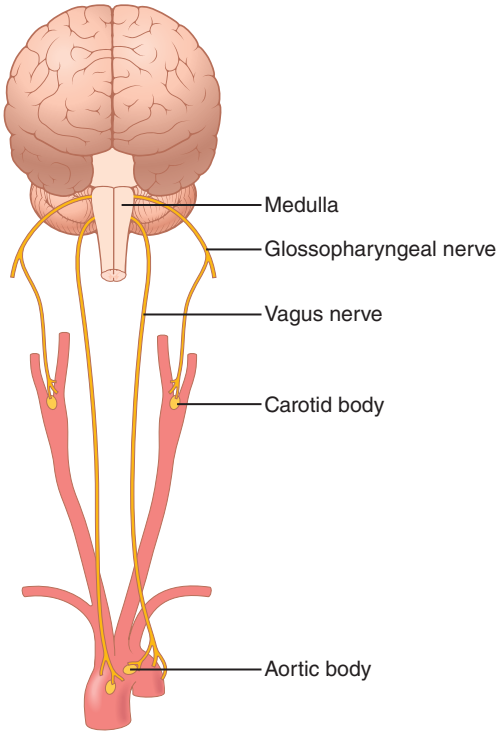

Figure 42.4 Respiratory control by peripheral chemoreceptors in the carotid and aortic bodies.

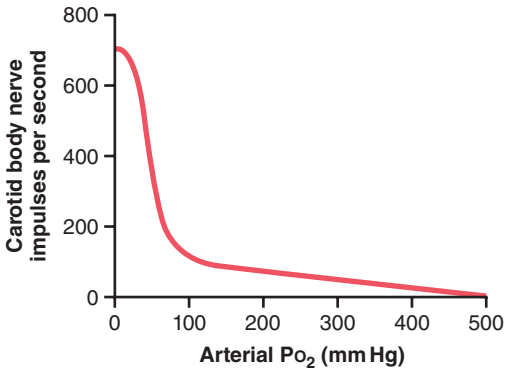

Figure 42.5 Effect of arterial Po_2 on impulse rate from the carotid body.

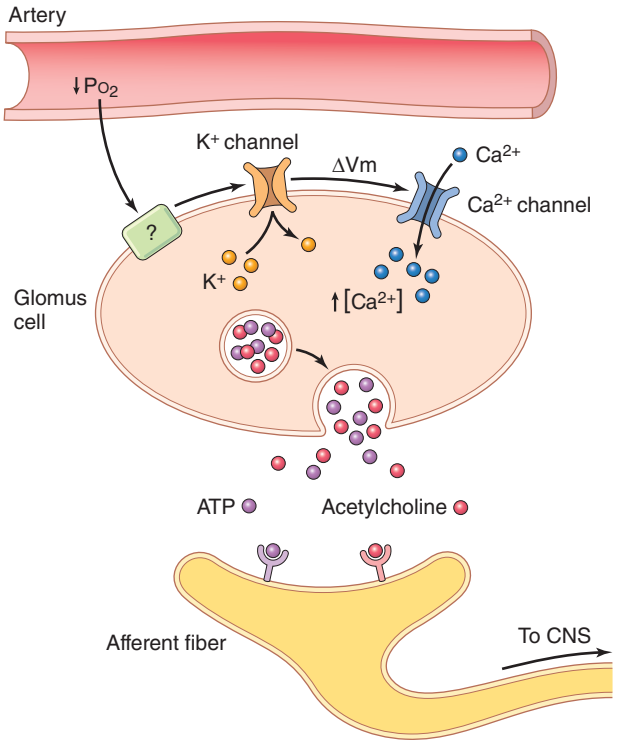

Figure 42.6 Carotid body glomus cell oxygen sensing. When the Po_2 decreases below around 60 mm Hg, potassium channels close, causing cell depolarization, opening of calcium channels, and increased cytosolic calcium ion concentration. This stimulates transmitter release (adenosine triphosphate [ATP] is likely the most important), which activates afferent fibers that send signals to the central nervous system (CNS) and stimulate respiration. The mechanisms whereby low Po_2 influences potassium channel activity are still unclear. *ΔVm*, Change in membrane voltage.

medulla. The *aortic bodies* are located along the arch of the aorta; their afferent nerve fibers pass through the *vagi*, also to the dorsal medullary respiratory area.

Each of the chemoreceptor bodies receives its own special blood supply through a minute artery directly from the adjacent arterial trunk. Blood flow through these bodies is extremely high, 20 times the weight of the bodies themselves each minute. Therefore, the percentage of O_2 removed from the flowing blood is virtually zero, which means that *the chemoreceptors are exposed at all times to arterial blood*, not venous blood, and their Po_2 values are arterial Po_2 values.

Stimulation of the Chemoreceptors By Decreased Arterial Po_2. When the oxygen concentration in the arterial blood falls below normal, the chemoreceptors become strongly stimulated. This effect is demonstrated in **Fig. 42.5**, which shows the effect of different levels of *arterial* Po_2 on the rate of nerve impulse transmission from a carotid body. Note that the impulse rate is particularly sensitive to changes in arterial Po_2 in the range of 60 mm Hg down to 30 mm Hg, a range in which hemoglobin saturation with oxygen decreases rapidly.

The carotid and aortic bodies have multiple, highly characteristic glandular-like cells, called *glomus cells*, that synapse directly or indirectly with the nerve endings. Current evidence suggests that these glomus cells function as the chemoreceptors and then stimulate the nerve endings (**Fig. 42.6**). Glomus cells are *O_2-sensitive and send signals to membrane ion channels, including potassium channels that are inactivated when blood Po_2 decreases markedly.* This inactivation causes the cell to depolarize, which in turn opens *voltage-gated calcium channels* and increases intracellular calcium ion concentration. The increased number of calcium ions stimulates release of a neurotransmitter that activates afferent neurons and sends signals to the central nervous system to stimulate respiration. *Adenosine triphosphate* (ATP) appears to be the key excitatory neurotransmitter released by the carotid glomus cells during hypoxia, although dopamine or acetylcholine may also serve as glomus cell neurotransmitters.

Increased CO_2 and H^+ Concentration Stimulates the Chemoreceptors. An increase in CO_2 or H^+ concentration also excites the chemoreceptors and, in this way, indirectly increases respiratory activity. However, the direct effects of both these factors in the respiratory center are much more powerful than their effects mediated through the chemoreceptors (about seven times as powerful). One important difference between the peripheral and central effects of CO_2 is that stimulation via the peripheral chemoreceptors occurs as much as five times as rapidly as central stimulation. Therefore, the peripheral chemoreceptors are especially important in increasing the rapidity of response to CO_2, for example, at the onset of exercise.

Effect of Low Arterial P_{O_2} to Stimulate Alveolar Ventilation When Arterial CO_2 and H^+ Concentrations Remain Normal

Fig. 42.7 shows the effect of low arterial P_{O_2} on alveolar ventilation when the P_{CO_2} and H^+ concentrations are kept constant at their normal levels. In other words, in this figure, only the ventilatory drive caused by low O_2 on the chemoreceptors is active. **Fig. 42.7** shows almost no effect on ventilation as long as the arterial P_{O_2} remains greater than 100 mm Hg. However, at pressures lower than 100 mm Hg, ventilation approximately doubles when the arterial P_{O_2} falls to 60 mm Hg and can increase as much as 5-fold at very low P_{O_2} values. Under these conditions, low arterial P_{O_2} drives the ventilatory process quite strongly.

Because the effect of hypoxia on ventilation is modest when P_{O_2} is greater than 60 to 80 mm Hg, the P_{CO_2} and H^+ responses are mainly responsible for regulating ventilation in healthy humans at sea level.

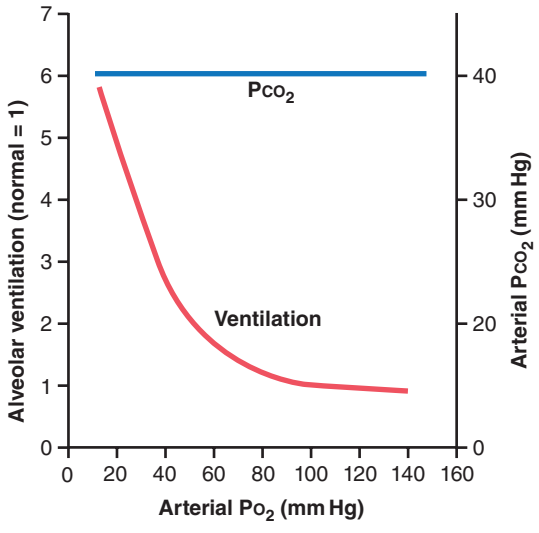

Figure 42.7 The *lower red curve* demonstrates the effect of different levels of arterial P_{O_2} on alveolar ventilation, showing a 6-fold increase in ventilation as the P_{O_2} decreases from the normal level of 100 mm Hg to 20 mm Hg. The *upper blue line* shows that the arterial P_{CO_2} was kept at a constant level during the measurements of this study; pH also was kept constant.

Chronic Breathing of Low O_2 Greatly Stimulates Respiration—The Phenomenon of "Acclimatization"

When mountain climbers ascend a mountain slowly, over a period of days rather than a period of hours, they breathe much more deeply and therefore can withstand far lower atmospheric O_2 concentrations than when they ascend rapidly. This phenomenon is called *acclimatization*.

The reason for acclimatization is that within 2 to 3 days, the respiratory center in the brain stem loses about 80% of its sensitivity to changes in P_{CO_2} and H^+. Therefore, the excess ventilatory blow-off of CO_2 that normally would inhibit an increase in respiration fails to occur, and low O_2 can drive the respiratory system to a much higher level of alveolar ventilation than under acute conditions. Instead of the 70% increase in ventilation that might occur after acute exposure to low O_2, the alveolar ventilation often increases by 400% to 500% after 2 to 3 days of low O_2, which helps immensely in supplying additional O_2 to the mountain climber.

Composite Effects of P_{CO_2}, pH, and P_{O_2} on Alveolar Ventilation

Fig. 42.8 provides an overview of the manner in which P_{O_2}, P_{CO_2}, and pH together affect alveolar ventilation. To understand this diagram, first observe the four red curves. These curves were recorded at different levels of arterial P_{O_2}—40, 50, 60, and 100 mm Hg. For each of these curves, the P_{CO_2} was changed from lower to higher levels. Thus, this family of red curves represents the combined effects of alveolar P_{CO_2} and P_{O_2} on ventilation.

Now observe the blue curves. Whereas the red curves were measured at a blood pH of 7.4, the blue curves were measured at a pH of 7.3. We now have two families of curves representing the combined effects of P_{CO_2} and P_{O_2} on ventilation at two different pH values. Still other

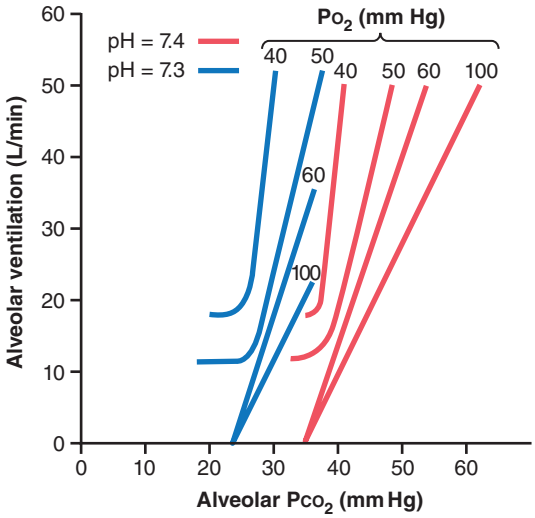

Figure 42.8 Composite diagram showing the interrelated effects of P_{CO_2}, P_{O_2}, and pH on alveolar ventilation. *(Data from Cunningham DJC, Lloyd BB.* The Regulation of Human Respiration. *Oxford: Blackwell Scientific; 1963.)*

families of curves would be displaced to the right at higher pH and displaced to the left at lower pH. Therefore, using this diagram, one can predict the level of alveolar ventilation for combinations of alveolar P_{CO_2}, alveolar P_{O_2}, and arterial pH.

REGULATION OF RESPIRATION DURING EXERCISE

During strenuous exercise, O_2 consumption and CO_2 formation can increase as much as 20-fold. Yet, in healthy athletes, as illustrated in **Fig. 42.9**, alveolar ventilation ordinarily increases almost exactly in step with the increased level of oxygen metabolism, and the arterial P_{O_2}, P_{CO_2}, and pH remain *almost exactly normal*.

Measurements of arterial P_{CO_2}, pH, and P_{O_2} show that none of these values become abnormal enough to stimulate respiration as vigorously as observed during strenuous exercise. Therefore, what causes intense ventilation during exercise? At least one effect seems to be predominant. The brain, on transmitting motor impulses to the exercising muscles, is believed to transmit collateral impulses into the brain stem at the same time to excite the respiratory center. This action is analogous to the stimulation of the vasomotor center of the brain stem during exercise that causes a simultaneous increase in arterial pressure.

When a person begins to exercise, a large share of the total increase in ventilation begins almost immediately on initiation of the exercise, before any blood chemicals have had time to change. It is likely that most of the increase in respiration results from neurogenic signals transmitted directly into the brain stem respiratory center at the same time that signals go to the body muscles to cause muscle contraction.

Interrelationship Between Chemical and Nervous Factors in Controlling Respiration During Exercise. When a person exercises, direct nervous signals presumably stimulate the respiratory center by *almost* the proper amount to supply the extra O_2 required for exercise and to blow off extra CO_2. Occasionally, however, the nervous respiratory control signals are too strong or too weak. Chemical factors then play a significant role in bringing about the final adjustment of respiration required to keep the O_2, CO_2, and H^+ concentrations of the body fluids as nearly normal as possible.

This process is demonstrated in **Fig. 42.10**. The lower curve shows changes in alveolar ventilation during 1 minute of exercise, and the upper curve shows changes in arterial P_{CO_2}. Note that at the onset of exercise, the alveolar ventilation increases almost instantaneously, without an initial increase in arterial P_{CO_2}. In fact, this increase in ventilation is usually great enough so that at first it actually *decreases* arterial P_{CO_2} below normal, as shown in the figure. The presumed reason why the ventilation forges ahead of the buildup of blood CO_2 is that the brain provides an "anticipatory" stimulation of respiration at the onset of exercise, causing extra alveolar ventilation even before it is necessary. However, after 30 to 40 seconds, the amount of CO_2 released into the blood from the active muscles approximately matches the increased rate of ventilation, and the arterial P_{CO_2} returns essentially to normal, even as the exercise continues. This is shown toward the end of 1 minute of exercise in the figure.

Fig. 42.11 summarizes the control of respiration during exercise in another way, this time more quantitatively. The lower curve of this figure shows the effect of different levels of arterial P_{CO_2} on alveolar ventilation when the body is at rest—that is, not exercising. The upper curve shows the approximate shift of this ventilatory curve caused by neurogenic drive from the respiratory center that occurs during heavy exercise. The points indicated on the two curves show the arterial P_{CO_2} first in the resting state and then in the exercising state. Note in both cases that the P_{CO_2} is at the normal level of 40 mm Hg. In other words, the neurogenic factor shifts the curve about

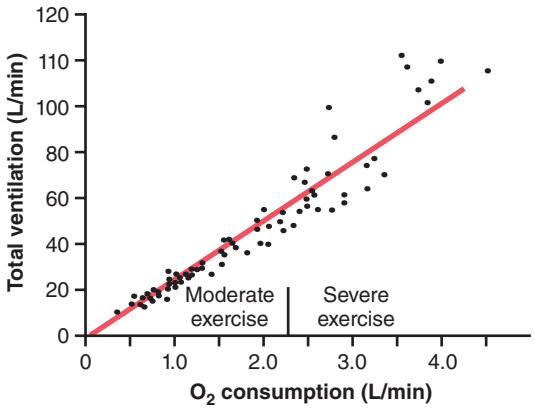

Figure 42.9 Effect of moderate and severe exercise on oxygen consumption and ventilatory rate. *(From Gray JS.* Pulmonary Ventilation and Its Physiological Regulation. *Springfield, IL: Charles C Thomas; 1950.)*

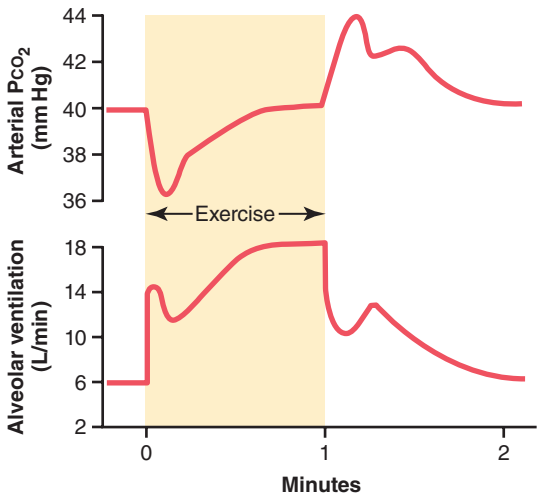

Figure 42.10 Changes in alveolar ventilation (bottom curve) and arterial P_{CO_2} (top curve) during a 1-minute period of exercise and also after termination of exercise. *(Drawn from data in Bainton CR. Effect of speed vs. grade and shivering on ventilation in dogs during active exercise.* J Appl Physiol. *1972;33:778-787.)*

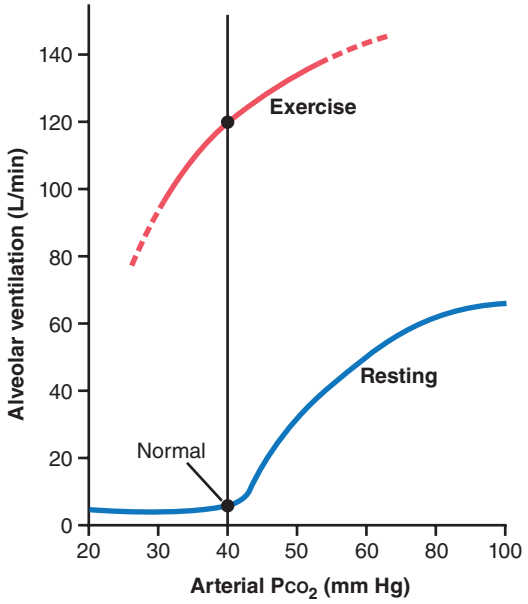

Figure 42.11 Approximate effect of maximum exercise in an athlete to shift the alveolar P_{CO_2}–ventilation response curve to a level much higher than normal. The shift, believed to be caused by neurogenic factors, is almost exactly the right amount to maintain arterial P_{CO_2} at the normal level of 40 mm Hg in the resting state and during heavy exercise.

20-fold in the upward direction, so ventilation almost matches the rate of CO_2 release, thus keeping arterial P_{CO_2} near its normal value. The upper curve of **Fig. 42.11** also shows that if during exercise the arterial P_{CO_2} does change from its normal value of 40 mm Hg, it has an extra stimulatory effect on ventilation at a P_{CO_2} value greater than 40 mm Hg and a depressant effect at a P_{CO_2} value less than 40 mm Hg.

Neurogenic Control of Ventilation During Exercise May Be Partly a Learned Response. Many experiments suggest that the brain's ability to shift the ventilatory response curve during exercise, as shown in **Fig. 42.11**, is at least partly a *learned* response. That is, with repeated periods of exercise, the brain becomes progressively more able to provide the proper signals required to keep the blood P_{CO_2} at its normal level. Also, the cerebral cortex appears to be involved in this learning because experiments that block only the cortex also block the learned response.

Other Factors That Affect Respiration

Effect of Irritant Receptors in the Airways. The epithelium of the trachea, bronchi, and bronchioles is supplied with sensory nerve endings called *pulmonary irritant receptors* (or *airway nociceptors*) that are stimulated by many factors, including (1) irritants, such as capsaicin found in chili peppers or acid from stomach contents; (2) respiratory pathogens and inflammatory mediators, such as cytokines or bradykinin; and (3) mechanical stimuli that occur, for example, with accumulation of airway mucus or inhalation of particulate matter. These receptors initiate coughing or sneezing, as discussed in Chapter 38. They may also cause bronchial constriction in persons with diseases such as asthma and emphysema.

The receptors involved in transducing the irritant stimuli include *G-protein coupled receptors*, as well as *transient receptor potential (TRP) channels*, a large family of ion channel receptors on respiratory sensory neurons.

Function of Lung J Receptors. A few sensory nerve endings have been described in the alveolar walls in *juxtaposition* to the pulmonary capillaries—hence, the name *J receptors*. They are stimulated especially when the pulmonary capillaries become engorged with blood or when pulmonary edema occurs in conditions such as congestive heart failure. Although the functional role of the J receptors is not clear, their excitation may give the person a feeling of *dyspnea* (shortness of breath) and stimulate increased respiration rate.

Brain Edema Depresses the Respiratory Center. The activity of the respiratory center may be depressed or even inactivated by acute brain edema resulting from a brain concussion. For example, the head might be struck against some solid object, after which the damaged brain tissues swell, compressing the cerebral arteries against the cranial vault and thus partially blocking the cerebral blood supply.

Occasionally, respiratory depression resulting from brain edema can be relieved temporarily by intravenous injection of a hypertonic solution, such as a highly concentrated mannitol solution. These solutions osmotically remove some of the fluids of the brain, thus relieving intracranial pressure and sometimes reestablishing respiration within a few minutes.

Overdosage of Anesthetics and Narcotics. Perhaps the most prevalent cause of respiratory depression and respiratory arrest is overdosage with anesthetics or narcotics. For example, sodium pentobarbital depresses the respiratory center considerably more than many other anesthetics, such as halothane. At one time, morphine was used as an anesthetic, but this drug is now used only as an adjunct to anesthetics because it greatly depresses the respiratory center while having less ability to anesthetize the cerebral cortex.

Because of their capacity to cause respiratory depression, opioids are responsible for a high proportion of fatal drug overdoses around the world. In the United States, over 100,000 people die each year from drug overdose, largely due to respiratory arrest.

Periodic Breathing. An abnormality of respiration called *periodic breathing* occurs in several disease conditions. The person breathes deeply for a short interval and then breathes slightly or not at all for an additional interval, with the cycle repeating itself over and over. One type of periodic breathing, *Cheyne-Stokes breathing*, is characterized by slowly waxing and waning respiration occurring about every 40 to 60 seconds, as illustrated in **Fig. 42.12**.

Basic Mechanism of Cheyne-Stokes Breathing. When a person overbreathes, thus blowing off too much CO_2 from the pulmonary blood while at the same time increasing blood O_2, it takes several seconds before the changed pulmonary blood can be transported to the brain and inhibit

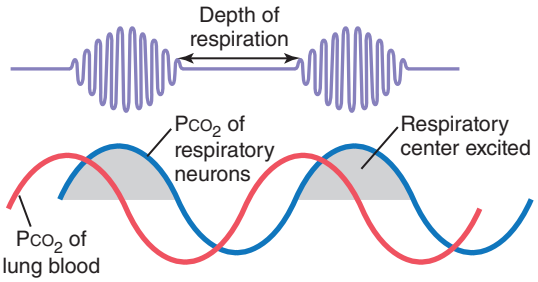

Figure 42.12 Cheyne-Stokes breathing, showing changing P_{CO_2} in the pulmonary blood *(red line)* and delayed changes in the P_{CO_2} of the fluids of the respiratory center *(blue line)*.

the excess ventilation. By this time, the person has already overventilated for an extra few seconds. Therefore, when the overventilated blood finally reaches the brain respiratory center, the center becomes depressed to an excessive amount, at which point the opposite cycle begins—that is, CO_2 increases and O_2 decreases in the alveoli. Again, it takes a few seconds before the brain can respond to these new changes. When the brain does respond, the person breathes hard once again and the cycle repeats.

The basic cause of Cheyne-Stokes breathing occurs in everyone. However, under normal conditions, this mechanism is highly damped. That is, the fluids of the blood and respiratory center control areas have large amounts of dissolved and chemically bound CO_2 and O_2. Therefore, the lungs normally do not build up enough extra CO_2 or depress the O_2 sufficiently in a few seconds to cause the next cycle of the periodic breathing. However, under two separate conditions, the damping factors can be overridden, and Cheyne-Stokes breathing occurs:

1. When a *long delay occurs for transport of blood from the lungs to the brain*, changes in CO_2 and O_2 in the alveoli can continue for many more seconds than usual. Under these conditions, the storage capacities of the alveoli and pulmonary blood for these gases are exceeded; then, after a few more seconds, the periodic respiratory drive becomes extreme and Cheyne-Stokes breathing begins. This type of Cheyne-Stokes breathing often occurs in patients with *severe cardiac failure* because blood flow is slow, thus delaying the transport of blood gases from the lungs to the brain. In patients with chronic heart failure, Cheyne-Stokes breathing can sometimes occur on and off for months.
2. Another cause of Cheyne-Stokes breathing is *increased negative feedback gain* in the respiratory control areas, which means that a change in blood CO_2 or O_2 causes a far greater change in ventilation than normal. For example, instead of the normal 2- to 3-fold increase in ventilation that occurs when the P_{CO_2} rises by 3 mm Hg, the same rise of P_{CO_2} might increase ventilation by 10- to 20-fold. The brain feedback tendency for periodic breathing is now strong enough to cause Cheyne-Stokes breathing without extra blood flow delay between the lungs and brain. This type of Cheyne-Stokes breathing occurs mainly in patients with *damage to the respiratory centers of the brain*. The brain damage often turns off the respiratory drive entirely for a few seconds, and then an extra-intense increase in blood CO_2 turns it back on with great force. Cheyne-Stokes breathing of this type is frequently a prelude to death from brain malfunction.

Typical changes in pulmonary and respiratory center P_{CO_2} during Cheyne-Stokes breathing are illustrated in **Fig. 42.12**. Note that the P_{CO_2} of the pulmonary blood changes *in advance* of the P_{CO_2} of the respiratory neurons. However, the depth of respiration corresponds with the P_{CO_2} in the brain, not with the P_{CO_2} in the pulmonary blood where the ventilation is occurring.

Sleep Apnea

The term *apnea* means absence of spontaneous breathing. Occasional apneas occur during normal sleep, but in persons with *sleep apnea*, the frequency and duration are greatly increased, with episodes of apnea lasting for 10 seconds or longer and occurring 300 to 500 times each night. Sleep apneas can be caused by obstruction of the upper airways, especially the pharynx, or by an impaired central nervous system respiratory drive.

Obstructive Sleep Apnea Is Caused By Blockage of the Upper Airway. The muscles of the pharynx normally keep this passage open to allow air to flow into the lungs during inspiration. During sleep, these muscles usually relax, but the airway passage remains open enough to permit adequate airflow. Some people have an especially narrow passage, and relaxation of these muscles during sleep causes the pharynx to close completely so that air cannot flow into the lungs.

In persons with sleep apnea, loud *snoring* and *labored breathing* occur soon after falling asleep. The snoring proceeds, often becoming louder, and is then interrupted by a long silent period during which no breathing (apnea) occurs. These periods of apnea result in significant decreases in P_{O_2} and increases in P_{CO_2}, which greatly stimulate respiration. This stimulation, in turn, causes sudden attempts to breathe, which result in loud snorts and gasps followed by snoring and repeated episodes of apnea. The periods of apnea and labored breathing are repeated several hundred times during the night, resulting in fragmented, restless sleep. Therefore, patients with sleep apnea usually have excessive daytime *drowsiness*, as well as other disorders, including increased sympathetic activity, high heart rate, pulmonary and systemic hypertension, and a greatly elevated risk for cardiovascular disease.

Obstructive sleep apnea often occurs in persons who are older and/or obese and in whom there is increased fat deposition in the soft tissues of the pharynx or compression of the pharynx due to excessive fat masses in the neck. In some individuals, sleep apnea may be associated with nasal obstruction, a very large tongue, enlarged tonsils, or certain shapes of the palate that greatly increase resistance to the flow of air to the lungs during inspiration. The most common treatments of obstructive sleep apnea include the following: (1) surgery to remove excess fat tissue at the back of the throat (a procedure called *uvulopalatopharyngoplasty*), to remove enlarged tonsils or adenoids, or to create an opening in the trachea (tracheostomy) to bypass the obstructed airway during sleep; and (2) nasal ventilation with *continuous positive airway pressure* (CPAP).

"Central" Sleep Apnea Occurs When the Neural Drive to Respiratory Muscles Is Transiently Abolished. In a few

persons with sleep apnea, the central nervous system drive to the ventilatory muscles transiently ceases. Disorders that can cause cessation of the ventilatory drive during sleep include *damage to the central respiratory centers* or *abnormalities of the respiratory neuromuscular apparatus*. Patients affected by central sleep apnea may have decreased ventilation even when they are awake, although they are fully capable of normal voluntary breathing. During sleep, their breathing disorders usually worsen, resulting in more frequent episodes of apnea that decrease P_{O_2} and increase P_{CO_2} until a critical level is reached that eventually stimulates respiration. These transient instabilities of respiration cause restless sleep and clinical features similar to those observed in people with obstructive sleep apnea.

In most patients with central sleep apnea the cause is unknown, although instability of the respiratory drive can result from strokes or other disorders that make the respiratory centers of the brain less responsive to the stimulatory effects of CO_2 and H^+. Patients with this disease are extremely sensitive to even small doses of sedatives or narcotics, which further reduce the responsiveness of the respiratory centers to the stimulatory effects of CO_2. Medications that stimulate the respiratory centers can sometimes be helpful, but ventilation with CPAP at night is usually necessary.

In some cases, sleep apnea may be caused by a combination of obstructive and central mechanisms. This "mixed" type of sleep apnea is estimated to account for approximately 15% of all sleep apnea cases, whereas pure "central" sleep apnea accounts for less than 1% of cases. The most common cause of sleep apnea is obstruction of the upper airway.

Voluntary Control of Respiration.

Thus far, we have discussed mainly the involuntary system for control of respiration. However, we all know that respiration can be controlled voluntarily for short periods and that a person can hyperventilate or hypoventilate to such an extent that serious derangements in P_{CO_2}, pH, and P_{O_2} can occur in the blood. In fact, the world record for duration of voluntary breath-holding (apnea) under static resting conditions (and not hyperventilating with pure oxygen before the attempt) is reported to be 11 minutes and 54 seconds. Hyperventilation with pure oxygen and expelling large amounts of CO_2 before the apnea attempt has permitted individuals to hold their breath underwater for over 24 minutes. Ultra-elite apnea competitors are able to suppress respiratory urges to the point where oxygen saturations fall to as low as about 50%, and unconsciousness limits the duration of breath-holding.

CHAPTER 43

Respiratory Insufficiency—Pathophysiology, Diagnosis, Oxygen Therapy

Diagnosis and treatment of most respiratory disorders depend heavily on understanding the basic physiological principles of respiration and gas exchange. Some respiratory diseases result from inadequate ventilation. Others are caused by abnormalities of diffusion through the pulmonary membrane or abnormal blood transport of gases between the lungs and tissues. Therapy is often entirely different for these diseases, so it is not satisfactory simply to make a diagnosis of "respiratory insufficiency."

METHODS FOR STUDYING RESPIRATORY ABNORMALITIES

In the previous few chapters, we discussed several methods for studying respiratory abnormalities, including measuring vital capacity, tidal air, functional residual capacity, dead space, physiological shunt, and physiological dead space. This array of measurements is only part of the armamentarium of the clinical pulmonary physiologist. Some other tools are described here.

STUDY OF BLOOD GASES AND BLOOD pH

Among the most fundamental of all tests of pulmonary performance are determinations of the blood partial pressure of oxygen (P_{O_2}), carbon dioxide (CO_2), and pH. It is often important to make these measurements rapidly as an aid in determining appropriate therapy for acute respiratory distress or acute abnormalities of acid–base balance. The following simple and rapid methods have been developed to make these measurements within minutes, using no more than a few drops of blood.

Determination of Blood pH. Blood pH is measured using pH meters, which usually have a glass electrode and a reference electrode contained within a single miniaturized probe. The pH meter measures the difference in electrical potential (voltage) between the glass pH electrode and the reference electrode. The voltage generated is amplified and displayed digitally as pH units. The pH meter is calibrated with solutions of known pH.

Determination of Blood CO_2. A glass electrode pH meter can also be used to determine blood CO_2. When a weak solution of sodium bicarbonate is exposed to CO_2 gas, the CO_2 dissolves in the solution until an equilibrium state is reached. In this equilibrium state, the pH of the solution is a function of the CO_2 and bicarbonate ion (HCO_3^-) concentrations in accordance with the Henderson-Hasselbalch equation explained in Chapter 31:

$$pH = 6.1 + \log \frac{HCO_3^-}{CO_2}$$

When the glass electrode is used to measure CO_2 in blood, a miniature glass electrode is surrounded by a thin plastic membrane. A solution of sodium bicarbonate of known concentration is in the space between the electrode and plastic membrane. Blood is then superfused onto the outer surface of the plastic membrane, allowing CO_2 to diffuse from the blood into the bicarbonate solution. Only a drop or so of blood is required. Next, the pH is measured by the glass electrode, and the CO_2 is calculated using the formula that was previously provided.

Determination of Blood P_{O_2}. The concentration of O_2 in a fluid can be measured by a technique called *polarography*. Electric current is made to flow between a small negative electrode and the solution. If the voltage of the electrode is more than −0.6 volt different from the voltage of the solution, O_2 will deposit on the electrode. Furthermore, the rate of current flow through the electrode will be directly proportional to the concentration of O_2 (and therefore to P_{O_2} as well). In practice, a negative platinum electrode with a surface area of about 1 square millimeter is used, and this electrode is separated from the blood by a thin plastic membrane that allows diffusion of O_2 but not diffusion of proteins or other substances that will "poison" the electrode.

Often, all three of the measuring devices for pH, CO_2, and P_{O_2} are built into the same apparatus, and all these measurements can be made within a minute or so using a single droplet-sized sample of blood. Thus, changes in the blood gas levels and pH can be followed almost moment by moment at the bedside.

MEASUREMENT OF MAXIMUM EXPIRATORY FLOW

In many respiratory diseases, particularly in asthma, the resistance to airflow becomes especially great during

expiration, sometimes causing tremendous difficulty in breathing. This condition has led to the concept called *maximum expiratory flow*, which can be defined as follows. When a person expires with great force, the expiratory airflow reaches a maximum flow beyond which the flow cannot be increased any more, even with greatly increased additional force. This is the maximum expiratory flow. The maximum expiratory flow is much greater when the lungs are filled with a large volume of air than when they are almost empty. These principles can be understood by referring to **Fig. 43.1**.

Fig. 43.1A shows the effect of increased pressure applied to the outsides of the alveoli and air passageways caused by compressing the chest cage. The arrows indicate that the same pressure compresses the outsides of the alveoli and bronchioles. Therefore, not only does this pressure force air from the alveoli toward the bronchioles, but it also tends to collapse the bronchioles at the same time, which will oppose movement of air to the exterior. Once the bronchioles have almost completely collapsed, further expiratory force can still increase the alveolar pressure greatly, but it also increases the degree of bronchiolar collapse and airway resistance by an equal amount, thus preventing further increase in flow. Therefore, beyond a critical degree of expiratory force, a maximum expiratory flow has been reached.

Fig. 43.1B shows the effect of different degrees of lung collapse (and therefore also of bronchiolar collapse) on the maximum expiratory flow. The curve recorded in this section shows the maximum expiratory flow at all levels of lung volume after a healthy person first inhales as much air as possible and then expires with maximum expiratory effort until they can expire at no greater rate. Note that the person quickly reaches a *maximum expiratory airflow* of more than 400 L/min. However, regardless of how much additional expiratory effort the person exerts, this is still the maximum flow rate that they can achieve.

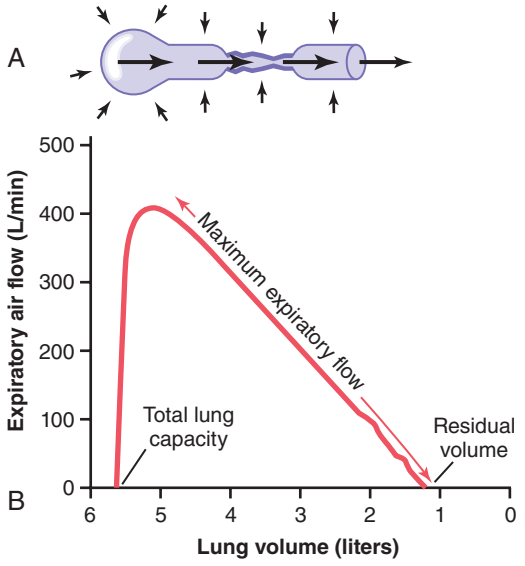

Figure 43.1 (A) Collapse of the respiratory passageway during maximum expiratory effort, an effect that limits expiratory flow rate. (B) Effect of lung volume on the maximum expiratory airflow, showing decreasing maximum expiratory airflow as the lung volume becomes smaller.

Note also that as the lung volume becomes smaller, the maximum expiratory flow rate also decreases. The main reason for this phenomenon is that in the enlarged lung, the bronchi and bronchioles are held open partially by way of elastic pull on their outsides by lung structural elements. However, as the lung becomes smaller, these structures are relaxed so that the bronchi and bronchioles are collapsed more easily by external chest pressure, thus progressively reducing the maximum expiratory flow rate as well.

Abnormalities of the Maximum Expiratory Flow-Volume Curve. **Fig. 43.2** shows the normal maximum expiratory flow-volume curve, along with two additional flow-volume curves recorded in two types of lung diseases: constricted lungs and partial airway obstruction. Note that the *constricted lungs* have both reduced total lung capacity (TLC) and reduced residual volume (RV). Furthermore, because the lung cannot expand to a normal maximum volume, even with the greatest possible expiratory effort, the maximal expiratory flow cannot rise to equal that of the normal curve. Constricted lung diseases include fibrotic diseases of the lung, such as *tuberculosis* and *silicosis*, and diseases that constrict the chest cage, such as *kyphosis, scoliosis*, and *fibrotic pleurisy*.

In diseases with *airway obstruction*, it is usually much more difficult to expire than to inspire because the closing tendency of the airways is greatly increased by the extra positive pressure required in the chest to cause expiration. By contrast, the extra negative pleural pressure that occurs during inspiration actually "pulls" the airways open at the same time that it expands the alveoli. Therefore, air tends to enter the lung easily but then becomes trapped in the lungs. Over a period of months or years, this effect increases both the TLC and RV, as shown by the green curve in **Fig. 43.2**. Also, because of the obstruction of the airways, and because they collapse more easily than normal airways, the maximum expiratory flow rate is greatly reduced.

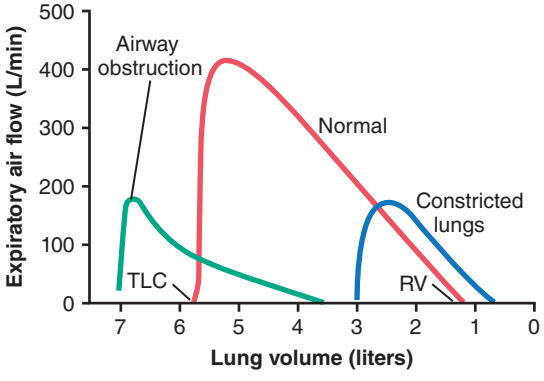

Figure 43.2 Effect of two respiratory abnormalities—constricted lungs and airway obstruction—on the maximum expiratory flow-volume curve. *RV*, Residual volume; *TLC*, total lung capacity.

The classic disease that causes severe airway obstruction is *asthma*. Serious airway obstruction also occurs in some stages of *emphysema*.

FORCED EXPIRATORY VITAL CAPACITY AND FORCED EXPIRATORY VOLUME

Another useful clinical pulmonary test, and one that is also easy to perform, is to record the *forced expiratory vital capacity* (FVC) on a spirometer. Such a recording is shown in **Fig. 43.3A** for a person with normal lungs and in **Fig. 43.3B** for a person with partial airway obstruction. In performing the FVC maneuver, the person first inspires maximally to the TLC and then exhales into the spirometer with maximum expiratory effort as rapidly and as completely as possible. The total distance of the downslope of the lung volume record represents the FVC, as shown in the figure.

Now, study the difference between the two records for (1) normal lungs and (2) *partial* airway obstruction. The total volume changes of the FVCs are not greatly different, indicating only a moderate difference in basic lung volumes in the two persons. There is, however, a *major difference in the amounts of air that these persons can expire each second*, especially during the first second. Therefore, it is customary to compare the *recorded forced expiratory volume during the first second* (FEV_1) with the normal value. In the normal person (see **Fig. 43.3A**), the percentage of the FVC that is expired in the first second divided by the total FVC (FEV_1/FVC%) is 80%. However, note in **Fig. 43.3B** that with airway obstruction, this value decreases to only 47%. In persons with serious airway obstruction, as often occurs with acute asthma, this value can decrease to less than 20%.

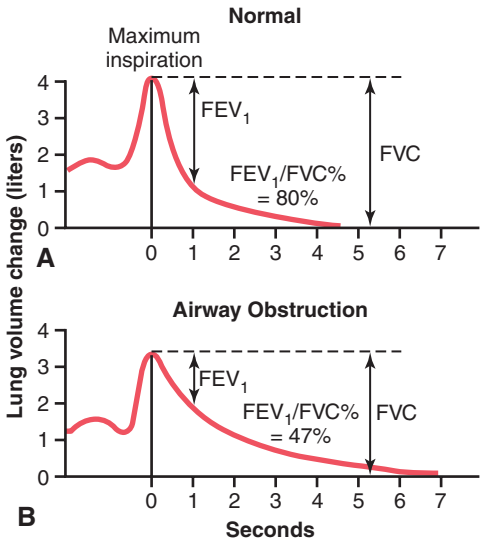

Figure 43.3 Recordings during the forced vital capacity maneuver in a healthy person (A) and in a person with partial airway obstruction (B). (The "zero" on the volume scale is residual volume.) *FEV_1*, Forced expiratory volume during the first second; *FVC*, forced expiratory vital capacity.

PATHOPHYSIOLOGY OF SPECIFIC PULMONARY ABNORMALITIES

CHRONIC PULMONARY EMPHYSEMA

The term *pulmonary emphysema* literally means excess air in the lungs. However, this term is usually used to describe a complex obstructive and destructive process of the lungs caused by many years of smoking, or in some cases by chronic exposure to air pollution, dust, or chemical fumes. It results from the following major pathophysiological changes in the lungs:

1. *Chronic infection*, caused by inhaling smoke or other substances that irritate the bronchi and bronchioles. The chronic infection seriously deranges the normal protective mechanisms of the airways, including partial paralysis and eventually destruction of the cilia of the respiratory epithelium, an effect caused by toxicants in tobacco smoke and air pollution. As a result, mucus cannot be moved easily out of the passageways. Also, stimulation of excess mucus secretion occurs, which further exacerbates the condition. There is also inhibition of the alveolar macrophages, so they become less effective in combating infection.
2. The infection, excess mucus, and inflammatory edema of the bronchiolar epithelium together cause *chronic obstruction* of many of the smaller airways.
3. The obstruction of the airways makes it especially difficult to expire, thus causing *entrapment of air in the alveoli* and overstretching them. This effect, combined with the lung infection, causes *marked destruction of as much as 50% to 80% of the alveolar walls*. Therefore, the final picture of the emphysematous lung is that shown in **Figs. 43.4** (*top*) and **43.5**.

The physiological effects of chronic emphysema are variable, depending on the severity of the disease and the relative degrees of bronchiolar obstruction versus lung parenchymal destruction. The different abnormalities include the following:

1. The bronchiolar obstruction *increases airway resistance* and results in greatly increased work of breathing. It is especially difficult for the person to move air through the bronchioles during expiration because the compressive force on the outside of the lung not only compresses the alveoli but also compresses the bronchioles, which further increases their resistance during expiration.
2. The marked loss of alveolar walls greatly *decreases the diffusing capacity* of the lung. This reduces the ability of the lungs to oxygenate the blood and remove CO_2 from the blood.
3. The obstructive process is frequently much worse in some parts of the lungs than in other parts, so some portions of the lungs are well ventilated, whereas other portions are poorly ventilated. This situation often causes *extremely abnormal ventilation-perfusion ratios*, with a very low $\dot{V}_A/\dot{Q}$ in some parts

(physiological shunt), resulting in poor aeration of the blood, and a very high $\dot{V}_A/\dot{Q}$ in other parts *(physiological dead space)*, resulting in wasted ventilation, with both effects occurring in the same lungs.

4. Loss of large portions of the alveolar walls also decreases the number of pulmonary capillaries through which blood can pass. As a result, the pulmonary vascular resistance often increases markedly, causing *pulmonary hypertension*, which in turn overloads the right side of the heart and frequently causes *right-sided heart failure*.

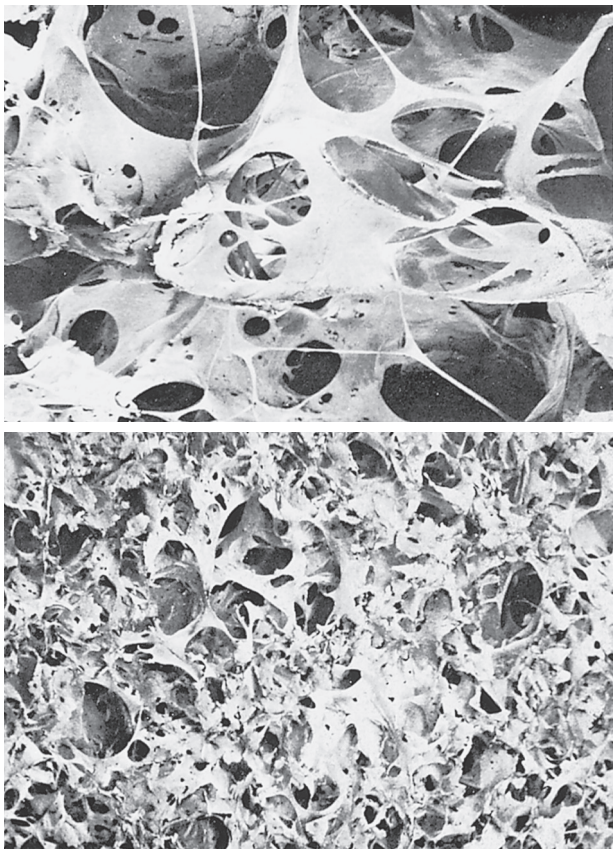

Figure 43.4 Contrast of the emphysematous lung *(top)* with the normal lung *(bottom)*, showing extensive alveolar destruction in emphysema. (*Courtesy Patricia Delaney and the Department of Anatomy, The Medical College of Wisconsin, Milwaukee, WI.*)

Chronic emphysema usually progresses slowly over many years. Both hypoxia and hypercapnia develop because of hypoventilation of many alveoli plus loss of alveolar walls. The net result of all these effects is severe, prolonged, devastating *air hunger* (*dyspnea*) that can last for years until the hypoxia and hypercapnia cause death—a high penalty to pay for smoking.

PNEUMONIA—LUNG INFLAMMATION AND FLUID IN ALVEOLI

The term *pneumonia* includes any inflammatory condition of the lung in which some or all of the alveoli are filled with fluid and blood cells, as shown in **Fig. 43.5**. A common type of pneumonia is *bacterial pneumonia*, caused most frequently by *pneumococci*. This disease begins with infection in the alveoli; the pulmonary membrane becomes inflamed and highly porous so that fluid and even red and white blood cells leak out of the blood into the alveoli. Thus, the infected alveoli become progressively filled with fluid and cells, and the infection spreads by extension of bacteria or virus from alveolus to alveolus. Eventually, large areas of the lungs, sometimes whole lobes or even a whole lung, become "consolidated," which means that they are filled with fluid and cellular debris.

In persons with pneumonia, the gas exchange functions of the lungs decline in different stages of the disease. In early stages, the pneumonia process might well be localized to only one lung, with alveolar ventilation being reduced while blood flow through the lung continues normally. This condition causes two major pulmonary abnormalities: (1) reduction in the total available surface area of the respiratory membrane; and (2) a decreased ventilation-perfusion ratio. Both these effects cause *hypoxemia* (low blood O_2) and *hypercapnia* (high blood CO_2).

Fig. 43.6 shows the effect of the decreased ventilation-perfusion ratio in pneumonia. The blood passing through the aerated lung becomes 97% saturated with O_2, whereas that passing through the unaerated lung is about 60% saturated. Therefore, the average saturation of the blood pumped by the left heart into the aorta is only about 78%, which is far below normal.

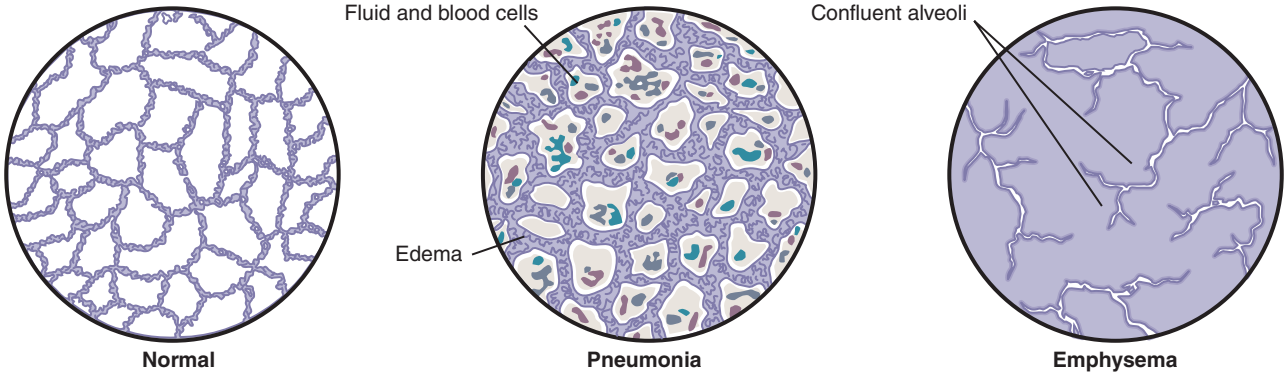

Figure 43.5 Lung alveolar changes in pneumonia and emphysema.

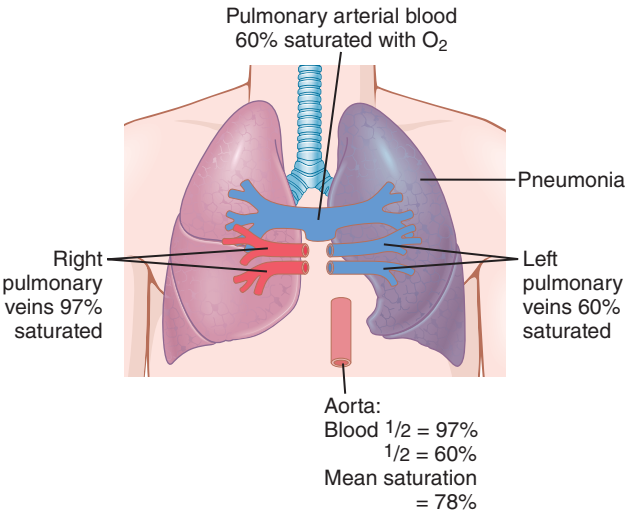

Figure 43.6 Effect of pneumonia on percentage saturation of oxygen (O_2) in the pulmonary artery, the right and left pulmonary veins, and the aorta.

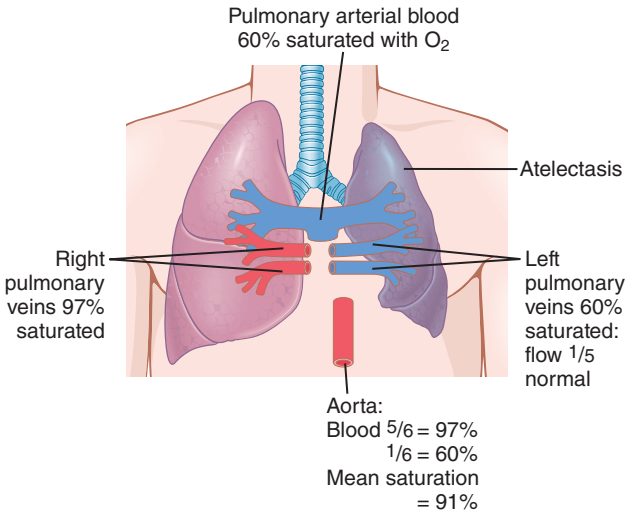

Figure 43.7 Effect of atelectasis on aortic blood oxygen (O_2) saturation.

ATELECTASIS—COLLAPSE OF THE ALVEOLI

Atelectasis means collapse of the alveoli. It can occur in localized areas of a lung or in an entire lung. Common causes of atelectasis are (1) total obstruction of the airway and (2) lack of surfactant in the fluids lining the alveoli.

Airway Obstruction Causes Lung Collapse. The airway obstruction type of atelectasis usually results from the following: (1) blockage of many small bronchi with mucus; or (2) obstruction of a major bronchus by a large mucous plug or some solid object, such as a tumor. The air entrapped beyond the block is absorbed within minutes to hours by the blood flowing in the pulmonary capillaries. If the lung tissue is pliable enough, this will lead simply to collapse of the alveoli. However, if the lung is rigid because of fibrotic tissue and cannot collapse, absorption of air from the alveoli creates very negative pressures within the alveoli, which pull fluid out of the pulmonary capillaries into the alveoli, thus causing the alveoli to fill completely with edema fluid. This process almost always is the effect that occurs when an entire lung becomes atelectatic, a condition called *massive collapse of the lung*.

The effects on overall pulmonary function caused by massive collapse (atelectasis) of an entire lung are shown in **Fig. 43.7**. Collapse of the lung tissue not only occludes the alveoli but also almost always *increases the resistance to blood flow* through the pulmonary vessels of the collapsed lung. This resistance increase occurs partially because of the lung collapse, which compresses and folds the vessels as the volume of the lung decreases. In addition, hypoxia in the collapsed alveoli causes additional vasoconstriction, as explained in Chapter 39.

Because of the vascular constriction, blood flow through the atelectatic lung is greatly reduced. Fortunately, most of the blood is routed through the ventilated lung and therefore becomes well aerated. In the situation shown in **Fig. 43.7**, five-sixths of the blood passes through the aerated lung, and only one-sixth passes through the unaerated lung. As a result, the overall ventilation-perfusion ratio is only moderately compromised, so the aortic blood has only mild O_2 desaturation, despite total loss of ventilation in an entire lung.

Lack of Surfactant as a Cause of Lung Collapse. The secretion and function of *surfactant* in the alveoli were discussed in Chapter 38. Surfactant is secreted by special alveolar epithelial cells into the fluids that coat the inside surface of the alveoli. The surfactant in turn decreases the surface tension in the alveoli by 2- to 10-fold, which normally plays a major role in preventing alveolar collapse. However, in several conditions, such as in *hyaline membrane disease* (also called *respiratory distress syndrome*), which often occurs in newborn premature babies, the quantity of surfactant secreted by the alveoli is so greatly depressed that the surface tension of the alveolar fluid becomes several times greater than normal. This surfactant deficiency causes a serious tendency for the lungs of these babies to collapse or to become filled with fluid.

In the absence of treatment, many of these infants die of suffocation when large portions of the lungs become atelectatic. Although treatment of premature newborn babies with surfactant, assisted ventilation, corticosteroids before birth, and other therapies has greatly improved their survival, hyaline membrane disease continues to be an important cause of morbidity and mortality in preterm infants. The more premature the baby, the more severe is the respiratory distress.

ASTHMA—SPASMODIC CONTRACTION OF SMOOTH MUSCLES IN BRONCHIOLES

Asthma is characterized by spastic contraction of the smooth muscle in the bronchioles, which partially obstructs the bronchioles and causes extremely difficult

breathing. The prevalence of asthma has been increasing and affects 7% to 8% of all people in the United States, with even higher rates in some groups such as non-Hispanic Black individuals. The World Health Organization estimates that over 262 million people worldwide suffer from asthma.

The usual cause of asthma is contractile hypersensitivity of the bronchioles in response to foreign substances in the air. In about 70% of patients younger than 30 years, the asthma is caused by allergic hypersensitivity, especially sensitivity to plant pollens. In older people, the cause is almost always hypersensitivity to nonallergenic types of irritants in the air, such as irritants in smog.

The typical allergic person tends to form abnormally large amounts of immunoglobulin E (IgE) antibodies, and these antibodies cause allergic reactions when they react with the specific antigens that have caused them to develop in the first place, as explained in Chapter 35. In persons with asthma, these *antibodies are mainly attached to mast cells* that are present in the lung interstitium in close association with the bronchioles and small bronchi. When a person with asthma breathes in pollen to which they are sensitive (i.e., to which the person has developed IgE antibodies), the pollen reacts with the mast cell–attached antibodies and causes the mast cells to release several different substances. Among them are the following: (1) *histamine*; (2) *slow-reacting substance of anaphylaxis* (which is a mixture of leukotrienes); (3) *eosinophilic chemotactic factor*; and (4) *bradykinin*. The combined effects of all these factors, especially the slow-reacting substance of anaphylaxis, are to produce the following: (1) localized edema in the walls of the small bronchioles, as well as secretion of thick mucus into the bronchiolar lumens; and (2) spasm of the bronchiolar smooth muscle. Therefore, the airway resistance increases greatly.

As discussed earlier in this chapter, the bronchiolar diameter becomes reduced more during expiration than during inspiration in persons with asthma as a result of bronchiolar collapse during expiratory effort that compresses the outsides of the bronchioles. Because the bronchioles of the asthmatic lungs are already partially occluded, further occlusion resulting from the external pressure creates especially severe obstruction during expiration. That is, the person with asthma often can inspire quite adequately but has great difficulty expiring. Clinical measurements show (1) greatly reduced maximum expiratory rate, and (2) reduced timed expiratory volume. Also, all this together results in *dyspnea*, or "air hunger," discussed later in this chapter.

The *functional residual capacity* and *residual volume* of the lung become especially increased during an acute asthma attack because of the difficulty in expiring air from the lungs. Also, over a period of years, the chest cage becomes permanently enlarged, causing a so-called *barrel chest*, and both the functional residual capacity and lung residual volume become permanently increased.

TUBERCULOSIS

In tuberculosis, the tubercle bacilli cause a peculiar tissue reaction in the lungs, including (1) invasion of the infected tissue by macrophages, and (2) "walling off" of the lesion by fibrous tissue to form the so-called *tubercle*. This walling-off process helps limit further transmission of the tubercle bacilli in the lungs and therefore is part of the protective process against extension of the infection. However, if tuberculosis is not treated, the walling-off process fails in about 3% of people in whom the disease develops, and tubercle bacilli spread throughout the lungs, often causing extreme destruction of lung tissue, with formation of large abscess cavities.

Thus, tuberculosis in its late stages is characterized by many areas of fibrosis throughout the lungs, as well as by reduced total amount of functional lung tissue. These effects cause the following: (1) *increased "work"* on the part of the respiratory muscles to cause pulmonary ventilation and *reduced vital capacity and breathing capacity*; (2) *reduced total respiratory membrane surface area* and *increased thickness of the respiratory membrane*, causing progressively *diminished pulmonary diffusing capacity*; and (3) *abnormal ventilation-perfusion ratio* in the lungs, further reducing overall pulmonary diffusion of O_2 and CO_2.

HYPOXIA AND OXYGEN THERAPY

Almost any of the conditions discussed in the past few sections of this chapter can cause serious cellular hypoxia throughout the body. Sometimes O_2 therapy is of great value, other times it is of moderate value, and at still other times it is of almost no value. Therefore, it is important to understand the different types of hypoxia, and then we can discuss the physiological principles of oxygen therapy. The following is a descriptive classification of the causes of hypoxia:

1. Inadequate oxygenation of the blood in the lungs because of extrinsic reasons
   a. Deficiency of O_2 in the atmosphere
   b. Hypoventilation (neuromuscular disorders)
2. Pulmonary disease
   a. Hypoventilation caused by increased airway resistance or decreased pulmonary compliance
   b. Abnormal alveolar ventilation-perfusion ratio (including increased physiological dead space or increased physiological shunt)
   c. Diminished respiratory membrane diffusion
3. Venous-to-arterial shunts (right-to-left cardiac shunts)
4. Inadequate O_2 transport to the tissues by the blood
   a. Anemia or abnormal hemoglobin
   b. General circulatory deficiency
   c. Localized circulatory deficiency (peripheral, cerebral, coronary vessels)
   d. Tissue edema

5. Inadequate tissue capability of using O_2
   a. Poisoning of cellular oxidation enzymes
   b. Diminished cellular metabolic capacity for using oxygen because of toxicity, vitamin deficiency, or other factors

This classification of the types of hypoxia is mainly self-evident from the discussions earlier in the chapter. Only one type of hypoxia in the classification needs further elaboration—the hypoxia caused by inadequate capability of the body's tissue cells to use O_2.

Inadequate Tissue Capability to Use Oxygen. The classic cause of inability of the tissues to use O_2 is *cyanide poisoning*, in which the action of the enzyme *cytochrome oxidase* is blocked by cyanide to such an extent that the tissues simply cannot use O_2, even when plenty is available. Also, deficiencies of some of the *tissue cellular oxidative enzymes* or of other elements in the tissue oxidative system can lead to this type of hypoxia. A special example occurs in the disease *beriberi*, in which several important steps in tissue utilization of oxygen and the formation of CO_2 are compromised because of *vitamin B deficiency*.

Effects of Hypoxia on the Body. Hypoxia, if severe enough, can cause death of cells throughout the body, but in less severe degrees, it mainly causes (1) depressed mental activity, sometimes culminating in coma, and (2) reduced work capacity of the muscles. These effects are specifically discussed in Chapter 44 in relation to high-altitude physiology.

OXYGEN THERAPY IN DIFFERENT TYPES OF HYPOXIA

O_2 can be administered by the following: (1) placing the patient's head in a "tent" that contains air fortified with O_2; (2) allowing the patient to breathe pure O_2 or high concentrations of O_2 from a mask; or (3) administering O_2 through an intranasal tube.

Recalling the basic physiological principles of the different types of hypoxia, one can readily decide when O_2 therapy will be of value and, if so, how valuable.

In *atmospheric hypoxia*, O_2 therapy can completely correct the depressed O_2 level in the inspired gases and, therefore, provide 100% effective therapy.

In *hypoventilation hypoxia*, a person breathing 100% O_2 can move five times as much O_2 into the alveoli with each breath as when breathing normal air. Here again, O_2 therapy can be extremely beneficial. However, this O_2 therapy provides no benefit for the excess blood CO_2 also caused by the hypoventilation.

In *hypoxia caused by impaired alveolar membrane diffusion*, essentially the same result occurs as in hypoventilation hypoxia because O_2 therapy can increase the P_{O_2} in the lung alveoli from the normal value of about 100 mm Hg to as high as 600 mm Hg. This action raises the O_2 pressure gradient for diffusion of oxygen from the alveoli to the blood from the normal value of 60 mm Hg to as high as 560 mm Hg, an increase of more than 800%. This highly beneficial effect of O_2 therapy in diffusion hypoxia is demonstrated in **Fig. 43.8**, which shows that the pulmonary blood in this patient with pulmonary edema picks up O_2 three to four times as rapidly as would occur with no therapy.

In *hypoxia caused by anemia, abnormal hemoglobin transport of O_2, circulatory deficiency, or physiological shunt*, O_2 therapy is of much less value because normal O_2 is already available in the alveoli. Instead, the problem is that one or more of the mechanisms for transporting oxygen from the lungs to the tissues are deficient. Even so, a small amount of extra O_2, between 7% and 30%, can be *transported in the dissolved state* in the blood when alveolar O_2 is increased to maximum, even though the amount transported by the hemoglobin is hardly altered. This small amount of extra O_2 may be the difference between life and death.

In the different types of *hypoxia caused by inadequate tissue use of O_2*, there is no abnormality of O_2 pickup by the lungs or of transport to the tissues. Instead, the tissue metabolic enzyme system is simply incapable of using the O_2 that is delivered. Therefore, O_2 therapy provides no measurable benefit.

CYANOSIS

The term *cyanosis* means blueness of the skin; its cause is excessive amounts of deoxygenated hemoglobin in the skin blood vessels, especially in the capillaries. This deoxygenated hemoglobin has an intense dark blue–purple color that is transmitted through the skin.

In general, definite cyanosis appears whenever the *arterial blood* contains more than 5 grams of deoxygenated hemoglobin in each 100 mL of blood. A person with *anemia* almost never becomes cyanotic because there is not enough hemoglobin for 5 grams to be deoxygenated in 100 mL of arterial blood. Conversely, in a person with excess red blood cells, as in *polycythemia vera*, the great excess of available hemoglobin that can become

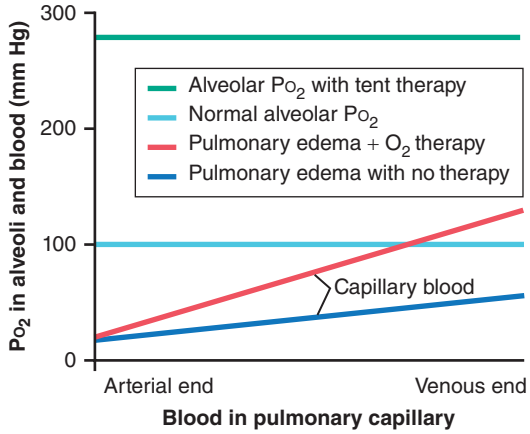

Figure 43.8 Absorption of oxygen into the pulmonary capillary blood in pulmonary edema, with and without oxygen tent therapy.

deoxygenated leads frequently to cyanosis, even under otherwise normal conditions.

HYPERCAPNIA—EXCESS CARBON DIOXIDE IN THE BODY FLUIDS

One might suspect, on first thought, that any respiratory condition that causes hypoxia would also cause hypercapnia. However, hypercapnia usually occurs in association with hypoxia only when the hypoxia is caused by *hypoventilation* or *circulatory deficiency* for the following reasons.

Hypoxia caused by *too little O_2 in the air, too little hemoglobin*, or *poisoning of the oxidative enzymes* involves only the availability of O_2 or use of O_2 by the tissues. Therefore, it is readily understandable that hypercapnia is *not* associated with these types of hypoxia.

In hypoxia resulting from poor diffusion through the pulmonary membrane or the tissues, serious hypercapnia usually does not occur at the same time because CO_2 diffuses 20 times as rapidly as O_2. If hypercapnia does begin to occur, this immediately stimulates pulmonary ventilation, which corrects the hypercapnia but not necessarily the hypoxia.

Conversely, in hypoxia caused by hypoventilation, CO_2 transfer between the alveoli and the atmosphere is affected as much as O_2 transfer. Hypercapnia then occurs along with the hypoxia. In circulatory deficiency, diminished flow of blood decreases CO_2 removal from the tissues, resulting in tissue hypercapnia in addition to tissue hypoxia. However, the transport capacity of the blood for CO_2 is more than three times that for O_2, and thus the resulting tissue hypercapnia is much less than the tissue hypoxia.

When the alveolar P_{CO_2} rises above about 60 to 75 mm Hg, an otherwise normal person by then is breathing about as rapidly and deeply as they can, and dyspnea becomes severe.

If the P_{CO_2} rises to 80 to 100 mm Hg, the person becomes lethargic and sometimes even semicomatose. Anesthesia and death can result when the P_{CO_2} rises to 120 to 150 mm Hg. At these higher levels of P_{CO_2}, the excess CO_2 now begins to depress respiration rather than stimulate it, thus causing a vicious cycle: (1) more CO_2, (2) further decrease in respiration, (3) then more CO_2, and so forth—culminating rapidly in a respiratory death.

DYSPNEA

Dyspnea means shortness of breath and mental anguish associated with inability to ventilate enough to satisfy the demand for air. A common synonym is *air hunger*.

At least three factors often contribute to development of the sensation of dyspnea: (1) abnormality of respiratory gases in the body fluids, especially hypercapnia and, to a much less extent, hypoxia; (2) the amount of work that must be performed by the respiratory muscles to provide adequate ventilation; and (3) state of mind.

A person becomes especially dyspneic from excess buildup of CO_2 in the body fluids. At times, however, the levels of both CO_2 and O_2 in the body fluids are normal, but to attain this normality of the respiratory gases the person has to breathe forcefully. In these cases, the forceful activity of the respiratory muscles frequently gives the person a sensation of dyspnea.

Most people have the sensation of severe dyspnea after only 1 to 2 minutes of voluntary breath-holding (apnea). However, as discussed in Chapter 42, some individuals can train themselves to suppress respiratory urges for more than 10 minutes, despite buildup of CO_2 and very low O_2 in the body fluids.

Finally, dyspnea may be experienced because of an abnormal state of mind, even though the person's respiratory functions, as well as CO_2 and O_2 in the body fluids, may be normal. This condition is called *neurogenic dyspnea* or *emotional dyspnea*. For example, almost anyone momentarily thinking about the act of breathing may suddenly start taking breaths a little more deeply than ordinarily because of a feeling of mild dyspnea. This feeling is greatly enhanced in people who have a psychological fear of not being able to receive a sufficient quantity of air, such as when entering a small or crowded room.

RESPIRATORY RESUSCITATION AND MECHANICAL VENTILATORS

In patients who suffer from respiratory arrest or who have inadequate ventilation, respiratory resuscitation may be required. For example, during the coronavirus disease 2019 (COVID-19) pandemic, it became evident that respiratory failure is one of the main features in severe cases of the disease and that many patients require respiratory support, including noninvasive ventilation, as well as invasive mechanical ventilation via an endotracheal tube.

Fortunately, treatment of respiratory failure has improved dramatically since the polio epidemic in the 1950s, when tank respirators ("iron lungs") were used to create negative and positive pressures inside the tank, causing inspiration and expiration. Many less invasive devices are now available for respiratory resuscitation, and each has its own characteristic principles of operation. The most basic manual respiratory resuscitator consists of a flexible self-inflating bag attached to a face mask via a low-resistance valve and filter (**Fig. 43.9A**). When the bag is squeezed, air or oxygen is forced into the lungs; when the bag is released, it self-inflates, drawing in air or oxygen from the other end of the bag while permitting the patient's lungs to deflate and expire air to the ambient environment, rather than the bag, through the one-way valve.

There are multiple types of more complex mechanical ventilator systems that basically consist of a tank supply of O_2 or air, a mechanism for applying intermittent positive pressure to the O_2/air supply (some machines also provide negative pressure), and a mask that fits over the face

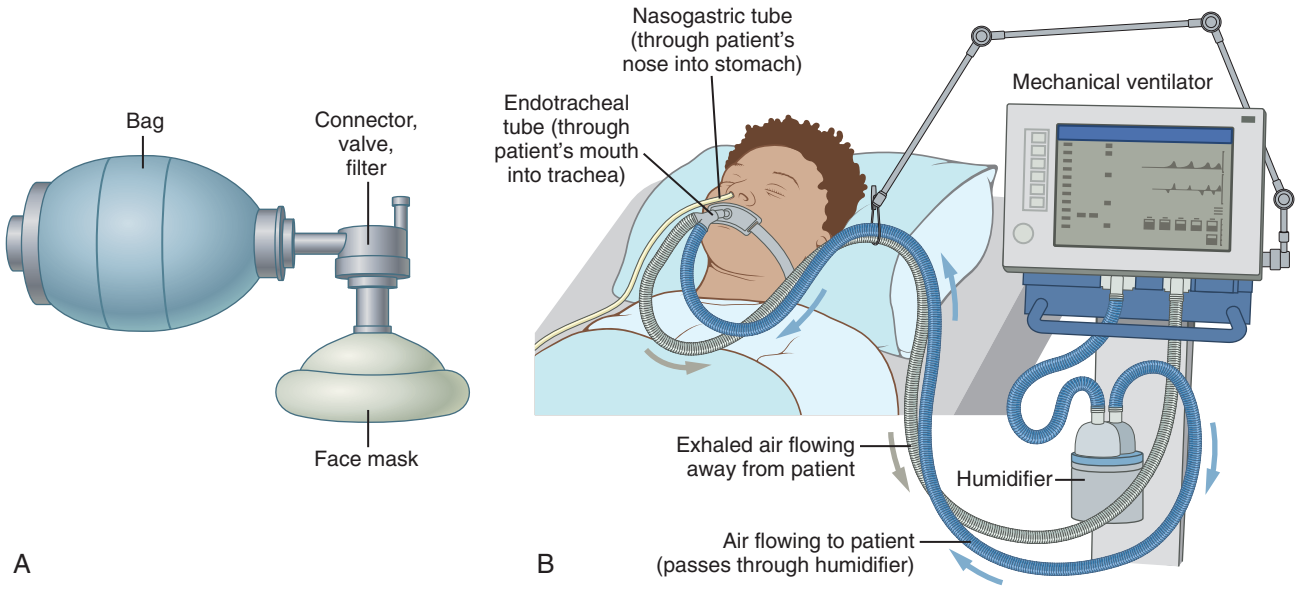

Figure 43.9 (A) Manual respiratory resuscitator. (B) Mechanical ventilator.

of the patient or a connector that joins the equipment to an endotracheal tube (**Fig. 43.9B**). The ventilator forces air through the mask or endotracheal tube into the lungs of the patient during the positive-pressure cycle of the ventilator and then usually allows the air to flow passively out of the lungs during the remainder of the cycle.

Modern ventilator systems are computer-controlled so that they can be adjusted to match the needs of a patient and minimize adverse effects to the lungs. They now have adjustable positive-pressure limits that are commonly set at 12 to 15 cm H_2O pressure for normal lungs, but sometimes much higher for noncompliant lungs. Ventilators provide lifesaving respiratory support (mechanical ventilation), but without appropriate safeguards they can also cause injury to the lungs and diaphragm, as well as impair hemodynamics.

Effect of the Ventilator on Venous Return. When air is forced into the lungs under positive pressure by a resuscitator, the pressure inside the lungs becomes greater than pressure everywhere else in the body. Flow of blood into the chest and heart from the peripheral veins becomes impeded. As a result, use of excessive pressures with the resuscitator can reduce the cardiac output, sometimes to very low levels. For example, continuous exposure for more than a few minutes to more than 30 mm Hg of positive pressure in the lungs can cause death because of inadequate venous return to the heart.

CHAPTER 44

Aviation, High Altitude, and Space Physiology

As humans have ascended to higher and higher altitudes in aviation, mountain climbing, and space exploration, it has become progressively more important to understand the physiological effects of altitude and low gas pressures on the body. This chapter deals with these problems and acceleratory forces, weightlessness, and other challenges to homeostasis that occur at high altitudes and in space flight.

EFFECTS OF LOW OXYGEN PRESSURE ON THE BODY

Barometric Pressures at Different Altitudes. **Table 44.1** lists the approximate *barometric* and *oxygen pressures* at different altitudes, showing that at sea level, the barometric pressure is 760 mm Hg; at 10,000 feet, it is only 523 mm Hg; and at 50,000 feet, it is 87 mm Hg. This decrease in barometric pressure is the basic cause of all the hypoxia problems in high-altitude physiology, because as the barometric pressure decreases, the atmospheric oxygen partial pressure (P_{O_2}) decreases proportionately, remaining at all times slightly less than 21% of the total barometric pressure; at sea level, P_{O_2} is about 159 mm Hg, but at 50,000 feet, P_{O_2} is only 18 mm Hg.

ALVEOLAR P_{O_2} AT DIFFERENT ELEVATIONS

Carbon Dioxide and Water Vapor Decrease the Alveolar Oxygen. Even at high altitudes, carbon dioxide (CO_2) is continually excreted from the pulmonary blood into the alveoli. In addition, water vaporizes into the inspired air from the respiratory surfaces. These two gases dilute the O_2 in the alveoli, thus reducing the O_2 concentration. Water vapor pressure in the alveoli remains at 47 mm Hg as long as the body temperature is normal, regardless of altitude.

In the case of CO_2, during exposure to very high altitudes, the alveolar partial pressure of CO_2 (P_{CO_2}) falls from the sea level value of 40 mm Hg to lower values. In the *acclimatized* person, who increases ventilation about 5-fold, the P_{CO_2} falls to about 7 mm Hg because of increased respiration.

Now let us see how the pressures of these two gases affect the alveolar O_2. For example, assume that the barometric pressure falls from the normal sea level value of 760 to 253 mm Hg, which is the usual measured value at the top of 29,032-foot Mount Everest. Of this, 47 mm Hg must be water vapor, leaving only 206 mm Hg for all the other gases. In the *acclimatized* person, 7 mm Hg of the 206 mm Hg must be CO_2, leaving only 199 mm Hg. If there were no use of O_2 by the body, one-fifth of this 199 mm Hg would be O_2 and four-fifths would be nitrogen—that is, the P_{O_2} in the alveoli would be about 40 mm Hg. However, some of this remaining alveolar O_2 is continually being absorbed into the blood, leaving about 35 mm Hg O_2 pressure in the alveoli. At the summit of Mount Everest, only the best acclimatized people can barely survive when breathing air. However, the effect is very different when the person is breathing pure O_2, as we see in the following discussions.

Alveolar P_{O_2} at Different Altitudes. The fifth column of **Table 44.1** shows the approximate P_{O_2} values in the alveoli at different altitudes when one is breathing air for both the *unacclimatized* and the *acclimatized* person. At sea level, the alveolar P_{O_2} is 104 mm Hg. At 20,000 feet altitude, it falls to about 40 mm Hg in the unacclimatized person but only to 53 mm Hg in the acclimatized person. The reason for the difference between these two is that alveolar ventilation increases much more in the acclimatized person than in the unacclimatized person, as we discuss later.

Hemoglobin Oxygen Saturation at Different Altitudes. **Fig. 44.1** shows arterial blood O_2 saturation at different altitudes while a person is breathing air and while breathing O_2. Up to an altitude of about 10,000 feet, even when air is breathed, the arterial O_2 saturation remains at least as high as 90%. Above 10,000 feet, the arterial O_2 saturation falls rapidly, as shown by the blue curve of the figure, until it is slightly less than 70% at 20,000 feet and much less at still higher altitudes.

Effect of Breathing Pure Oxygen on Alveolar P_{O_2} at Different Altitudes. When a person breathes pure O_2 instead of air, most of the space in the alveoli formerly occupied by nitrogen becomes occupied by O_2. At 30,000 feet, an aviator could have an alveolar P_{O_2} as high as 139 mm Hg instead of 18 mm Hg when breathing air (see **Table 44.1**).

The red curve of **Fig. 44.1** shows arterial blood hemoglobin O_2 saturation at different altitudes when a person

Table 44.1 Effects of Acute Exposure to Low Atmospheric Pressures on Alveolar Gas Concentrations and Arterial Oxygen Saturation[a]

			Breathing Air			Breathing Pure Oxygen		
Altitude (ft/m)	Barometric Pressure (mm Hg)	P_{O_2} in Air (mm Hg)	P_{CO_2} in Alveoli (mm Hg)	P_{O_2} in Alveoli (mm Hg)	Arterial Oxygen Saturation (%)	P_{CO_2} in Alveoli (mm Hg)	P_{O_2} in Alveoli (mm Hg)	Arterial Oxygen Saturation (%)
0	760	159	40 (40)	104 (104)	97 (97)	40	673	100
10,000/3048	523	110	36 (23)	67 (77)	90 (92)	40	436	100
20,000/6096	349	73	24 (10)	40 (53)	73 (85)	40	262	100
30,000/9144	226	47	24 (7)	18 (30)	24 (38)	40	139	99
40,000/12,192	141	29				36	58	84
50,000/15,240	87	18				24	16	15

[a] Numbers in parentheses are acclimatized values.

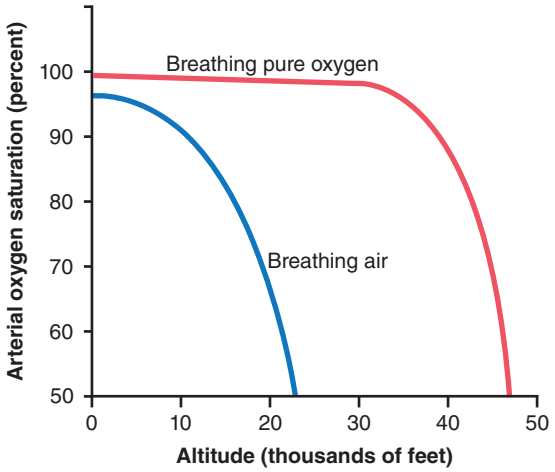

Figure 44.1 Effect of high altitude on arterial oxygen saturation when breathing air or pure oxygen.

is breathing pure O_2. Note that the saturation remains above 90% until the aviator ascends to about 39,000 feet; then it falls rapidly to about 50% at about 47,000 feet.

The "Ceiling" When Breathing Air and When Breathing Oxygen in an Unpressurized Airplane. When comparing the two arterial blood O_2 saturation curves in **Fig. 44.1**, one notes that an aviator breathing pure O_2 in an unpressurized airplane can ascend to far higher altitudes than one breathing air. For example, the arterial saturation at 47,000 feet when one is breathing O_2 is about 50% and is equivalent to the arterial O_2 saturation at 23,000 feet when one is breathing air. In addition, because an unacclimatized person usually can remain conscious until the arterial O_2 saturation falls to 50%, the ceiling for an aviator for short exposure times in an unpressurized airplane when breathing air is about 23,000 feet and, when breathing pure O_2, is about 47,000 feet, provided that the equipment supplying the O_2 operates perfectly.

ACUTE EFFECTS OF HYPOXIA

Some of the important acute effects of hypoxia in the unacclimatized person breathing air, beginning at an altitude of about 12,000 feet, are drowsiness, lassitude, mental and muscle fatigue, sometimes headache, occasionally nausea, and sometimes euphoria. These effects progress to a stage of twitchings or seizures above 18,000 feet and, above 23,000 feet in the unacclimatized person, end in coma, followed shortly thereafter by death.

One of the most important effects of hypoxia is decreased mental proficiency, which decreases judgment, memory, and performance of discrete motor movements. For example, if an unacclimatized aviator stays at 15,000 feet for 1 hour, mental proficiency ordinarily falls to about 50% of normal and, after 18 hours at this level, it falls to about 20% of normal.

ACCLIMATIZATION TO LOW P_{O_2}

A person remaining at high altitudes for days, weeks, or years becomes more and more *acclimatized* to the low P_{O_2}, so it causes fewer deleterious effects on the body. After acclimatization, a person is able to work harder without hypoxic effects or to ascend to still higher altitudes.

The principal means whereby acclimatization comes about are as follows: (1) a great increase in pulmonary ventilation; (2) increased numbers of red blood cells; (3) increased diffusing capacity of the lungs; (4) increased vascularity of the peripheral tissues; and (5) increased ability of the tissue cells to use O_2, despite low P_{O_2}.

Increased Pulmonary Ventilation—Role of Arterial Chemoreceptors. Immediate exposure to low P_{O_2} stimulates the arterial chemoreceptors, increasing alveolar ventilation to a maximum of about 1.65 times normal. This compensation for high altitude occurs within seconds, allowing the person to rise several thousand feet higher than would be possible without the increased ventilation. If the person remains at a very high altitude for several days, the chemoreceptors increase ventilation still more, up to about five times normal.

The immediate increase in pulmonary ventilation on rising to a high altitude blows off large quantities of CO_2, reducing the P_{CO_2} and increasing the pH of the body fluids. These changes *inhibit* the brain stem respiratory

center and thereby *oppose the effect of low P_{O_2} to stimulate respiration via the peripheral arterial chemoreceptors in the carotid and aortic bodies*. However, this inhibition fades away during the ensuing 2 to 5 days, allowing the respiratory center to respond with full force to the peripheral chemoreceptor stimulus from hypoxia, and ventilation increases to about five times normal.

The cause of this fading inhibition is believed to be mainly a reduction of bicarbonate ion concentration in the cerebrospinal fluid, as well as in the brain tissues. This reduction, in turn, decreases the pH in the fluids surrounding the chemosensitive neurons of the respiratory center, thus increasing the respiratory stimulatory activity of the center.

An important mechanism for the gradual decrease in bicarbonate concentration is compensation by the kidneys for the respiratory alkalosis, as discussed in Chapter 31. The kidneys respond to decreased P_{CO_2} by reducing hydrogen ion secretion and increasing bicarbonate excretion. This metabolic compensation for the respiratory alkalosis gradually reduces plasma and cerebrospinal fluid bicarbonate concentrations and pH toward normal and removes part of the inhibitory effect on respiration of a low hydrogen ion concentration. Thus, the respiratory centers are much more responsive to the peripheral chemoreceptor stimulus caused by the hypoxia after the kidneys compensate for the alkalosis.

Increase in Red Blood Cells and Hemoglobin Concentration During Acclimatization. As discussed in Chapter 33, hypoxia is a major stimulus for increasing red blood cell production. When a person remains exposed to low O_2 for weeks at a time, the hematocrit usually rises slowly from a normal value of 40% to 45% to an average of about 60%, with an average increase in whole blood hemoglobin concentration from a normal value of 15 g/dL to about 20 g/dL.

In addition, the blood volume also increases, often by 20% to 30%, and this increase, multiplied by the increased blood hemoglobin concentration, gives an increase in total body hemoglobin of 50% or more.

Increased Diffusing Capacity During Acclimatization. The normal diffusing capacity for O_2 through the pulmonary membrane is about 21 mL/mm Hg per minute, and this diffusing capacity can increase as much as 3-fold during exercise. A similar increase in diffusing capacity occurs at high altitudes.

Part of the increase results from increased pulmonary capillary blood volume, which expands the capillaries and increases the surface area through which O_2 can diffuse into the blood. Another part of this increase results from an increase in lung air volume, which further expands the surface area of the alveolar-capillary interface. A third part results from an increase in pulmonary arterial blood pressure, which forces blood into greater numbers of alveolar capillaries than normal, especially in the upper parts of the lungs, which are poorly perfused under usual conditions.

Peripheral Circulatory System Changes During Acclimatization—Increased Tissue Capillarity. The cardiac output (total blood flow to the tissues) often increases as much as 30% immediately after a person ascends to a high altitude. The elevated tissue blood flow and cardiac output serves as a compensatory response that helps maintain adequate oxygen delivery to the tissues. However, cardiac output then decreases back toward normal *over a period of weeks as the blood hematocrit increases*, so the amount of O_2 transported to the peripheral body tissues remains about normal.

Another circulatory adaptation is *growth of increased numbers of systemic circulatory capillaries* in the nonpulmonary tissues. This adaptive *angiogenesis* occurs especially in animals born and bred at high altitudes but less so in animals that become exposed to high altitudes later in life.

In active tissues exposed to chronic hypoxia, the increase in capillarity is especially marked. For example, capillary density in right ventricular muscle increases markedly because of the combined effects of hypoxia and excess workload on the right ventricle caused by pulmonary hypertension at high altitude.

Cellular Acclimatization. In animals native to altitudes of 13,000 to 17,000 feet, cell mitochondria and cellular oxidative enzyme systems are slightly more plentiful than in sea level inhabitants. Therefore, it is presumed that the tissue cells of high altitude–acclimatized human beings also can use O_2 more effectively than can their sea level counterparts.

HYPOXIA-INDUCIBLE FACTORS—A "MASTER SWITCH" FOR THE BODY'S RESPONSE TO HYPOXIA

Hypoxia-inducible factors (HIFs) are DNA-binding transcription factors that respond to decreased oxygen availability and activate several genes that encode proteins needed for adequate oxygen delivery to tissues and energy metabolism. HIFs are found in virtually all oxygen-breathing species, ranging from primitive worms to humans. Some of the genes controlled by HIFs, especially HIF-1, include the following:

- Genes associated with vascular endothelial growth factor, which stimulates angiogenesis
- Erythropoietin genes that stimulate red blood cell production
- Mitochondrial genes involved with energy utilization
- Glycolytic enzyme genes involved with anaerobic metabolism
- Genes that increase availability of nitric oxide, which causes pulmonary vasodilation

In the presence of adequate oxygen, the subunits of HIF required to activate various genes are downregulated and inactivated by specific HIF hydroxylases. During

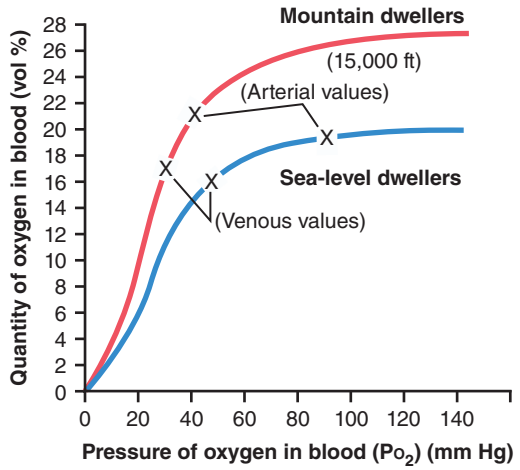

Figure 44.2 Oxygen-hemoglobin dissociation curves for blood of high-altitude residents *(red curve)* and sea level residents *(blue curve)*, showing the respective arterial and venous Po_2 levels and oxygen contents as recorded in their native surroundings. *(Data from Pan American Health Organization. Oxygen-dissociation curves for bloods of high-altitude and sea-level residents. Life at high altitudes. Washington, DC: Pan American Health Organization Scientific Publication No. 140; 1966.)*

hypoxia, the HIF hydroxylases are themselves inactive, allowing formation of a transcriptionally active HIF complex. Thus, the HIFs serve as a "master switch" that permits the body to respond appropriately to hypoxia.

NATURAL ACCLIMATIZATION OF NATIVE PEOPLE LIVING AT HIGH ALTITUDES

Many native people in the Andes and in the Himalayas live at altitudes above 13,000 feet. One group in the Peruvian Andes lives at an altitude of 17,500 feet and works in a mine at an altitude of 19,000 feet. Many of these natives are born at these high altitudes and live there all their lives. They are superior to even the best-acclimatized lowlanders in all aspects of acclimatization, even though the lowlanders might have lived at high altitudes for 10 or more years.

Acclimatization of the natives begins in infancy. The chest size is greatly increased, whereas the body size is somewhat decreased, giving a high ratio of ventilatory capacity to body mass. The hearts of natives, which from birth onward pump extra amounts of cardiac output, are also considerably larger than the hearts of lowlanders.

Delivery of O_2 by the blood to the tissues is also highly facilitated in these natives who live at high altitudes. For example, **Fig. 44.2** shows O_2-hemoglobin dissociation curves for natives who live at sea level and for their counterparts who live at 15,000 feet. Note that the arterial Po_2 in the natives at a high altitude is only 40 mm Hg but, because of the greater quantity of hemoglobin, the quantity of O_2 in their arterial blood is greater than that in the blood of the natives at the lower altitude. Note also that the venous Po_2 in the high-altitude natives is only 15 mm Hg less than the venous Po_2 for the lowlanders, despite the very low arterial Po_2, indicating that O_2 transport to the tissues is exceedingly effective in the naturally acclimatized high-altitude natives.

Table 44.2 Differences in Work Capacities

	Work Capacity (% of Normal)
Unacclimatized, working at 17,000 feet	50
Acclimatized for 2 months, working at 17,000 feet	68
Native living at 13,200 feet but working at 17,000 feet	87

REDUCED WORK CAPACITY AT HIGH ALTITUDES AND POSITIVE EFFECT OF ACCLIMATIZATION

In addition to the mental depression caused by hypoxia, the work capacity of all muscles, cardiac as well as skeletal muscle, is greatly decreased in a state of hypoxia. In general, work capacity is reduced in direct proportion to the decrease in maximum rate of O_2 uptake that the body can achieve.

To give an idea of the importance of acclimatization in increasing work capacity, consider the large differences in work capacities as a percentage of normal for unacclimatized and acclimatized people at an altitude of 17,000 feet, shown in **Table 44.2**. Thus, naturally acclimatized native persons can achieve a daily work output even at a high altitude almost equal to that of a lowlander at sea level, but even well-acclimatized lowlanders can almost never achieve this result.

Acute Mountain Sickness and High-Altitude Pulmonary Edema

Acute mountain sickness, a syndrome associated with fatigue, headache, dizziness, nausea, and vomiting, may develop in unacclimatized individuals after rapid ascent to altitudes greater than 8000 to 9000 feet. A small percentage of people who develop acute mountain sickness are severely affected and can die if not given O_2 or rapidly moved to a low altitude. The sickness begins from a few hours up to about 2 days after ascent. Two events frequently occur:

1. *Acute cerebral edema*. This edema is believed to result from local vasodilation of the cerebral blood vessels, which is caused by the hypoxia. Dilation of the arterioles increases blood flow into the capillaries, thus increasing capillary pressure, which in turn causes fluid to leak into the cerebral tissues. Hypoxia may also stimulate chemical factors such as vascular endothelial growth factor and inflammatory cytokines that contribute to edema by increasing endothelial cell permeability. The cerebral edema can then lead to severe disorientation and other effects related to cerebral dysfunction.
2. *Acute pulmonary edema*. The cause of acute pulmonary edema is still uncertain, but may be explained by the following. The severe hypoxia causes the pulmonary

arterioles to constrict powerfully, but the constriction is much greater in some parts of the lungs than in other parts, so more and more of the pulmonary blood flow is forced through fewer and fewer still unconstricted pulmonary vessels. The postulated result is that the capillary pressure in these areas of the lungs becomes especially high, and local edema occurs. Extension of the process to progressively more areas of the lungs leads to spreading pulmonary edema and severe pulmonary dysfunction that can be lethal. Allowing the person to breathe O_2 usually reverses the process within hours. The same chemical factors that have been suggested to increase capillary permeability in the brain may also contribute to increased pulmonary capillary permeability and edema in the lungs.

Chronic Mountain Sickness

Occasionally, a person who remains at a high altitude too long experiences *chronic mountain sickness*, in which the following effects occur:

1. The red blood cell mass and hematocrit become exceptionally high.
2. The pulmonary arterial pressure becomes elevated even more than the normal elevation that occurs during acclimatization.
3. The right side of the heart becomes greatly enlarged.
4. The peripheral arterial pressure begins to fall.
5. Congestive heart failure ensues.
6. Death often follows unless the person is moved to a lower altitude.

There are probably three main causes of this sequence of events:

1. The red blood cell mass becomes so great that the blood viscosity increases severalfold. This increased viscosity tends to *decrease* tissue blood flow so that O_2 delivery also begins to decrease.
2. The pulmonary arterioles become vasoconstricted because of the lung hypoxia. This vasoconstriction results from the hypoxic vascular constrictor effect that normally operates to divert blood flow from low-O_2 to high-O_2 alveoli, as explained in Chapter 39. However, because *all* the alveoli are now in the low-O_2 state, all the arterioles become constricted, the pulmonary arterial pressure rises excessively, and the right side of the heart fails.
3. The alveolar arteriolar spasm diverts much of the blood flow through nonalveolar pulmonary vessels, thus causing an excess of pulmonary shunt blood flow where the blood is poorly oxygenated, which further compounds the problem. Most people with this condition recover within days or weeks when they are moved to a lower altitude.

Effects of Acceleratory Forces on the Body in Aviation and Space Physiology

Because of rapid changes in velocity and direction of motion in airplanes or spacecraft, several types of acceleratory forces affect the body during flight. At the beginning of flight, simple linear acceleration occurs; at the end of flight, deceleration occurs; and every time the vehicle turns, centrifugal acceleration occurs.

Centrifugal Acceleratory Forces

When an airplane makes a turn, the force of centrifugal acceleration is determined by the following relationship:

$$f = \frac{mv^2}{r}$$

in which f is centrifugal acceleratory force, m is the mass of the object, v is velocity of travel, and r is the radius of curvature of the turn. As the velocity increases, the *force of centrifugal acceleration increases in proportion to the square of the velocity*. Also, the force of acceleration is *directly proportional to the sharpness of the turn (the smaller the radius)*.

Measurement of Acceleratory Force—"G Force." When an aviator is simply sitting in their seat, the force with which they are pressing against the seat results from the pull of gravity and is equal to the person's weight. The intensity of this force is said to be +1 G because it is equal to the pull of gravity. If the force with which the person presses against the seat becomes five times the normal weight during pullout from a dive, the force acting on the seat is +5 G.

If the airplane goes through an outside loop so that the person is held down by the seat belt, *negative G* is applied to the body. If the force with which the person is pulled away from the seat (held down by the seat belt) is equal to the weight of the body, the negative force is −1 G.

Effects of Centrifugal Acceleratory Force on the Body (Positive G)

Effects on the Circulatory System. The most important effect of centrifugal acceleration is on the circulatory system because blood is mobile and can be translocated by centrifugal forces.

When an aviator is subjected to *positive G*, blood is centrifuged toward the lowermost part of the body. Thus, if the centrifugal acceleratory force is +5 G and the person is in an immobilized standing position, the pressure in the veins of the feet becomes greatly increased (to ~450 mm Hg). In the sitting position, the pressure becomes nearly 300 mm Hg. In addition, as pressure in the vessels of the lower body increases, these vessels passively dilate so that a major portion of the blood from the upper body is translocated into the lower vessels. Because the heart cannot pump unless blood returns to it, the greater the quantity of blood "pooled" in this way in the lower body, the less is available for the cardiac output.

Fig. 44.3 shows the changes in systolic and diastolic arterial pressures (top and bottom curves, respectively) in the upper body when a centrifugal acceleratory force of +3.3 G is suddenly applied to a sitting person. Note that both these pressures fall below 22 mm Hg for the first few seconds after the acceleration begins but then return to a systolic pressure of about 55 mm Hg and a diastolic pressure of 20 mm Hg within another 10 to 15 seconds. This secondary recovery is caused mainly by activation of the baroreceptor reflexes.

Acceleration greater than 4 to 6 G causes "blackout" of vision within a few seconds and unconsciousness shortly thereafter. If this great degree of acceleration is continued, the person will die.

Effects on the Vertebrae. Extremely high acceleratory forces for even a fraction of a second can fracture the vertebrae. The degree of positive acceleration that the average person can withstand in the sitting position before vertebral fracture occurs is about 20 G.

Negative G. The effects of negative G on the body are less dramatic acutely but possibly more damaging permanently than the effects of positive G. An aviator can usually go through outside loops up to negative acceleratory forces of −4 to −5 G without causing permanent harm, although causing intense momentary hyperemia of the head. Occasionally, psychotic disturbances lasting for 15 to 20 minutes occur as a result of brain edema.

Occasionally, negative G forces can be so great (e.g., −20 G), and centrifugation of the blood into the head is so great, that the cerebral blood pressure reaches 300 to 400 mm Hg, sometimes causing small vessels on the surface of the head and in the brain to rupture. However, the vessels inside the cranium show less tendency for rupture than would be expected for the following reason. The cerebrospinal fluid is centrifuged toward the head at the same time that blood is centrifuged toward the cranial vessels, and the greatly increased pressure of the cerebrospinal fluid acts as a cushioning buffer on the outside of the brain to prevent intracerebral vascular rupture.

Because the eyes are not protected by the cranium, intense hyperemia occurs in them during strong negative G. As a result, the eyes often become temporarily blinded with what is called *redout.*

Protection of the Body Against Centrifugal Acceleratory Forces. Specific procedures and apparatus have been developed to protect aviators from circulatory collapse that might occur during positive G. First, if the aviator tightens their abdominal muscles to an extreme degree and leans forward to compress the abdomen, some of the pooling of blood in the large vessels of the abdomen can be prevented, delaying the onset of blackout. Also, special "anti-G" suits have been developed to prevent pooling of blood in the lower abdomen and legs. The simplest of these applies positive pressure to the legs and abdomen by inflating compression bags as the G force increases.

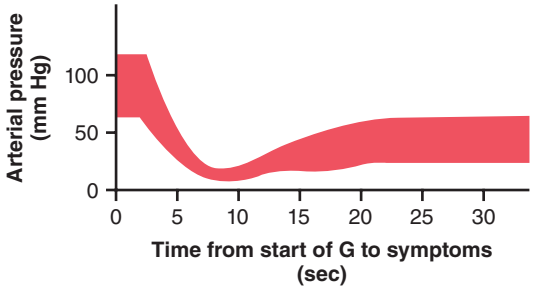

Figure 44.3 Changes in systolic *(top of curve)* and diastolic *(bottom of curve)* arterial pressures after abrupt and continuing exposure of a sitting person to an acceleratory force from top to bottom of 3.3 G. *(Data from Martin EE, Henry JP. Effects of time and temperature upon tolerance to positive acceleration.* J Aviation Med. *1951;22:382.)*

Effects of Linear Acceleratory Forces on the Body

Acceleratory Forces in Space Travel. Unlike an airplane, a spacecraft cannot make rapid turns, and therefore centrifugal acceleration is of little importance except when the spacecraft goes into abnormal gyrations. However, blast-off acceleration and landing deceleration can be tremendous; both are types of *linear acceleration*, with one being positive and the other negative.

Fig. 44.4 shows an approximate profile of acceleration during blastoff in a three-stage spacecraft, demonstrating that the first-stage booster causes acceleration as high as 9 G and the second-stage booster as high as 8 G. In the standing position, the human body could not withstand this much acceleration, but in a semi-reclining position *transverse to the axis of acceleration*, this amount of acceleration can be withstood easily, despite the fact that the acceleratory forces continue for as long as several minutes at a time. Therefore, the reason for the reclining seats used by astronauts can be understood.

Problems also occur during deceleration when the spacecraft reenters the atmosphere. A person traveling at Mach 1 (the speed of sound and of fast airplanes) can be safely decelerated in a distance of about 0.12 mile, whereas a person traveling at a speed of Mach 100 (a speed possible in interplanetary space travel) would require a distance of about 10,000 miles for safe deceleration. The principal reason for this difference is that the total amount of energy that must be dispelled during deceleration is proportional to the *square* of the velocity, which alone increases the required distance for decelerations between Mach 1 versus Mach 100 by about 10,000-fold. Therefore, deceleration must be accomplished much more slowly from a high velocity than from a lower velocity.

Deceleratory Forces Associated With Parachute Jumps. When the parachuting aviator leaves the airplane, the velocity of fall is at first exactly 0 feet/sec. However, because of the acceleratory force of gravity, within 1 second the velocity of fall is 32 feet/sec (if there is no air resistance), in 2 seconds it is 64 feet/sec, and so on. As the velocity of fall increases, the air resistance tending to slow the fall also increases. Finally, the deceleratory force of the air resistance exactly balances the acceleratory force of gravity, so after falling for about 12 seconds, the person

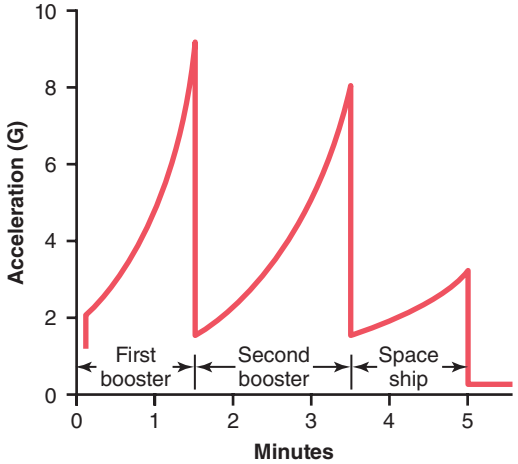

Figure 44.4 Acceleratory forces during takeoff of a spacecraft.

will be falling at a terminal velocity of 109 to 119 miles/hr (175 feet/sec). If the parachutist has already reached terminal velocity before opening the parachute, an "opening shock load" of up to 1200 pounds could occur on the parachute shrouds.

The usual-sized parachute slows the fall of the parachutist to about one-ninth the terminal velocity. In other words, the speed of landing is about 20 feet/sec, and the force of impact against the earth is 1/81, the impact force without a parachute. Even so, the force of impact is still great enough to cause considerable damage to the body unless the parachutist is properly trained in landing. Actually, the force of impact with the earth is about the same as that which would be experienced by jumping without a parachute from a height of about 6 feet. Unless forewarned, the parachutist will be tricked by their senses into striking the earth with extended legs, and this position, on landing, will result in tremendous deceleratory forces along the skeletal axis of the body, resulting in potential fracture of the pelvis, vertebrae, or leg. Consequently, the trained parachutist strikes the earth with knees bent but muscles taut to cushion the shock of landing. With newer sport parachutes (rectangular canopies) that flare at the end of the descent, the final deceleration is even greater so that the landing is relatively gentle.

"Artificial Climate" in the Sealed Spacecraft

Because there is no atmosphere in outer space, an artificial atmosphere and climate must be produced in a spacecraft. Most importantly, the O_2 concentration must remain high enough and the CO_2 concentration low enough to prevent suffocation. In some earlier space missions, a capsule atmosphere containing pure O_2 at about 260 mm Hg pressure was used; however, in modern space travel, gases about equal to those in normal air are used, with four times as much nitrogen as O_2 and a total pressure of 760 mm Hg. The presence of nitrogen in the mixture greatly diminishes the likelihood of fire and explosion. It also protects against development of local patches of lung atelectasis that often occur when breathing pure O_2 because O_2 is absorbed rapidly when small bronchi are temporarily blocked by mucous plugs.

For space travel lasting more than several months, it is impractical to carry along an adequate O_2 supply. For this reason, recycling techniques have been proposed to use the same O_2 over and over again. Some recycling processes depend on purely physical procedures, such as electrolysis of water to release O_2. Others depend on biological methods, such as use of algae with their large store of chlorophyll to release O_2 from CO_2 by the process of photosynthesis. A completely satisfactory system for recycling has yet to be achieved.

Weightlessness (Microgravity) in Space

A person in an orbiting satellite or a nonpropelled spacecraft experiences *weightlessness*, or a state of near-zero G force, sometimes called *microgravity*. That is, the person is not drawn toward the bottom, sides, or top of the spacecraft but simply floats inside its chambers. The cause of this weightlessness is not failure of gravity to pull on the body because gravity from any nearby heavenly body is still active. However, the gravity acts on the spacecraft and the person at the same time so that both are pulled with exactly the same acceleratory forces and in the same direction. For this reason, the person simply is not attracted toward any specific wall of the spacecraft.

Physiological Challenges of Weightlessness (Microgravity). The physiological challenges of weightlessness have not proved to be of much significance as long as the period of weightlessness is not too long. Many of the problems that do occur are related to three effects of the weightlessness: (1) motion sickness during the first few days of travel; (2) translocation of fluids within the body because of failure of gravity to cause normal hydrostatic pressures; and (3) diminished physical activity because no strength of muscle contraction is required to oppose the force of gravity.

Almost 50% of astronauts experience motion sickness, with nausea and sometimes vomiting, during the first 2 to 5 days of space travel. This motion sickness probably results from an unfamiliar pattern of motion signals arriving in the equilibrium centers of the brain and, at the same time, lack of gravitational signals.

The observed effects of a prolonged stay in space are the following: (1) decrease in blood volume; (2) decrease in red blood cell mass; (3) decrease in muscle strength and work capacity; (4) decrease in maximum cardiac output; and (5) loss of calcium and phosphate from the bones, as well as loss of bone mass. Most of these same effects also occur in people who lie in bed for an extended period. For this reason, exercise programs are carried out by astronauts during prolonged space missions.

In previous space laboratory expeditions, in which the exercise program was less vigorous, the astronauts had severely decreased work capacities for the first few days after returning to Earth. They also tended to faint (and still do, to some extent) when they stood up during the first day or so after return to gravity because of diminished blood volume and diminished responses of the arterial pressure control mechanisms.

Cardiovascular, Muscle, and Bone "Deconditioning" During Prolonged Exposure to Weightlessness. During very long space flights and prolonged exposure to microgravity, gradual "deconditioning" effects occur on the cardiovascular system, skeletal muscles, and bone, despite rigorous exercise during the flight. Studies of astronauts on space flights lasting several months have shown that they may lose as much 1.0% of their bone mass each month, even though they continue to exercise. Substantial atrophy of cardiac and skeletal muscles also occurs during prolonged exposure to a microgravity environment.

One of the most serious effects is cardiovascular "deconditioning," which includes decreased work capacity, reduced blood volume, impaired baroreceptor reflexes, and reduced orthostatic tolerance. These changes greatly limit the astronaut's ability to stand upright or perform normal daily activities after returning to the full gravitational force of Earth.

Astronauts returning from space flights lasting 4 to 6 months are also susceptible to bone fractures and may require several weeks before they return to preflight cardiovascular, bone, and muscle fitness. As space flights become longer in preparation for possible human exploration of

Mars or other planets, the effects of prolonged microgravity could pose a very serious threat to astronauts after they land, especially in the event of an emergency landing. Therefore, considerable research effort has been directed toward developing countermeasures, in addition to exercise, that can prevent or more effectively attenuate these changes. One such countermeasure that is being tested is the application of intermittent "artificial gravity" caused by short periods (e.g., 1 hour each day) of centrifugal acceleration of the astronauts while they sit in specially designed short-arm centrifuges that create forces of up to 2 to 3 G.

Physiology of Deep-Sea Diving and Other Hyperbaric Conditions

When people descend beneath the sea, the pressure around them increases progressively as they go to greater depths. To keep the lungs from collapsing, air must be supplied at very high pressure to keep them inflated. This maneuver exposes the blood in the lungs to extremely high alveolar gas pressures, a condition called *hyperbarism*. Beyond certain limits, these high pressures cause major alterations in body physiology and can be lethal.

Relationship of Pressure to Sea Depth. A column of seawater 33 feet (10.1 meters) deep exerts about the same pressure at its bottom as the pressure of the atmosphere above the sea. Therefore, a person 33 feet beneath the ocean surface is exposed to 2 atmospheres (2 atm) pressure, with 1 atm of pressure caused by the weight of the air above the water and the second atmosphere caused by the weight of the water. At 66 feet, the pressure is 3 atm, and so forth, in accord with the table in **Fig. 45.1**.

Effect of Sea Depth on the Volume of Gases—Boyle's Law. Another important effect of depth is compression of gases to smaller and smaller volumes. The illustration in **Fig. 45.1** shows a bell jar at sea level containing 1 liter of air. At 33 feet beneath the sea, where the pressure is 2 atm, the volume has been compressed to only a half-liter, and at 8 atm (233 feet) it has been compressed to one-eighth liter. Thus, the volume to which a given quantity of gas is compressed is inversely proportional to the pressure. This principle of physics is called *Boyle's law*, and it is extremely important in diving physiology because increased pressure can collapse the air chambers of the diver's body, especially the lungs, and may cause serious damage.

Often in this chapter it is necessary to refer to *actual volume* versus *sea level volume*. For example, we might speak of an actual volume of 1 liter at a depth of 300 feet; this is the same *quantity* of air as a sea level volume of 10 liters.

EFFECT OF HIGH PARTIAL PRESSURES OF INDIVIDUAL GASES ON THE BODY

The individual gases to which a diver is exposed when breathing air are *nitrogen*, O_2, and CO_2; each of these, at times, can cause significant physiological effects at high pressures.

Nitrogen Narcosis at High Nitrogen Pressures

About four-fifths of the air is nitrogen. At sea level pressure, the nitrogen has no significant effect on bodily function, but at high pressures, it can cause varying degrees of narcosis. When the diver remains beneath the sea for 1 hour or more and is breathing compressed air, the depth at which the first symptoms of mild narcosis appear is about 120 feet. At this level, the diver begins to exhibit light-headedness, euphoria, impaired judgment, and loss of fine motor coordination. At 150 to 200 feet, the diver becomes drowsy. At 200 to 250 feet, the person's strength wanes considerably, and the diver often becomes too clumsy to perform the work required. Beyond 250 to 300 feet, the diver usually experiences severe symptoms and may lose consciousness as a result of nitrogen narcosis if they remain at these depths too long.

Nitrogen narcosis has characteristics similar to those of alcohol intoxication, and for this reason it has frequently been called "raptures of the depths." The mechanism of this narcotic effect is believed to be the same as that of most other gas anesthetics. That is, it dissolves in the fatty substances in neuronal membranes and, because of its *physical* effect on altering ionic conductance through the membranes, it reduces neuronal excitability. Ascent to a shallower depth reverses the narcosis within a few minutes, with no known long-term effects if the ascent is not too rapid.

Oxygen Toxicity at High Pressures

Effect of Very High P_{O_2} on Blood Oxygen Transport. When the P_{O_2} in the blood rises above 100 mm Hg, the amount of O_2 dissolved in the water of the blood increases markedly. This effect is shown in **Fig. 45.2**, which depicts the same O_2-hemoglobin dissociation curve as shown in Chapter 41 but with the alveolar P_{O_2} extended to more than 3000 mm Hg. Also depicted by the lowest curve (green) in the figure is the *volume of O_2 dissolved in the fluid of the blood* at each P_{O_2} level. Note that in the normal range of alveolar P_{O_2} (<120 mm Hg), almost none of the total O_2 in the blood is accounted for by dissolved O_2, but as the O_2 pressure rises into the thousands of mm Hg, a large portion of the total O_2 is then

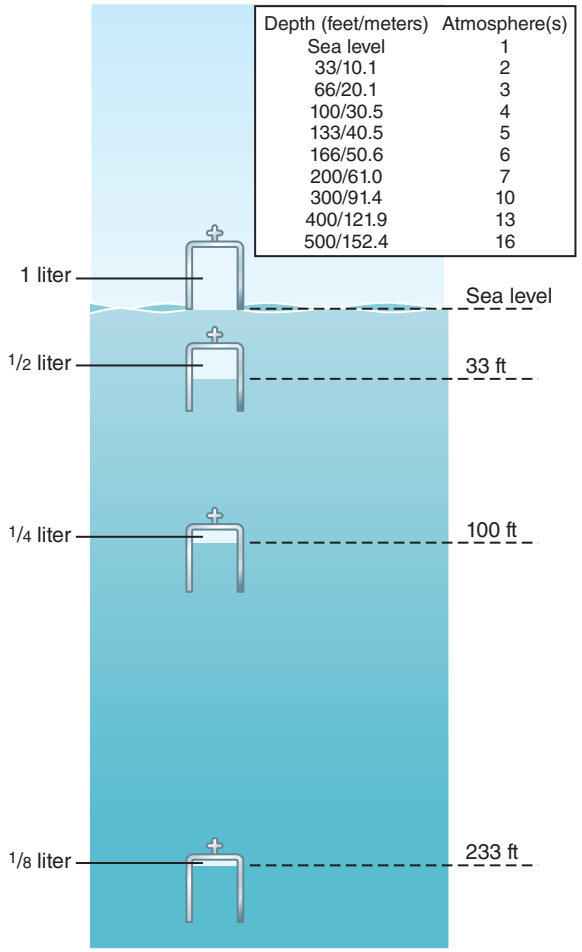

Figure 45.1 Effect of sea depth on pressure *(top)* and on gas volume *(bottom)*.

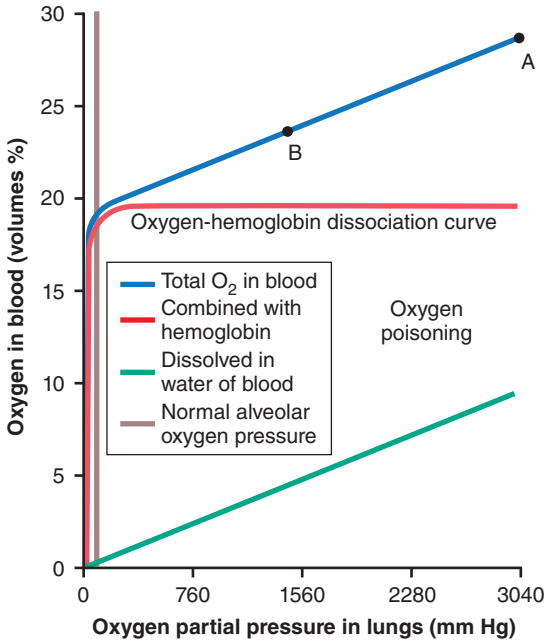

Figure 45.2 Quantity of O_2 dissolved in the fluid of the blood and in combination with hemoglobin at very high P_{O_2} values.

dissolved in the water of the blood, in addition to that bound with hemoglobin.

Effect of High Alveolar P_{O_2} on Tissue P_{O_2}. Let us assume that the P_{O_2} in the lungs is about 3000 mm Hg (4 atm pressure). Referring to **Fig. 45.2**, one finds that this pressure represents a total O_2 content in each 100 mL of blood of about 29 volumes percent, as demonstrated by point **A** in the figure, which means 20 volumes percent bound with hemoglobin and 9 volumes percent dissolved in the blood water. As this blood passes through the tissue capillaries, and the tissues use their normal amount of O_2, about 5 mL from each 100 mL of blood, the O_2 content on leaving the tissue capillaries is still 24 volumes percent (point **B** in the figure). At this point, the P_{O_2} is approximately 1200 mm Hg, which means that O_2 is delivered to the tissues at this extremely high pressure instead of at the normal value of 40 mm Hg. Thus, once the alveolar P_{O_2} rises above a critical level, the hemoglobin-O_2 buffer mechanism (discussed in Chapter 41) is no longer capable of keeping the tissue P_{O_2} in the normal safe range, between 20 and 60 mm Hg.

Acute Oxygen Poisoning. The extremely high tissue P_{O_2} that occurs when O_2 is breathed at a very high alveolar O_2 pressure can be detrimental to many of the body's tissues. For example, breathing O_2 at 4 atm pressure of O_2 (P_{O_2} = 3040 mm Hg) will cause *brain seizures followed by coma* in most people within 30 to 60 minutes. The seizures often occur without warning and, for obvious reasons, are likely to be lethal to divers submerged beneath the sea.

Other symptoms encountered in acute O_2 poisoning include nausea, muscle twitchings, dizziness, disturbances of vision, irritability, and disorientation. Exercise greatly increases the diver's susceptibility to O_2 toxicity, causing symptoms to appear much earlier and with far greater severity than in the resting person.

Excessive Intracellular Oxidation as a Cause of Nervous System Oxygen Toxicity—Oxidizing Free Radicals. Molecular O_2 has little capability of oxidizing other chemical compounds. Instead, it must first be converted into an active form of oxygen. There are several forms of active oxygen, called *oxygen free radicals*. One of the most important of these is the *superoxide free radical* O_2^-, and another is the *peroxide radical* in the form of *hydrogen peroxide*. Even when the tissue P_{O_2} is normal at the level of 40 mm Hg, small amounts of free radicals are continually being formed from the dissolved O_2. Fortunately, the tissues also contain several enzymes that rapidly remove these free radicals, including *peroxidases, catalases*, and *superoxide dismutases*. Therefore, as long as the hemoglobin-O_2 buffering mechanism maintains a normal tissue P_{O_2}, the oxidizing free radicals are usually removed rapidly enough that they have little or no effect in the tissues.

Above a critical alveolar P_{O_2} (i.e., > ~2 atm P_{O_2}), the hemoglobin-O_2 buffering mechanism fails, and the tissue P_{O_2} can then rise to hundreds or thousands of mm Hg. At

these high levels, the amounts of oxidizing free radicals literally swamp the enzyme systems designed to remove them, and at this point they can have serious destructive and even lethal effects on the cells. One of the principal effects is to oxidize the polyunsaturated fatty acids that are essential components of many of the cell membranes. Another effect is to oxidize some of the cellular enzymes, thus damaging the cellular metabolic systems severely. The nervous tissues are especially susceptible because of their high lipid content. Therefore, most of the acute lethal effects of acute O_2 toxicity are caused by brain dysfunction.

Chronic Oxygen Poisoning Causes Pulmonary Disability. A person can be exposed to only 1 atm pressure of O_2 almost indefinitely without developing the *acute* oxygen toxicity of the nervous system just described. However, damage to the linings of the bronchi and alveoli begins to develop after about 12 hours of 1 atm O_2 exposure, leading to *lung passageway congestion, pulmonary edema*, and *atelectasis*. The reason for this effect in the lungs but not in other tissues is that the air spaces of the lungs are directly exposed to the high O_2 pressure, but O_2 is delivered to the other body tissues at almost normal Po_2 because of the hemoglobin-O_2 buffer system.

Carbon Dioxide Toxicity at Great Depths Underwater

If the diving gear is properly designed and functions properly, the diver has no problem due to toxicity because depth alone does not increase the CO_2 partial pressure in the alveoli. This is true because depth does not increase the rate of CO_2 production in the body, and as long as the diver continues to breathe a normal tidal volume and expires the CO_2 as it is formed, alveolar CO_2 pressure will be maintained at a normal value.

In certain types of diving gear, however, such as the diving helmet and some types of rebreathing apparatuses, CO_2 can build up in the dead space air of the apparatus and be rebreathed by the diver. Up to an alveolar CO_2 pressure (P_{CO_2}) of about 80 mm Hg, twice that in normal alveoli, the diver usually tolerates this buildup by increasing the minute respiratory volume a maximum of 8- to 11-fold to compensate for the increased CO_2. Beyond 80 mm Hg alveolar P_{CO_2}, however, the situation becomes intolerable, and eventually the respiratory center begins to be depressed, rather than excited, because of the negative tissue metabolic effects of high P_{CO_2}. The diver's respiration then begins to fail rather than compensate. In addition, the diver experiences severe respiratory acidosis and varying degrees of lethargy, narcosis, and finally even anesthesia.

Decompression of the Diver After Excess Exposure to High Pressure

When a person breathes air under high pressure for a long time, the amount of nitrogen dissolved in the body fluids increases. This is because blood flowing through the pulmonary capillaries becomes saturated with nitrogen to the same high pressure as that in the alveolar breathing mixture and, over several more hours, enough nitrogen is carried to all the tissues of the body to raise their tissue nitrogen partial pressure to equal the nitrogen pressure in the breathing air.

Because nitrogen is not metabolized by the body, it remains dissolved in all the body tissues until the nitrogen pressure in the lungs is decreased back to some lower level, at which time the nitrogen can be removed by the reverse respiratory process. However, this removal often takes hours to occur and is the source of multiple problems, collectively called *decompression sickness*.

Volume of Nitrogen Dissolved in the Body Fluids at Different Depths. At sea level, almost exactly 1 liter of nitrogen is dissolved in the entire body. Slightly less than one-half of this nitrogen is dissolved in the body water, and a little more than one-half is dissolved in the body fat, because nitrogen is five times as soluble in fat as in water.

After the diver has become saturated with nitrogen, the *sea level volume of nitrogen* dissolved in the body at different depths is as follows:

Feet	Liters
0	1
33	2
100	4
200	7
300	10

Several hours are required for the gas pressures of nitrogen in all the body tissues to come nearly to equilibrium with the gas pressure of nitrogen in the alveoli. The blood does not flow rapidly enough, and the nitrogen does not diffuse rapidly enough, to cause instantaneous equilibrium. The nitrogen dissolved in the water of the body comes to almost complete equilibrium in less than 1 hour, but the fat tissue, which requires five times as much transport of nitrogen and has a relatively poor blood supply, reaches equilibrium only after several hours. Thus, if a person remains under water at a deep level for only a few minutes, not much nitrogen dissolves in the body fluids and tissues, whereas if the person remains at a deep level for several hours, both the body water and body fat become saturated with nitrogen.

Decompression Sickness (Also Known as Bends, Compressed Air Sickness, Caisson Disease, Diver's Paralysis, Dysbarism). If a diver has been beneath the sea long enough that large amounts of nitrogen have dissolved in the body, and the diver then suddenly comes back to the surface of the sea, significant quantities of nitrogen bubbles can develop in the body fluids, either intracellularly or extracellularly, and can cause minor or serious damage in almost any area of the body, depending on the number and sizes of bubbles formed. This phenomenon is called *decompression sickness*.

The principles underlying bubble formation are shown in **Fig. 45.3**. In **Fig. 45.3A**, the diver's tissues have become equilibrated to a high *dissolved nitrogen pressure* (PN_2 = 3918 mm Hg), about 6.5 times the normal amount of nitrogen in the tissues. As long as the diver remains deep beneath the sea, the pressure against the outside of the body (5000 mm Hg) compresses all the body tissues sufficiently to keep the excess nitrogen gas dissolved. However, when the diver suddenly rises to sea level (**Fig. 45.3B**), the pressure on the outside of the body becomes only 1 atm (760 mm Hg), while the gas pressure inside the body fluids is the sum of the pressures of water vapor, CO_2, O_2, and nitrogen, or a total of 4065 mm Hg, 97% of which is caused by the nitrogen. Obviously, this total value of 4065 mm Hg is far greater than the 760-mm Hg pressure on the outside of the body. Therefore, the gases can escape from the dissolved state and form bubbles, composed almost entirely of nitrogen, both in the tissues and in the blood, where they plug many small blood vessels. The bubbles may not appear for many minutes to hours because sometimes the gases can remain dissolved in the "supersaturated" state for hours before bubbling.

Symptoms of Decompression Sickness ("Bends"). The symptoms of decompression sickness are caused by gas bubbles blocking many blood vessels in different tissues. At first, only the smallest vessels are blocked by minute bubbles, but as the bubbles coalesce, progressively larger vessels are affected. Tissue ischemia and sometimes tissue death result.

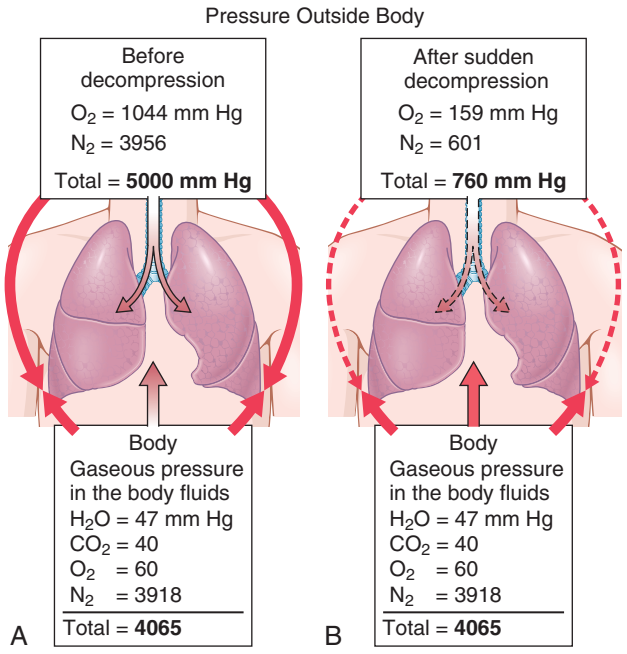

Figure 45.3 Gaseous pressures inside and outside the body showing (A) saturation of the body to high gas pressures when breathing air at a total pressure of 5000 mm Hg and (B) the great excesses of intrabody pressures responsible for bubble formation in the tissues when the lung intraalveolar pressure is suddenly returned from 5000 mm Hg to the normal pressure of 760 mm Hg.

In most people with decompression sickness, the symptoms are pain in the joints and muscles of the legs and arms, affecting 85% to 90% of persons who experience decompression sickness. The joint pain accounts for the term "bends" that is often used to describe this condition.

In 5% to 10% of people with decompression sickness, nervous system symptoms occur, ranging from dizziness in about 5% to paralysis or collapse and unconsciousness in as many as 3%. The paralysis may be temporary, but in some cases, damage is permanent.

About 2% of people with decompression sickness experience "the chokes," caused by massive numbers of microbubbles plugging the capillaries of the lungs. This condition is characterized by serious shortness of breath, often followed by severe pulmonary edema and, occasionally, death.

Nitrogen Elimination From the Body; Decompression Tables. If a diver is brought to the surface slowly, enough of the dissolved nitrogen can usually be eliminated by expiration through the lungs to prevent decompression sickness. About two-thirds of the total nitrogen is liberated in 1 hour, and about 90% is liberated in 6 hours.

Tables that detail procedures for safe decompression have been prepared by the US Navy. To give the reader an idea of the decompression process, a diver who has been breathing air and has been underwater for 60 minutes at a depth of 190 feet undergoes decompression according to the following schedule:

- 10 minutes at 50-feet depth
- 17 minutes at 40-feet depth
- 19 minutes at 30-feet depth
- 50 minutes at 20-feet depth
- 84 minutes at 10-feet depth

Thus, for a work period on the sea bottom of only 1 hour, the total time for decompression is about 3 hours.

Tank Decompression and Treatment of Decompression Sickness. Another procedure widely used for decompression of professional divers is to put the diver into a pressurized tank and then gradually lower the pressure back to normal atmospheric pressure, using essentially the same time schedule as noted earlier.

Tank decompression is even more important for treating people in whom symptoms of decompression sickness develop minutes or even hours after they have returned to the surface. In this case, the diver undergoes recompression immediately to a deep level, and then decompression is carried out over a period several times as long as the usual decompression period.

"Saturation Diving" and Use of Helium-Oxygen Mixtures in Deep Dives. When divers must work at very deep levels—between 250 feet and nearly 1000 feet—they frequently live in a large compression tank for days or weeks at a time, remaining compressed at a pressure level near that at which they will be working. This procedure keeps the tissues and fluids of the body saturated with the gases to which they will be exposed while diving. Then, when they return to the same tank after working, there are no significant changes in pressure, so decompression bubbles do not occur.

In very deep dives, especially during saturation diving, helium is usually used in the gas mixture instead of nitrogen for three reasons: (1) it has only about one-fifth the narcotic effect of nitrogen; (2) only about one-half as much volume of helium dissolves in the body tissues as nitrogen, and the volume that does dissolve diffuses out of the tissues during decompression several times as rapidly as does nitrogen, thus reducing the problem of decompression sickness; and (3) the low density of helium (one-seventh the density of nitrogen) keeps the airway resistance for breathing at a minimum, which is very important because highly compressed nitrogen is so dense that airway resistance can become extreme, sometimes making the work of breathing beyond endurance.

In very deep dives, it is also important to reduce the O_2 concentration in the gaseous mixture because otherwise O_2 toxicity would result. For example, at a depth of 700 feet (22 atm pressure), a 1% O_2 mixture will provide all the O_2 required by the diver, whereas a 21% mixture of O_2 (the percentage in air) delivers a P_{O_2} to the lungs of more than 4 atm, a level very likely to cause seizures in as little as 30 minutes.

SELF-CONTAINED UNDERWATER BREATHING APPARATUS (SCUBA) DIVING

Before the 1940s, almost all diving was done using a diving helmet connected to a hose through which air was pumped to the diver from the surface. Then, in 1943, the French explorer Jacques Cousteau popularized a *self-contained underwater breathing apparatus*, known as SCUBA. The type of SCUBA used in more than 99% of all sports and commercial diving is the *open-circuit demand system* shown in **Fig. 45.4**. This system consists of the following components: (1) one or more tanks of compressed air or some other breathing mixture; (2) a first-stage "reducing" valve for reducing the very high pressure from the tanks to a low pressure level; (3) a combination inhalation "demand" valve and exhalation valve that allows air to be pulled into the lungs with slight negative pressure of breathing and then to be exhaled into the sea at a pressure level slightly positive to the surrounding water pressure; and (4) a mask and tube system with small "dead space."

The demand system operates as follows. The first-stage reducing valve reduces the pressure from the tanks so that the air delivered to the mask has a pressure only a few mm Hg greater than the surrounding water pressure. The breathing mixture does not flow continually into the mask. Instead, with each inspiration, slight extra negative pressure in the demand valve of the mask pulls the diaphragm of the valve open, automatically releasing air from the tank into the mask and lungs. In this way, only the amount of air needed for inhalation enters the mask. Then, on expiration, the air cannot go back into the tank but, instead, is expired into the water.

The most important problem with SCUBA is the limited amount of time a diver can remain beneath the water surface; For example, only a few minutes are possible at a 200-foot depth. The reason for this limitation is that tremendous airflow from the tanks is required to wash CO_2 out of the lungs—the greater the depth, the greater the airflow in terms of *quantity* of air per minute required because the *volumes* have been compressed to small sizes.

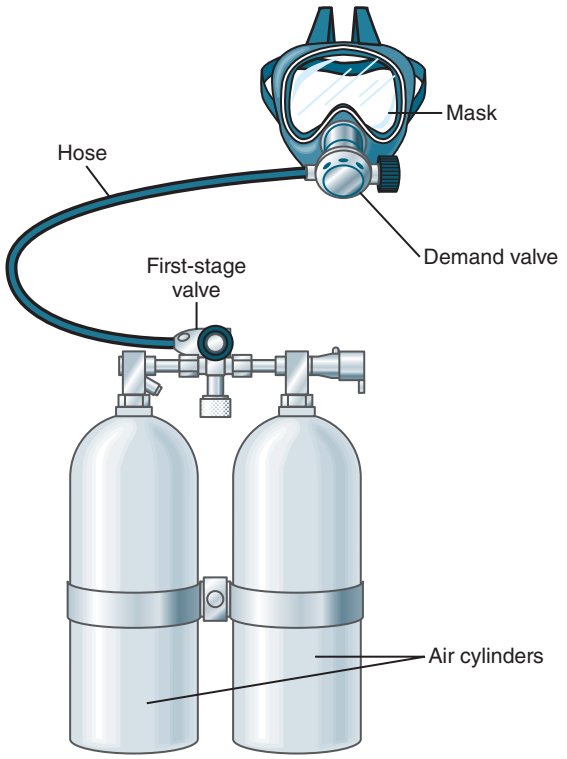

Figure 45.4 Open-circuit demand type of SCUBA (self-contained underwater breathing apparatus).

Special Physiological Problems in Submarines.

Escape From Submarines. Essentially the same problems encountered in deep sea diving are often found in relation to submarines, especially when it is necessary to escape from a submerged submarine. Escape is possible from as deep as 300 feet without use of any apparatus. However, proper use of rebreathing devices, especially when using helium, can theoretically allow escape from as deep as 600 feet or perhaps more.

One of the major problems of escape is prevention of air embolism. As the person ascends, the gases in the lungs expand and sometimes rupture a pulmonary blood vessel, forcing the gases to enter the vessel and causing air embolism of the circulation. Therefore, as the person ascends, they must make a special effort to exhale continually.

Health Problems in the Submarine Internal Environment. Except for escape, submarine medicine generally centers on several engineering problems to keep hazards out of the internal environment. First, in atomic submarines, there is the problem of radiation hazards, but with appropriate shielding, the amount of radiation received by the crew submerged beneath the sea has been less than the normal amount of radiation received above the surface of the sea from cosmic rays.

Second, poisonous gases, on occasion, escape into the atmosphere of the submarine and must be controlled rapidly. For example, during several weeks' submergence, cigarette smoking by the crew can liberate enough carbon monoxide, if not removed rapidly, to cause carbon monoxide poisoning. On occasion, even Freon gas has been found to diffuse out of refrigeration systems in sufficient quantity to cause toxicity.

Hyperbaric Oxygen Therapy

The intense oxidizing properties of high-pressure O_2 *(hyperbaric oxygen)* can have valuable therapeutic effects in several important clinical conditions. Therefore, large pressure tanks are now available in many medical centers into which patients can be placed and treated with hyperbaric O_2. The O_2 is usually administered at P_{O_2} values of 2 to 3 atm pressure through a mask or intratracheal tube, whereas the gas around the body is normal air compressed to the same high-pressure level.

The same oxidizing free radicals responsible for O_2 toxicity are also believed to be responsible for at least some of the therapeutic benefits. One successful use of hyperbaric O_2 has been for treatment of *gas gangrene*. The bacteria that cause this condition, *clostridial organisms*, grow best under anaerobic conditions and stop growing at O_2 pressures greater than about 70 mm Hg. Therefore, hyperbaric oxygenation of the tissues can frequently stop the infectious process entirely and thus convert a condition that formerly was almost 100% fatal into one that is cured in most cases by early treatment with hyperbaric therapy.

Other conditions in which hyperbaric O_2 therapy may be valuable include decompression sickness, arterial gas embolism, carbon monoxide poisoning, osteomyelitis, and myocardial infarction.

CHAPTER 46

Organization of the Nervous System, Basic Functions of Synapses and Neurotransmitters

The nervous system is unique in the vast complexity of thought processes and control actions that it can perform. Each minute it receives literally millions of bits of information from the different sensory nerves and sensory organs and then integrates all of this input to determine responses of the body.

Before beginning this discussion of the nervous system, the reader should review Chapters 5 and 7, which present the principles of membrane potentials and transmission of signals in nerves and through neuromuscular junctions.

GENERAL DESIGN OF THE NERVOUS SYSTEM

CENTRAL NERVOUS SYSTEM NEURON: THE BASIC FUNCTIONAL UNIT

The central nervous system is estimated to contain *80 to 100 billion neurons*. **Fig. 46.1** shows a typical neuron of a type found in the brain motor cortex. Incoming signals enter this neuron through synapses located mostly on the neuronal dendrites, but also on the cell body. For different types of neurons, there may be only a few hundred or as many as 200,000 synaptic connections from input fibers. In contrast, the output signal travels via a single axon leaving the neuron. This axon may then have many separate branches to other parts of the nervous system or peripheral body.

A special feature of most synapses is that the signal normally passes only in the forward direction, from the axon of a preceding neuron to dendrites on cell membranes of subsequent neurons. This feature forces the signal to travel in required directions to perform specific nervous functions.

SENSORY PART OF THE NERVOUS SYSTEM—SENSORY RECEPTORS

Most activities of the nervous system are initiated by sensory experiences that excite *sensory receptors*, including visual receptors in the eyes, auditory receptors in the ears, tactile receptors on the surface of the body, or other types of receptors. These sensory experiences can cause immediate reactions from the brain, or memories of the experiences can be stored in the brain for minutes, weeks, or years and determine bodily reactions at some future date.

Fig. 46.2 shows the *somatic* portion of the sensory system, which transmits sensory information from the receptors of the entire body surface and from some deep structures. This information enters the central nervous system through peripheral nerves and is conducted immediately to multiple sensory areas in (1) the spinal cord at all levels; (2) the reticular substance of the medulla, pons, and mesencephalon of the brain; (3) the cerebellum; (4) the thalamus; and (5) areas of the cerebral cortex.

MOTOR PART OF THE NERVOUS SYSTEM—EFFECTORS

The nervous system controls various bodily activities by controlling (1) contraction of appropriate skeletal muscles throughout the body; (2) contraction of smooth muscle in the internal organs; and (3) secretion of active chemical substances by both exocrine and endocrine glands in many parts of the body. These activities are collectively called *motor functions* of the nervous system, and the muscles and glands are called *effectors* because they are the actual anatomical structures that perform the functions dictated by the nerve signals.

Fig. 46.3 shows the *"skeletal" motor nerve axis* of the nervous system for controlling skeletal muscle contraction. Operating parallel to this axis is another system, called the *autonomic nervous system*, for controlling the heart, smooth muscles, glands, and other internal bodily systems; this system is discussed in Chapter 61.

Note in **Fig. 46.2** and **Fig. 46.3** that the skeletal muscles can be controlled from many levels of the central nervous system, including (1) the spinal cord; (2) the reticular substance of the medulla, pons, and mesencephalon; (3) the basal ganglia; (4) the cerebellum; and (5) the motor cortex. Each of these areas has its own specific role. The lower regions are concerned primarily with automatic, instantaneous muscle responses to sensory stimuli, and the higher regions are concerned with deliberate complex muscle movements controlled by thought processes of the brain.

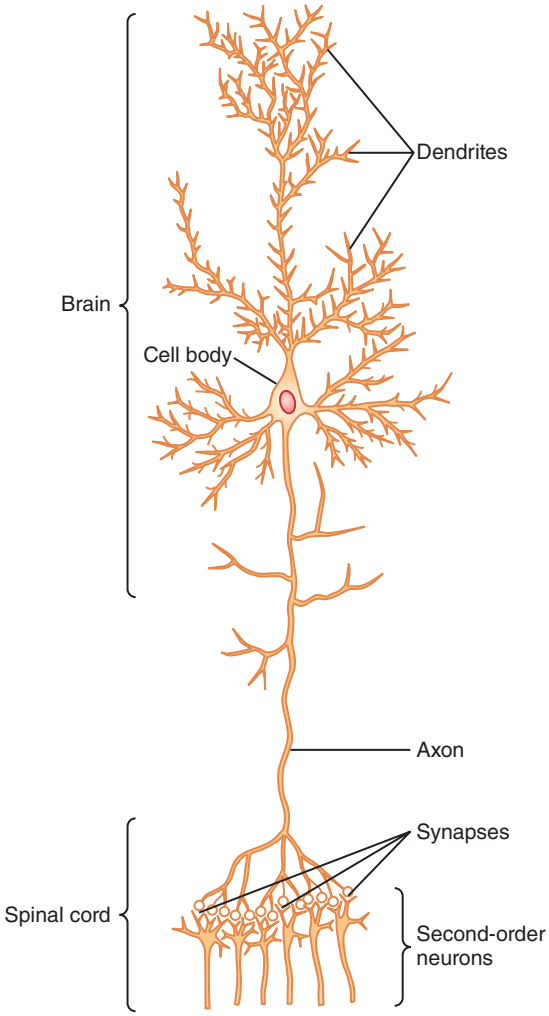

Figure 46.1 Structure of a large neuron in the brain, showing its important functional parts.

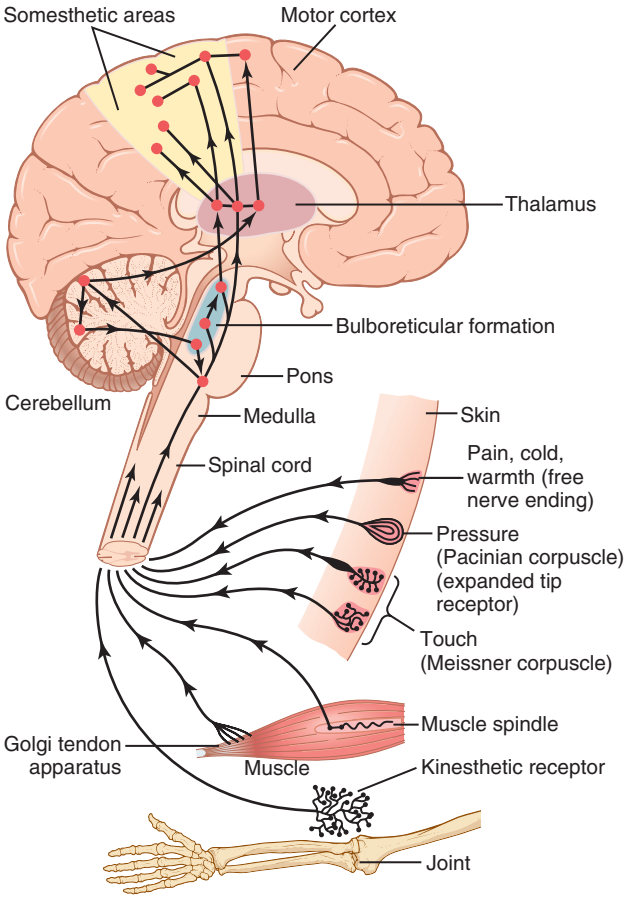

Figure 46.2 Somatosensory axis of the nervous system.

PROCESSING OF INFORMATION—INTEGRATIVE FUNCTION OF THE NERVOUS SYSTEM

One of the most important functions of the nervous system is to process incoming information in such a way that *appropriate* mental and motor responses will occur. More than 99% of all sensory information is discarded by the brain as irrelevant and unimportant. For example, one is ordinarily unaware of the parts of the body that are in contact with clothing, as well as the seat pressure when sitting. Likewise, attention is drawn only to an occasional object in one's field of vision, and even the perpetual noise of our surroundings is usually relegated to the subconscious.

However, when important sensory information excites the mind, it is immediately channeled into proper integrative and motor regions of the brain to cause desired responses. This channeling and processing of information is called the *integrative function* of the nervous system. Thus, if a person places a hand on a hot stove, the desired instantaneous response is to rapidly lift the hand. Other associated responses follow, such as moving the entire body away from the stove and perhaps even shouting with pain.

ROLE OF SYNAPSES IN PROCESSING INFORMATION

The synapse is the junction point from one neuron to the next. Later in this chapter, we discuss the details of synaptic function. However, it is important to note here that synapses determine the directions that the nervous signals will spread through the nervous system. Some synapses transmit signals from one neuron to the next with ease, whereas others transmit signals only with difficulty. Also, *facilitatory* and *inhibitory* signals from other areas in the nervous system can control synaptic transmission, sometimes opening the synapses for transmission and, at other times, closing them. In addition, some postsynaptic neurons respond with large numbers of output impulses, and others respond with only a few. Thus, the synapses perform a selective action, often blocking weak signals while allowing strong signals to pass but, at other times, selecting and amplifying certain weak signals and often channeling these signals in many directions rather than in only one direction.

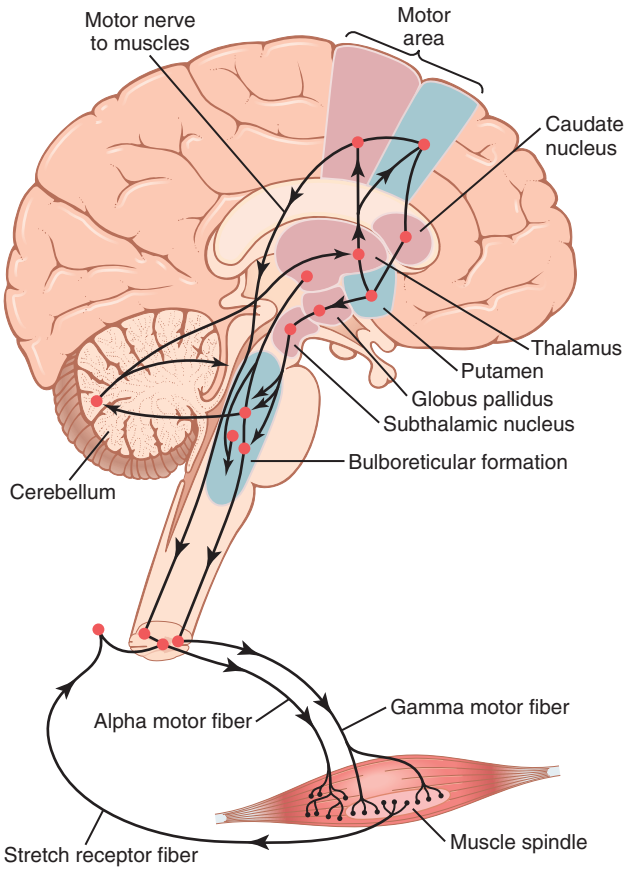

Figure 46.3 Skeletal motor nerve axis of the nervous system.

STORAGE OF INFORMATION—MEMORY

Only a small fraction of even the most important sensory information usually causes immediate motor responses. However, much of the information is stored for future control of motor activities and for use in the thinking processes. Most storage occurs in the *cerebral cortex*, but even the basal regions of the brain and the spinal cord can store small amounts of information.

The storage of information is the process called *memory*, which is also a function of the synapses. Each time certain types of sensory signals pass through sequences of synapses, these synapses become more capable of transmitting the same type of signal the next time, a process called *facilitation*. After the sensory signals have passed through the synapses a large number of times, the synapses become so facilitated that signals generated within the brain itself can also cause transmission of impulses through the same sequences of synapses, even when the sensory input is not excited. This process gives the person a perception of experiencing the original sensations, although the perceptions are only memories of the sensations.

The precise mechanisms whereby long-term facilitation of synapses occurs in the memory process are still uncertain, but additional details of the sensory memory process are discussed in Chapter 58.

Once memories have been stored in the nervous system, they become part of the brain processing mechanism for future "thinking." That is, the thinking processes of the brain compare new sensory experiences with stored memories; the memories then help select the important new sensory information and channel this into appropriate memory storage areas for future use or into motor areas to cause immediate bodily responses.

MAJOR LEVELS OF CENTRAL NERVOUS SYSTEM FUNCTION

The human nervous system has inherited special functional capabilities from each stage of human evolutionary development. From this heritage, three major levels of the central nervous system have specific functional characteristics: (1) the *spinal cord level;* (2) the *lower brain* or *subcortical level;* and (3) the *higher brain* or *cortical level*.

SPINAL CORD LEVEL

We often think of the spinal cord as being only a conduit for signals from the periphery of the body to the brain or in the opposite direction from the brain back to the body. This supposition is far from the truth. Even after the spinal cord has been cut in the high neck region, many highly organized spinal cord functions still occur. For example, neuronal circuits in the cord can cause (1) walking movements; (2) reflexes that withdraw portions of the body away from painful objects; (3) reflexes that stiffen the legs to support the body against gravity; and (4) reflexes that control local blood vessels, gastrointestinal movements, or urinary excretion. In fact, the upper levels of the nervous system often operate not by sending signals directly to the periphery of the body, but by sending signals to the control centers of the cord, simply "commanding" the cord centers to perform their functions.

LOWER BRAIN OR SUBCORTICAL LEVEL

Many, if not most, of what we call subconscious activities of the body are controlled in the lower areas of the brain—that is, in the medulla, pons, mesencephalon, hypothalamus, thalamus, cerebellum, and basal ganglia. For example, subconscious control of arterial pressure and respiration is achieved mainly in the medulla and pons. Control of equilibrium is a combined function of portions of the cerebellum and the reticular substance of the medulla, pons, and mesencephalon. Feeding reflexes, such as salivation and licking the lips in response to the taste of food, are controlled by areas in the medulla, pons, mesencephalon, amygdala, and hypothalamus. In addition, many emotional patterns, such as anger, excitement, sexual response, reaction to pain, and reaction to pleasure, can still occur after destruction of much of the cerebral cortex.

HIGHER BRAIN OR CORTICAL LEVEL

After the preceding account of the many nervous system functions that occur at the cord and lower brain levels, one may ask, "What is left for the cerebral cortex to do?" The answer to this question is complex, but it begins with the fact that the cerebral cortex is an extremely large memory storehouse. The cortex never functions alone but always in association with lower centers of the nervous system.

Without the cerebral cortex, the functions of the lower brain centers are often imprecise. The vast storehouse of cortical information usually converts these functions to determinative and precise operations.

Finally, the cerebral cortex is essential for most of our thought processes, but it cannot function by itself. In fact, it is the lower brain centers, not the cortex, that initiate *wakefulness* in the cerebral cortex, thereby opening its bank of memories to the thinking machinery of the brain. Thus, each portion of the nervous system performs specific functions, but it is the cortex that opens a world of stored information for use by the mind.

COMPARISON OF THE NERVOUS SYSTEM TO A COMPUTER

It is readily apparent that computers have many features in common with the nervous system. First, all computers have input circuits that can be compared with the sensory portion of the nervous system, as well as output circuits that are analogous to the motor portion of the nervous system.

In simple computers, the output signals are controlled directly by the input signals, operating in a manner similar to that of simple reflexes of the spinal cord. In more complex computers, the output is determined by input signals and by information that has already been stored in memory in the computer, which is analogous to the more complex reflex and processing mechanisms of the human higher nervous system. Furthermore, as computers become even more complex, it is necessary to add still another unit, called the *central processing unit*, which determines the sequence of all operations. This unit is analogous to the control mechanisms in the brain that direct a person's attention first to one thought or sensation or motor activity, then to another, and so forth, until complex sequences of thought or action take place.

Fig. 46.4 is a simple block diagram of a computer. Even a rapid study of this diagram demonstrates its similarity to the nervous system. The fact that the basic components of the general-purpose computer are analogous to those of the human nervous system demonstrates that the brain has many features of a computer, continuously collecting sensory information and using this, along with stored information, to compute the daily course of bodily activity.

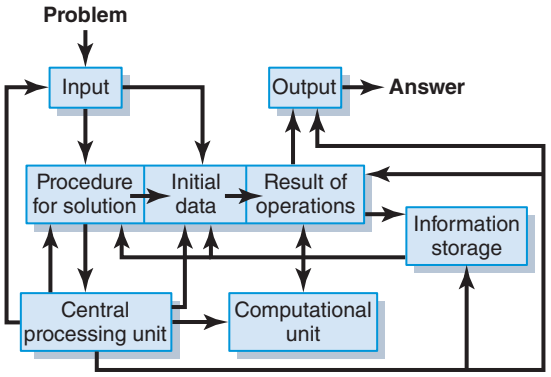

Figure 46.4 Block diagram of a general-purpose computer, showing the basic components and their interrelations.

CENTRAL NERVOUS SYSTEM SYNAPSES

Information is transmitted in the central nervous system mainly in the form of nerve action potentials, called *nerve impulses*, through a succession of neurons, one after another. However, each impulse (1) may be blocked in its transmission from one neuron to the next; (2) may be changed from a single impulse into repetitive impulses; or (3) may be integrated with impulses from other neurons to cause highly intricate patterns of impulses in successive neurons. All these functions can be classified as *synaptic functions of neurons*.

TYPES OF SYNAPSES—CHEMICAL AND ELECTRICAL

The two major types of synapses are (1) *chemical* and (2) *electrical* (**Fig. 46.5**).

Most synapses used for signal transmission in the central nervous system of the human being are *chemical synapses*. In these synapses, the first neuron secretes at its nerve ending synapse a chemical substance called a *neurotransmitter* (often called a *transmitter substance*), and this transmitter in turn acts on receptor proteins in the membrane of the next neuron to excite the neuron, inhibit it, or modify its sensitivity in some other way **(Video 46.1)**. More than 50 important neurotransmitters have been discovered thus far. Some of the best known are acetylcholine, norepinephrine, epinephrine, histamine, gamma-aminobutyric acid (GABA), glycine, serotonin, dopamine, and glutamate.

In *electrical synapses*, the cytoplasms of adjacent cells are directly connected by clusters of ion channels called *gap junctions* that allow free movement of ions from the interior of one cell to the interior of the next cell. Such junctions were discussed in Chapter 4, and it is by way of gap junctions and other similar junctions that action potentials are transmitted from one smooth muscle fiber to the next in visceral smooth muscle (Chapter 8) and from one cardiac muscle cell to the next in cardiac muscle (Chapter 9).

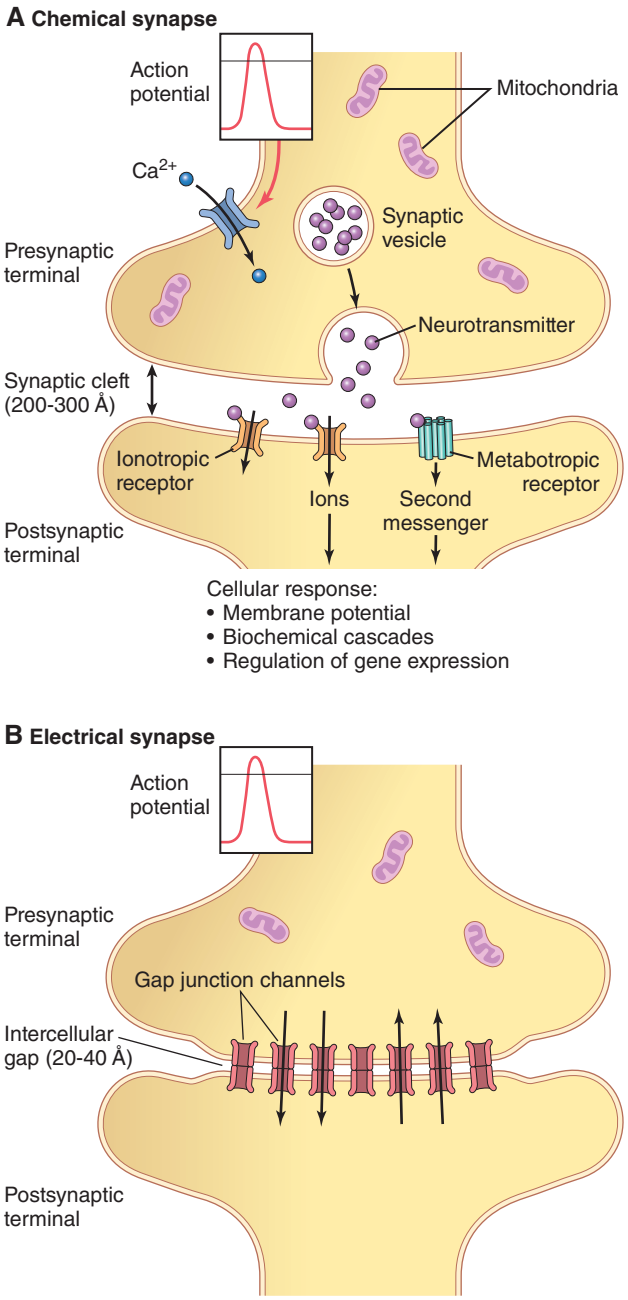

Figure 46.5 Physiological anatomy of (A) chemical synapse and (B) electrical synapse.

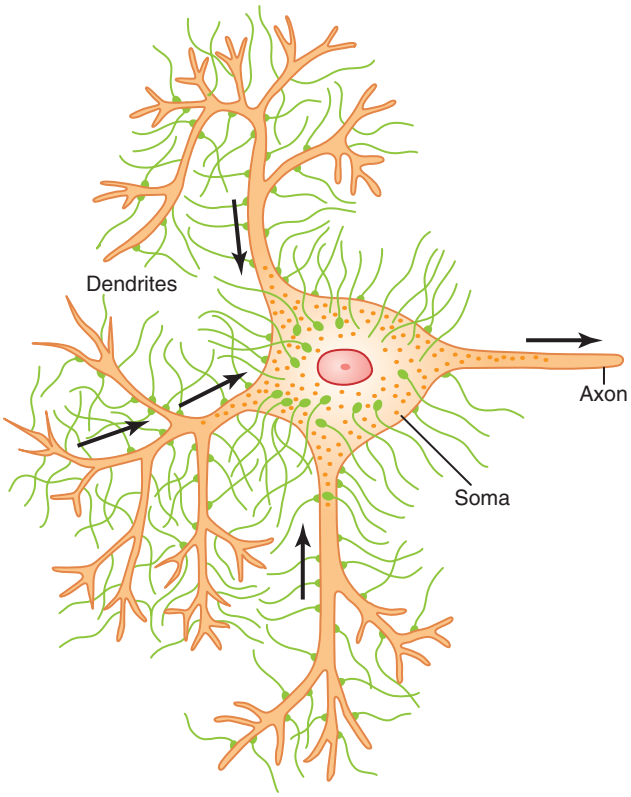

Figure 46.6 Typical anterior motor neuron showing presynaptic terminals on the neuronal soma and dendrites. Note also the single axon.

Although most synapses in the brain are chemical, electrical and chemical synapses may coexist and interact in the central nervous system. The bidirectional transmission of electrical synapses permits them to help coordinate the activities of large groups of interconnected neurons. For example, electrical synapses are useful in detecting the coincidence of simultaneous subthreshold depolarizations within a group of interconnected neurons; this enables increased neuronal sensitivity and promotes synchronous firing of a group of interconnected neurons. Also, some hormone-secreting neurons in the hypothalamus are connected by electrical synapses, permitting the connected neurons to fire action potentials at about the same time and facilitating a burst of hormone secretion into the circulation.

"One-Way" Conduction at Chemical Synapses. Chemical synapses always transmit signals in one direction—from the neuron that secretes the neurotransmitter, called the *presynaptic neuron*, to the neuron on which the transmitter acts, called the *postsynaptic neuron*. This *one-way conduction* at chemical synapses is different from conduction through electrical synapses, which often transmit signals in either direction.

A one-way conduction mechanism allows signals to be directed toward specific goals. Indeed, it is this specific transmission of signals to discrete and highly focused areas both within the nervous system and at the terminals of the peripheral nerves that allows the nervous system to perform its myriad functions of sensation, motor control, memory, and many other functions.

PHYSIOLOGICAL ANATOMY OF THE SYNAPSE

Fig. 46.6 shows a typical *anterior motor neuron* in the anterior horn of the spinal cord. It is composed of three major parts—the *soma*, which is the main body of the neuron, a single *axon*, which extends from the soma into a peripheral nerve that leaves the spinal cord, and *dendrites*, which are great numbers of branching projections

of the soma that extend as much as 1 millimeter into the surrounding areas of the cord.

As many as 10,000 to 200,000 minute synaptic knobs called *presynaptic terminals* lie on the surfaces of the dendrites and soma of the motor neuron, with about 80% to 95% of them on the dendrites and only 5% to 20% on the soma. These presynaptic terminals are the ends of nerve fibrils that originate from many other neurons. Many of these presynaptic terminals are *excitatory*—that is, they secrete a neurotransmitter that excites the postsynaptic neuron. However, other presynaptic terminals are *inhibitory*—that is, they secrete a neurotransmitter that inhibits the postsynaptic neuron.

Neurons in other parts of the cord and brain differ from the anterior motor neuron in (1) the size of the cell body; (2) the length, size, and number of dendrites, ranging in length from almost zero to many centimeters; (3) the length and size of the axon; and (4) the number of presynaptic terminals, which may range from only a few to as many as 200,000. These differences make neurons in various parts of the nervous system react differently to incoming synaptic signals and, therefore, perform many different functions.

Presynaptic Terminals. Electron microscopic studies of the presynaptic terminals show that they have varied anatomical forms, but most of them resemble small round or oval knobs and therefore are sometimes called *terminal knobs*, *boutons, end-feet*, or *synaptic knobs*.

Fig. 46.5A illustrates the basic structure of a chemical synapse, showing a single presynaptic terminal on the membrane surface of a postsynaptic neuron. The presynaptic terminal is separated from the postsynaptic neuronal soma by a *synaptic cleft* usually 200 to 300 angstroms (Å) wide. The terminal has two internal structures important to the excitatory or inhibitory function of the synapse: the *transmitter vesicles* and the *mitochondria*. The transmitter vesicles contain the *neurotransmitter* that is released into the synaptic cleft and *excites* or *inhibits* the postsynaptic neuron. It excites the postsynaptic neuron if the neuronal membrane contains *excitatory receptors*, and it inhibits the neuron if the membrane contains *inhibitory receptors*. The mitochondria provide adenosine triphosphate (ATP), which, in turn, supplies the energy for synthesizing new neurotransmitters.

When an action potential spreads over a presynaptic terminal, depolarization of its membrane causes a small number of vesicles to empty into the cleft. The released transmitter in turn binds to a receptor on the postsynaptic neuronal membrane, causing an immediate change in its permeability characteristics and leading to excitation or inhibition of the postsynaptic neuron, depending on the neurotransmitter released and the neuronal receptor characteristics.

Transmitter Release From Presynaptic Terminals and Role of Calcium Ions

The *presynaptic terminal membrane* contains *active zones*, where some vesicles containing small-molecule transmitters are docked and ready for immediate release of their contents upon arrival of the action potential. Additional vesicles filled with small-molecule neurotransmitters remain in a reserve pool outside of the active zone. Vesicles with neuropeptide transmitters do not dock at active zones. These vesicles are located outside of the active zone, away from the terminal membrane, and are slower to release compared to the small-molecule transmitters.

Docking of synaptic vesicles in the active zone occurs through complex interactions of *SNARE* (*soluble N-ethylmaleimide-sensitive factor attachment protein receptor*) *proteins* on the vesicle surface and terminal membrane. Although the precise interactions of these proteins that cause docking of the vesicles, fusion to the presynaptic terminal membrane, and ultimately release of neurotransmitters are not fully understood, **Fig. 46.7** illustrates a simplified model. A vesicle SNARE (v-SNARE) *synaptobrevin* binds to the membrane target SNARE proteins (t-SNAREs) *syntaxin* and *SNAP-25*. The interaction of these three proteins leads to vesicle docking at the active zone.

The active zones of the presynaptic terminal membrane contain large numbers of *voltage-gated calcium channels*. When an action potential depolarizes the presynaptic membrane, the calcium channels in the presynaptic terminal open and allow calcium ions to flow into the terminal (**Figs. 46.5A and 46.7**). The quantity of neurotransmitter that is then released from the terminal into the synaptic cleft is directly related to the number of calcium ions that enter **(Video 46.2)**.

Calcium ions entering the presynaptic terminal bind with *vesicle-bound calcium sensing proteins* (*synaptotagmin*) which, in turn, interact with the membrane-bound SNARE proteins. This interaction forms a molecular structure called a *trans-SNARE complex*, which results in fusion of the vesicular and terminal membranes (see **Fig. 46.7**). As the vesicular membrane merges with the interior of the terminal cell membrane, the contents of the vesicle are released into the synaptic cleft and then can interact with postsynaptic receptors. This *exocytosis* of the vesicles and release of their neurotransmitters occurs after each single action potential.

For vesicles that store the neurotransmitter acetylcholine, between 2000 and 10,000 molecules of acetylcholine are present in each vesicle, and there are enough vesicles in the presynaptic terminal to transmit from a few hundred to more than 10,000 action potentials.

Transmitter Actions on Postsynaptic Neurons—Function of Receptor Proteins

The membrane of the postsynaptic neuron contains large numbers of *receptor proteins*, also shown in **Fig. 46.5A**. The molecules of these receptors have two important components: (1) a *binding component* that protrudes outward from the membrane into the synaptic cleft, where it binds the neurotransmitter coming from the presynaptic

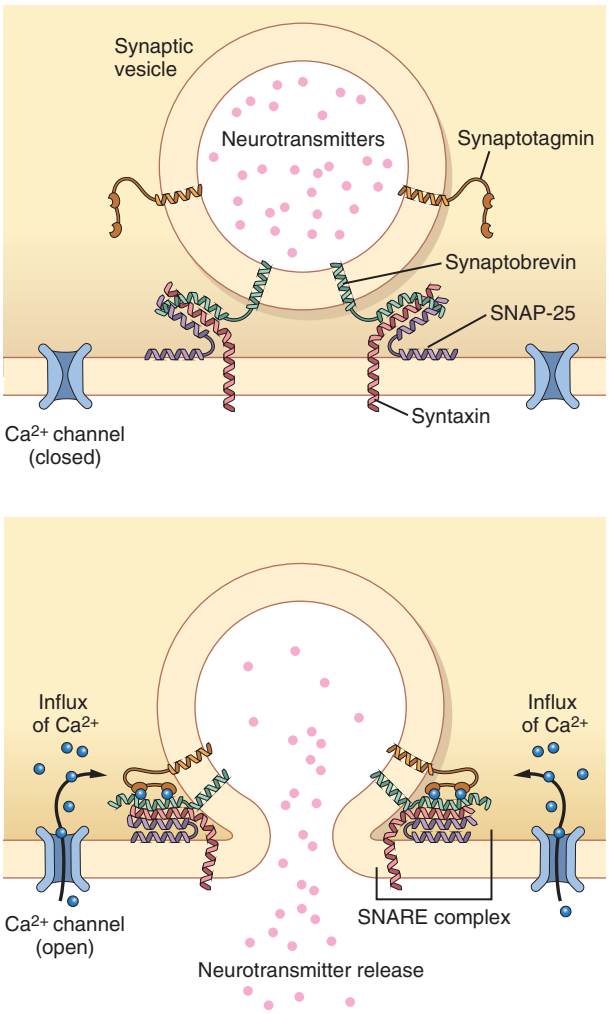

Figure 46.7 Potential mechanisms for neurotransmitter vesicle fusion with the presynaptic terminal membrane. SNARE proteins on the vesicle (synaptobrevin) interact with the membrane proteins (syntaxin and SNAP 25) to dock the vesicle in the active zone of the terminal. When an action potential depolarizes the presynaptic membrane, calcium channels open, Ca^{2+} enters the cell and binds to synaptotagmin, which then interacts with the SNARE complex, triggering fusion of the vesicle with the cell membrane and releasing the neurotransmitters into the synaptic cleft.

terminal; and (2) an *intracellular component* that passes all the way through the postsynaptic membrane to the interior of the postsynaptic neuron.

Receptor activation controls the opening of ion channels in the postsynaptic cell in one of two ways: (1) by *gating ion channels directly* and allowing passage of specified types of ions through the membrane; or (2) by activating a *"second messenger"* that is not an ion channel but, instead, is a molecule that protrudes into the cell cytoplasm and activates one or more substances inside the postsynaptic neuron. These second messengers increase or decrease specific cellular functions.

Neurotransmitter receptors that directly gate ion channels are often called *ionotropic receptors*, whereas those that act through second messenger systems are called *metabotropic receptors*.

Cation and Anion Channels. The ion channels in the postsynaptic neuronal membrane are usually of two types: (1) *cation channels*, which usually allow sodium ions to pass when opened but sometimes also allow potassium and/or calcium ions to pass; and (2) *anion channels*, which mainly allow chloride ions to pass but also allow minute quantities of other anions to pass. As discussed in Chapter 4, these ion channels are highly selective for transport of one or more specific ions. This selectivity of the channel depends on its diameter, shape, and the electrical charges and chemical bonds along its inside surfaces.

The *cation channels* that conduct sodium ions are lined with negative charges. These charges attract the positively charged sodium ions into the channel when the channel diameter increases to a size larger than that of the hydrated sodium ion. However, these same negative charges *repel chloride ions* and *other anions* and prevent their passage.

For the *anion channels*, when the channel diameters become large enough, chloride ions pass into the channels and on through to the opposite side, whereas sodium, potassium, and calcium cations are blocked, mainly because their hydrated ions are too large to pass.

We will learn later that when cation channels open and allow positively charged sodium ions to enter, the positive electrical charges of the sodium ions will in turn excite this neuron. Therefore, a neurotransmitter that opens cation channels is called an *excitatory transmitter*. Conversely, opening anion channels allows negative electrical charges to enter, which inhibits the neuron. Therefore, neurotransmitters that open these channels are called *inhibitory transmitters*.

When a neurotransmitter activates an ion channel, the channel usually opens within a fraction of a millisecond; when the transmitter substance is no longer present, the channel closes equally rapidly. The opening and closing of ion channels provide a means for very rapid control of postsynaptic neurons.

"Second Messenger" System in the Postsynaptic Neuron. Many functions of the nervous system—for example, the process of memory—require prolonged changes in neurons for seconds to months after the initial transmitter substance is gone. The ion channels are not suitable for causing prolonged postsynaptic neuronal changes because these channels close within milliseconds after the transmitter substance is no longer present. However, in many cases, prolonged postsynaptic neuronal excitation or inhibition is achieved by activating a second messenger chemical system inside the postsynaptic neuronal cell, and then it is the second messenger that causes the prolonged effect.

There are several types of second messenger systems. One of the most common types uses a group of proteins called *G proteins*. **Fig. 46.8** shows a membrane receptor G protein. The inactive G protein complex is free in the cytosol and consists of guanosine diphosphate (GDP)

plus three components: an alpha (α) component that is the *activator* portion of the G protein, and beta (β) and gamma (γ) components that are attached to the alpha component. As long as the G protein complex is bound to GDP, it remains inactive.

When the receptor is activated by a neurotransmitter, following a nerve impulse, the receptor undergoes a conformational change, exposing a binding site for the G protein complex, which then binds to the portion of the receptor that protrudes into the interior of the cell. This process permits the α subunit to release GDP and simultaneously bind guanosine triphosphate (GTP) while separating from the β and γ portions of the complex. The separated α-GTP complex is then free to move within the cytoplasm of the cell and perform one or more of several functions, depending on the specific characteristic of each type of neuron. The following four changes that can occur are shown in **Fig. 46.8**:

1. *Opening specific ion channels through the postsynaptic cell membrane.* Shown in the upper right of the figure is a potassium channel that is opened in response to the G protein; this channel often stays open for a prolonged time, in contrast to rapid closure of directly activated ion channels that do not use the second messenger system.
2. *Activation of cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate (cGMP) in the neuronal cell.* Recall that cAMP or cGMP can activate highly specific metabolic machinery in the neuron and, therefore, can initiate any one of many chemical results, including long-term changes in cell structure itself, which in turn alters long-term excitability of the neuron.
3. *Activation of one or more intracellular enzymes.* The G protein can directly activate one or more intracellular enzymes. In turn, the enzymes can cause many specific chemical functions in the cell.
4. *Activation of gene transcription.* Activation of gene transcription is one of the most important effects of activation of the second messenger systems because gene transcription can cause formation of new proteins within the neuron, thereby changing its metabolic machinery or its structure. It is well known that structural changes of appropriately activated neurons do occur, especially in long-term memory processes.

Inactivation of the G protein occurs when the GTP bound to the α subunit is hydrolyzed to GDP. This action causes the α subunit to release from its target protein, thereby inactivating the second messenger systems, and then to combine again with the β and γ subunits, returning the G protein complex to its inactive state.

It is clear that activation of second messenger systems within the neuron, whether of the G protein type or of other types, is extremely important for changing the long-term response characteristics of different neuronal pathways. We will return to this subject in more detail in Chapter 58 when we discuss memory functions of the nervous system.

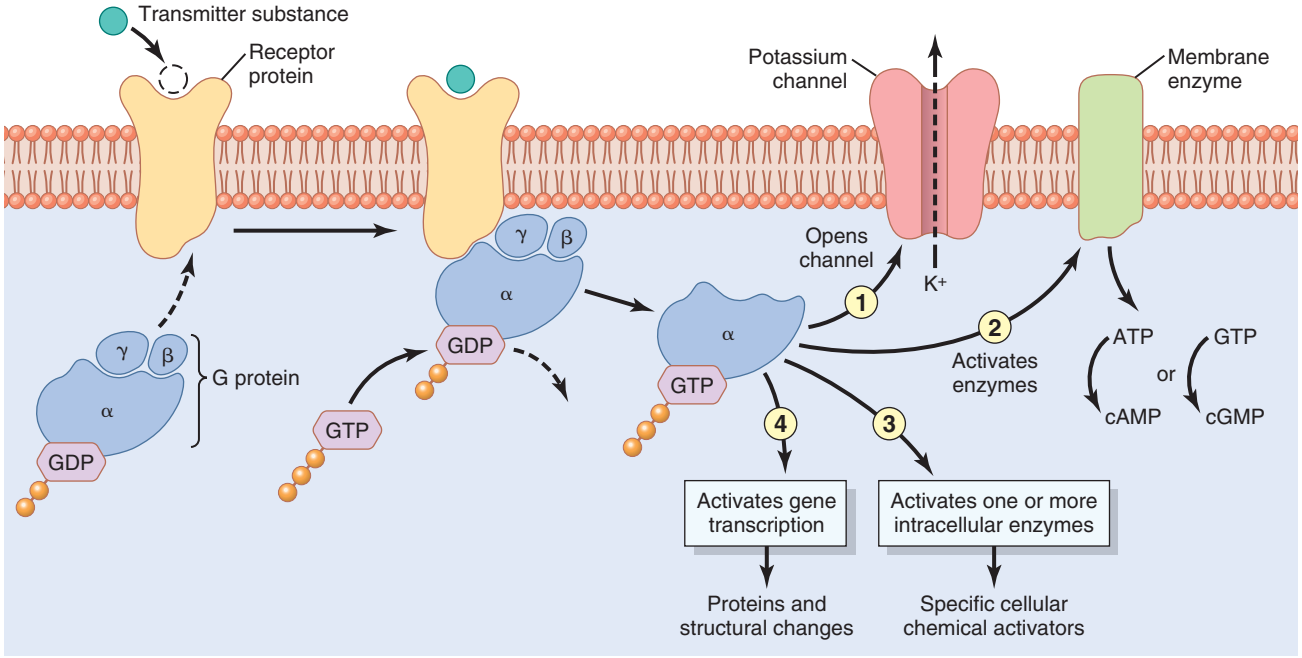

Figure 46.8 The second messenger system whereby a transmitter substance from an initial neuron can activate a second neuron by first causing a transformational change in the receptor that releases the activated alpha (α) subunit of the G protein into the second neuron's cytoplasm. Four subsequent possible effects of the G protein are shown, including the following: (1) opening an ion channel in the membrane of the second neuron; (2) activating an enzyme system in the neuron's membrane; (3) activating an intracellular enzyme system; and/or (4) causing gene transcription in the second neuron. Return of the G protein to the inactive state occurs when guanosine triphosphate (GTP) bound to the α subunit is hydrolyzed to guanosine diphosphate (GDP), and the β and γ subunits are reattached to the α subunit.

Excitatory or Inhibitory Receptors in the Postsynaptic Membrane

On activation, some postsynaptic receptors cause excitation of postsynaptic neurons, and others cause inhibition. The importance of having inhibitory and excitatory types of receptors is that this feature gives an additional dimension to nervous function, allowing restraint of nervous action and excitation.

The different molecular and membrane mechanisms used by the different receptors to cause excitation or inhibition include the following.

Excitation

1. *Opening of sodium channels to allow large numbers of positive electrical charges to flow to the interior of the postsynaptic cell*. This action tends to depolarize the cell membrane, raising the intracellular membrane potential in the positive direction up toward the threshold level for excitation. It is the most widely used means for causing excitation.
2. *Depressed conduction through chloride or potassium channels or both*. This action decreases the diffusion of negatively charged chloride ions to the inside of the postsynaptic neuron or decreases the diffusion of positively charged potassium ions to the outside. In either case, the effect is to make the internal membrane potential less negative than normal, which is excitatory.
3. *Various changes in the internal metabolism of the postsynaptic neuron to excite cell activity* or, in some cases, to increase the number of excitatory membrane receptors or decrease the number of inhibitory membrane receptors.

Inhibition

1. *Opening of chloride ion channels through the postsynaptic neuronal membrane*. This action allows rapid diffusion of negatively charged chloride ions from outside the postsynaptic neuron to the inside, thereby carrying negative charges inward and increasing the negativity inside, which is inhibitory.
2. *Increase in conductance of potassium ions out of the neuron*. This action allows positive ions to diffuse to the exterior, which causes increased negativity inside the neuron; this is inhibitory.
3. *Activation of receptor enzymes that inhibit cellular metabolic functions, increase the number of inhibitory synaptic receptors, or decrease the number of excitatory receptors*.

CHEMICAL SUBSTANCES THAT FUNCTION AS SYNAPTIC TRANSMITTERS

More than 50 chemical substances have been proved or postulated to function as synaptic transmitters. Some of them are listed in **Tables 46.1** and **46.2**, which provide two groups of synaptic transmitters. One group comprises *small-molecule, rapidly acting transmitters*. The other is made up of a large number of *neuropeptides* of much larger molecular size, which usually act much more slowly. A few *gaseous molecules*, such as nitric oxide (NO), hydrogen sulfide (H_2S), and carbon monoxide (CO), may also serve as transmitter modulators, although their role as true neurotransmitters is still unclear.

Table 46.1 Small-Molecule, Rapidly Acting Transmitters

Melatonin
Histamine
Class III: Amino Acids
Gamma-aminobutyric acid
Glycine
Glutamate
Aspartate
Class IV
ATP
Arachidonic acid
Nitric oxide
Carbon monoxide

The small-molecule, rapidly acting transmitters cause most acute responses of the nervous system, such as transmission of sensory signals to the brain and motor signals back to the muscles. The neuropeptides, in contrast, usually cause more prolonged actions, such as long-term changes in numbers of neuronal receptors, long-term opening or closure of certain ion channels, and possibly even long-term changes in numbers of synapses or sizes of synapses.

Small-Molecule, Rapidly Acting Transmitters

In most cases, the small-molecule transmitters are synthesized in the cytosol of presynaptic terminals and are absorbed via active transport into the many transmitter vesicles in the terminals. Then, each time an action potential reaches a presynaptic terminal, a few vesicles at a time release their transmitter into the synaptic cleft. This action usually occurs within a millisecond or less by the mechanism described earlier. The subsequent action of the small-molecule transmitter on the membrane receptors of the postsynaptic neuron usually also occurs within another millisecond or less. Most often, the effect is to increase or decrease conductance through ion channels; an example is to increase sodium conductance, which

causes excitation, or to increase potassium or chloride conductance, which causes inhibition.

Recycling of Small-Molecule Types of Vesicles. Vesicles that store and release small-molecule transmitters are continually recycled and used over and over again. After they fuse with the synaptic membrane and open to release their transmitters, the vesicle membrane at first simply becomes part of the synaptic membrane. However, within seconds to minutes, the vesicle portion of the membrane invaginates back to the inside of the presynaptic terminal and pinches off to form a new vesicle. The new vesicular membrane still contains appropriate enzyme proteins or transport proteins required for synthesizing and/or concentrating new transmitter substances inside the vesicle.

Acetylcholine is a typical small-molecule transmitter that obeys the principles of synthesis and release, as stated earlier. This transmitter substance is synthesized in the presynaptic terminal from acetyl coenzyme A and choline in the presence of the enzyme *choline acetyltransferase*. It is then transported into its specific vesicles. When the vesicles later release acetylcholine into the synaptic cleft during synaptic neuronal signal transmission, the acetylcholine is rapidly split again to acetate and choline by the enzyme *cholinesterase*, which is present in the proteoglycan reticulum that fills the space of the synaptic cleft. Then, once again, inside the presynaptic terminal, the vesicles are recycled, and choline is actively transported back into the terminal to be used again for synthesis of new acetylcholine.

Characteristics of Some Important Small-Molecule Transmitters. *Acetylcholine* is secreted by neurons in many areas of the nervous system but specifically by (1) the terminals of the large pyramidal cells from the motor cortex; (2) several different types of neurons in the basal ganglia; (3) motor neurons that innervate the skeletal muscles; (4) preganglionic neurons of the autonomic nervous system; (5) postganglionic neurons of the parasympathetic nervous system; and (6) some of the postganglionic neurons of the sympathetic nervous system. In most cases, acetylcholine has an excitatory effect; however, it is known to have inhibitory effects at some peripheral parasympathetic nerve endings, such as inhibition of the heart by the vagus nerves.

Norepinephrine is secreted by the terminals of many neurons whose cell bodies are located in the brain stem and hypothalamus. Specifically, norepinephrine-secreting neurons located in the *locus ceruleus* in the pons send nerve fibers to widespread areas of the brain to help control overall activity and mood of the mind, such as increasing the level of wakefulness. In most of these areas, norepinephrine activates excitatory receptors, but in a few areas, it activates inhibitory receptors instead. Norepinephrine is also secreted by most postganglionic neurons of the sympathetic nervous system, where it excites some organs but inhibits others.

Dopamine is secreted by neurons that originate in the substantia nigra. The termination of these neurons is mainly in the striatal region of the basal ganglia. The effect of dopamine is usually inhibition.

Glycine is secreted mainly at synapses in the spinal cord. It is believed to always act as an inhibitory transmitter.

Gamma-aminobutyric acid (GABA) is secreted by nerve terminals in the spinal cord, cerebellum, basal ganglia, and many areas of the cortex. It is the primary inhibitory neurotransmitter in the adult central nervous system. Yet, in the early stages of brain development, including the embryonic period and first week of postnatal life, GABA is thought to serve as an excitatory neurotransmitter.

Glutamate is secreted by the presynaptic terminals in many of the sensory pathways entering the central

nervous system, as well as in many areas of the cerebral cortex. It probably always causes excitation.

Serotonin is secreted by nuclei that originate in the median raphe of the brain stem and project to many brain and spinal cord areas, especially to the dorsal horns of the spinal cord and the hypothalamus. Serotonin acts as an inhibitor of pain pathways in the cord; an inhibitor action in the higher regions of the nervous system is believed to help control the mood of the person, perhaps even to cause sleep.

Nitric oxide is produced by nerve terminals in areas of the brain responsible for long-term behavior and memory. Therefore, this gaseous transmitter might explain some behavior and memory functions that thus far have defied understanding. Nitric oxide is different from other small-molecule transmitters in its mechanism of formation in the presynaptic terminal and in its actions on the postsynaptic neuron. It is not preformed and stored in vesicles in the presynaptic terminal, as are other transmitters. Instead, it is synthesized almost instantly as needed and then diffuses out of the presynaptic terminals over a period of seconds rather than being released in vesicular packets. Next, it diffuses into postsynaptic neurons nearby. In the postsynaptic neuron, it usually does not alter the membrane potential greatly but instead changes intracellular metabolic functions that modify neuronal excitability for seconds, minutes, or perhaps even longer.

Neuropeptides

Neuropeptides are synthesized differently and have actions that are usually slow and in other ways different from those of the small-molecule transmitters. The neuropeptides are not synthesized in the cytosol of the presynaptic terminals. Instead, they are synthesized as integral parts of large-protein molecules by ribosomes in the neuronal cell body.

The protein molecules then enter the spaces inside the endoplasmic reticulum of the cell body and subsequently inside the Golgi apparatus, where two changes occur. First, the neuropeptide-forming protein is enzymatically split into smaller fragments, some of which are either the neuropeptide itself or a precursor of it. Second, the Golgi apparatus packages the neuropeptide into minute transmitter vesicles that are released into the cytoplasm. Then, the transmitter vesicles are transported all the way to the tips of the nerve fibers by *axonal streaming* of the axon cytoplasm, traveling at the slow rate of only a few centimeters per day. Finally, these vesicles release their transmitter at neuronal terminals in response to action potentials in the same manner as for small-molecule transmitters. However, the vesicle is autolyzed and is not reused.

Because of this laborious method of forming the neuropeptides, much smaller quantities of neuropeptides than the small-molecule transmitters are usually released. This difference is partly compensated for by the fact that the neuropeptides are generally a thousand or more times as potent as the small-molecule transmitters. Another important characteristic of the neuropeptides is that they often cause much more prolonged actions. Some of these actions include prolonged closure of calcium channels, prolonged changes in the metabolic machinery of cells, prolonged changes in activation or deactivation of specific genes in the cell nucleus, and/or prolonged alterations in numbers of excitatory or inhibitory receptors. Some of these effects last for days, but others last perhaps for months or years.

Neuropeptide and Small-Molecule Transmitters May Coexist in the Same Neurons. Slowly acting neuropeptide transmitters and rapidly acting, small-molecule transmitters are often stored and released from the same neurons. In some cases, two or more of these transmitters are *co-localized* in the same synaptic vesicles and are *co-released* when an action potential reaches the presynaptic terminal (**Fig. 46.9A**). In other cases, these transmitters may be localized in different populations of synaptic vesicles of the same neuron and contribute to *co-transmission* of signals to a postsynaptic neuron. Moreover, their release may be differentially regulated because of different calcium ion sensitivities (**Fig. 46.9B**) or spatial segregation of the vesicles on different boutons (**Fig. 46.9C**).

The co-release of transmitters and co-transmission of signals obviously has important functional implications. Each different transmitter released from the same presynaptic neuron has its own specific receptors and may have inhibitory or excitatory influences on the postsynaptic target. Different neurons may release different combinations of fast-acting transmitters that directly activate postsynaptic receptors, as well as slow-acting transmitters that require activation of second messenger cascades and postsynaptic changes in gene expression.

An example of co-release of two small-molecule transmitters is found in the raphe nucleus, located in the brain stem. These neurons provide innervation to several brain regions, they can co-release serotonin and glutamate, and they play an important role in the cycle of sleeping and wakefulness (see Chapters 59 and 60).

ELECTRICAL EVENTS DURING NEURONAL EXCITATION

The electrical events in neuronal excitation have been studied especially in the large motor neurons of the anterior horns of the spinal cord. Therefore, the events described in the next few sections pertain essentially to these neurons. Except for quantitative differences, they also apply to most other neurons of the nervous system.

Resting Membrane Potential of the Neuronal Soma. **Fig. 46.10** shows the soma of a spinal motor neuron, indicating a *resting membrane potential* of about −65 millivolts (mV). This resting membrane potential is somewhat less negative than that found in large peripheral nerve fibers and in skeletal muscle fibers; the lower voltage is important because it allows both positive and

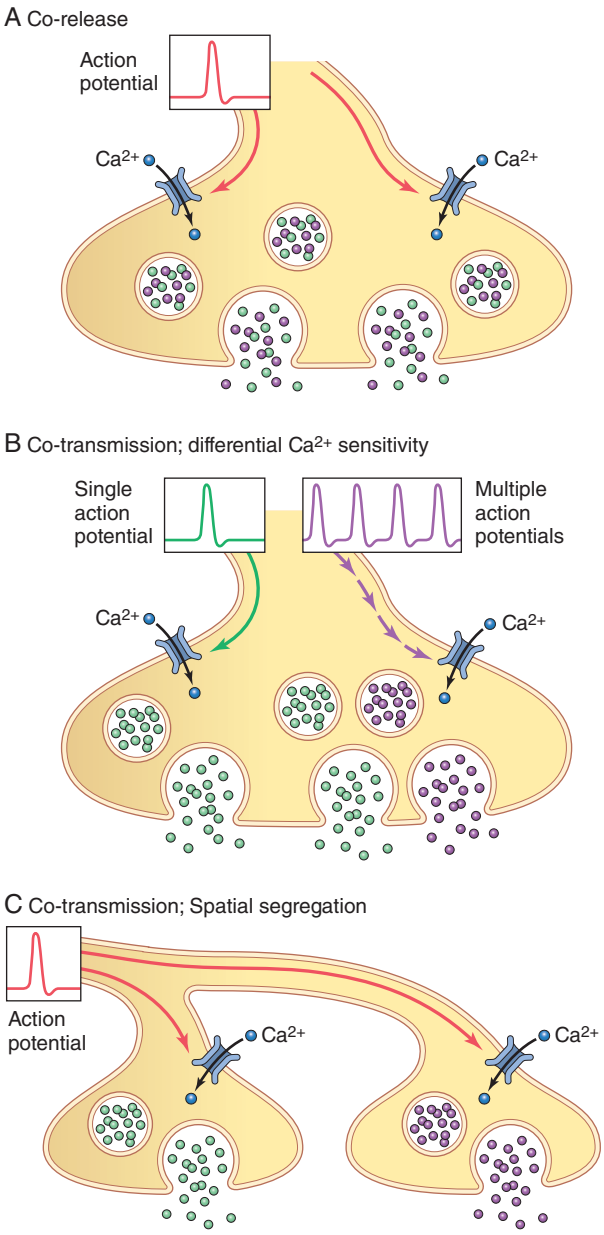

Figure 46.9 Co-release of neurotransmitters and co-transmission of neuronal signals. (A) With co-release, both transmitters (*green* and *purple*) are stored in the same set of synaptic vesicles and released together when an action potential reaches the presynaptic terminal. (B) With co-transmission, the transmitters are stored in different populations of synaptic vesicles with differential release mediated by different calcium ion (Ca^{2+}) sensitivities; a single action potential might release one set of vesicles (*green*), whereas multiple action potentials might be required to release both sets of vesicles (*green* and *purple*). (C) Co-transmission can also rely on the spatial segregation of vesicle populations to different boutons, allowing uniform information to be transmitted to different postsynaptic targets.

negative control of the degree of excitability of the neuron. That is, a less negative voltage makes the membrane of the neuron more excitable, whereas a more negative voltage makes the neuron less excitable. This mechanism is the basis for the two modes of function of the neuron—either excitation or inhibition—as explained in the next sections.

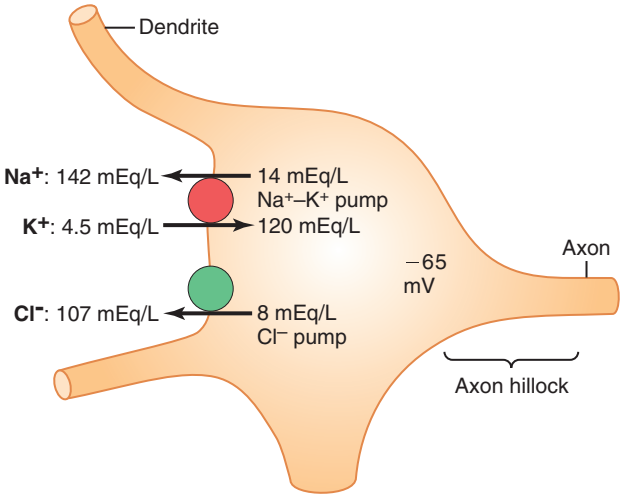

Figure 46.10 Distribution of sodium, potassium, and chloride ions across the neuronal somal membrane; origin of the intrasomal membrane potential.

Concentration Differences of Ions Across the Neuronal Somal Membrane. Fig. 46.10 also shows the concentration differences across the neuronal somal membrane of the three ions that are most important for neuronal function—sodium, potassium, and chloride ions. At the top of this figure, the *sodium ion concentration* is shown to be *high in the extracellular fluid* (142 mEq/L) but *low inside the neuron* (14 mEq/L). This sodium concentration gradient is caused by a strong somal membrane sodium-potassium pump that continually pumps sodium out of the neuron.

Fig. 46.10 also shows that *potassium ion concentration is high inside the neuronal soma* (120 mEq/L) but *low in the extracellular fluid* (4.5 mEq/L). Furthermore, it shows that the sodium-potassium pump transports potassium to the interior.

Fig. 46.10 depicts the *chloride ion* to be of *high concentration in the extracellular fluid* but of *low concentration inside the neuron*. The membrane may be somewhat permeable to chloride ions, and there may be a weak chloride pump. Yet, most of the reason for the low concentration of chloride ions inside the neuron is the −65 mV in the neuron. That is, this negative voltage repels the negatively charged chloride ions, forcing them outward through channels until the concentration is much less inside the membrane than outside.

Let us recall from Chapters 4 and 5 that an electrical potential across the cell membrane can oppose movement of ions through a membrane if the potential is of proper polarity and magnitude. A potential that *exactly* opposes movement of an ion is called the *Nernst potential* for that ion, represented by the following equation:

$$\text{EMF (mV)} = \pm 61 \times \log \left(\frac{\text{Concentration inside}}{\text{Concentration outside}} \right)$$

where *EMF* (electromotive force) is the Nernst potential in millivolts on the *inside of the membrane*. The potential will be negative (−) for positive ions and positive (+) for negative ions.

Now let us calculate the Nernst potential that will exactly oppose the movement of each of the three separate ions—sodium, potassium, and chloride.

For the sodium concentration difference shown in **Fig. 46.10** (142 mEq/L on the exterior and 14 mEq/L on the interior), the membrane potential that will oppose sodium ion movement through the sodium channels calculates to be +61 mV. However, the actual membrane potential is −65 mV, not +61 mV. Therefore, the sodium ions that leak to the interior are immediately pumped back to the exterior by the sodium pump, thus maintaining the −65-mV negative potential inside the neuron.

For potassium ions, the concentration gradient is 120 mEq/L inside the neuron and 4.5 mEq/L outside. This concentration gradient calculates to be a Nernst potential of −86 mV inside the neuron, which is more negative than the −65 that actually exists. Therefore, because of the high intracellular potassium ion concentration, there is a net tendency for potassium ions to diffuse to the outside of the neuron, but this action is opposed by continual pumping of these potassium ions back to the interior.

Finally, the chloride ion gradient, 107 mEq/L outside and 8 mEq/L inside, yields a Nernst potential of −70 mV inside the neuron, which is only *slightly* more negative than the actual measured value of −65 mV. Therefore, chloride ions tend to leak slightly to the interior of the neuron, but those few that do leak are moved back to the exterior by an active chloride pump.

Keep these three Nernst potentials in mind, and remember the direction in which the different ions tend to diffuse, because this information is important in understanding both excitation and inhibition of the neuron by synapse activation or inactivation of ion channels.

Uniform Distribution of Electrical Potential Inside the Neuronal Soma. The *intracellular fluid* of the neuron soma is a highly conductive electrolytic solution. Furthermore, the diameter of the neuronal soma is large (from 10 to 80 micrometers) and there is almost no resistance to conduction of electric current from one part of the somal interior to another part. Therefore, any change in potential in any part of the intrasomal fluid causes an almost exactly equal change in potential at all other points inside the soma, as long as the neuron is not transmitting an action potential. This principle is important because it plays a major role in "summation" of signals entering the neuron from multiple sources, as we discuss in subsequent sections of this chapter.

Effect of Synaptic Excitation on the Postsynaptic Membrane—Excitatory Postsynaptic Potential. **Fig. 46.11A** shows the resting neuron with an unexcited presynaptic terminal resting on its surface. The resting membrane potential everywhere in the soma is −65 mV.

Fig. 46.11B shows a presynaptic terminal that has secreted an excitatory transmitter into the cleft between the terminal and neuronal somal membrane. This transmitter acts on the membrane excitatory receptor *to increase the membrane's permeability to* Na^+. Because of the large sodium concentration gradient and large electrical negativity inside the neuron, sodium ions diffuse rapidly to the inside of the membrane.

The rapid influx of positively charged sodium ions to the interior neutralizes part of the negativity of the resting membrane potential. Thus, in **Fig. 46.11B**, the resting membrane potential has increased in the positive direction from −65 to −45 mV. This positive increase in voltage above the normal resting neuronal potential—that is, to a less negative value—is called the *excitatory postsynaptic potential* (EPSP), because if this potential rises high enough in the positive direction, it will elicit an action potential in the postsynaptic neuron, thus exciting it. (In this case, the EPSP is +20 mV—i.e., 20 mV more positive than the resting value.)

Discharge of a single presynaptic terminal does not increase the neuronal potential from −65 mV all the way up to −45 mV. An increase of this magnitude requires simultaneous discharge of many terminals—about 40 to 80 for the usual anterior motor neuron—at the same time or in rapid succession. This simultaneous discharge occurs by a process called *summation*, discussed in the next sections.

Generation of Action Potentials in the Initial Segment of the Axon Leaving the Neuron—Threshold for Excitation. When the EPSP rises high enough in the positive direction, an action potential is initiated in the neuron.

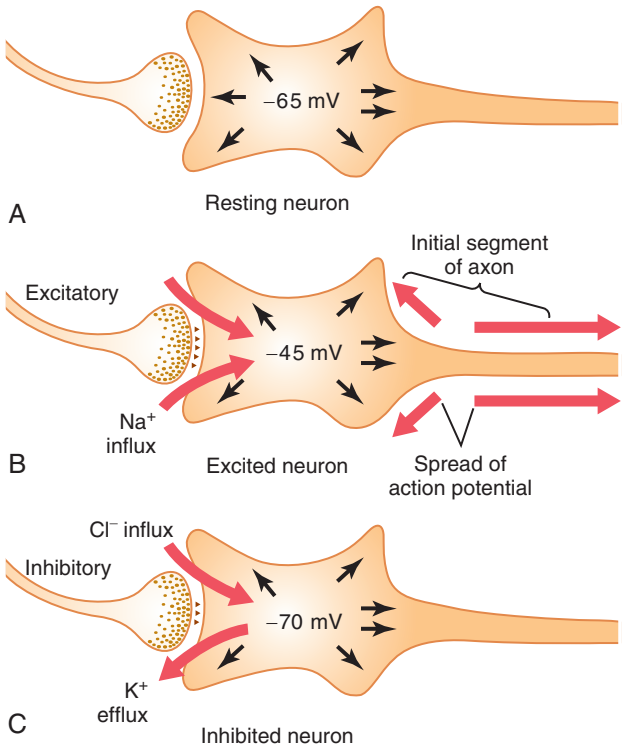

Figure 46.11 Three states of a neuron. (A) *Resting neuron*, with a normal intraneuronal potential of −65 mV. (B) *Neuron in an excited state*, with a less negative intraneuronal potential (−45 mV) caused by sodium influx. (C) *Neuron in an inhibited state*, with a more negative intraneuronal membrane potential (−70 mV) caused by potassium ion efflux, chloride ion influx, or both.

However, the action potential does not begin adjacent to the excitatory synapses. Instead, *it begins in the initial segment of the axon* where the axon leaves the neuronal soma. The soma has relatively few voltage-gated sodium channels in its membrane, which makes it difficult for the EPSP to open the required number of sodium channels to elicit an action potential. Conversely, *the membrane of the initial segment of the axon* has seven times as great a concentration of voltage-gated sodium channels as the soma and, therefore, can generate an action potential with much greater ease than can the soma. The EPSP that will elicit an action potential in the axon initial segment is between +10 and +20 mV, in contrast to the +30 or +40 mV or more required on the soma.

Once the action potential begins, it travels peripherally along the axon and usually also backward over the soma. In some cases, it travels backward into the dendrites but not into all of them because they, like the neuronal soma, have very few voltage-gated sodium channels and therefore frequently cannot generate action potentials at all. Thus, in **Fig. 46.11B**, the *threshold* for excitation of the neuron is about −45 mV, which represents an EPSP of +20 mV—that is, 20 mV more positive than the normal resting neuronal potential of −65 mV.

ELECTRICAL EVENTS DURING NEURONAL INHIBITION

Effect of Inhibitory Synapses on the Postsynaptic Membrane—Inhibitory Postsynaptic Potential. The inhibitory synapses *mainly open chloride channels*, allowing for easier passage of chloride ions. To understand how the inhibitory synapses inhibit the postsynaptic neuron, recall what we learned about the Nernst potential for chloride ions. We calculated the Nernst potential for chloride ions to be about −70 mV. This potential is more negative than the −65 mV normally present inside the resting neuronal membrane. Therefore, opening the chloride channels will allow negatively charged chloride ions to move from the extracellular fluid to the interior, which will make the interior membrane potential more negative than normal, approaching the −70 mV level.

Opening potassium channels will allow positively charged potassium ions to move to the exterior and will also make the interior membrane potential more negative than usual. Thus, both chloride influx and potassium efflux increase the degree of intracellular negativity, called *hyperpolarization*. The neuron is inhibited because the membrane potential is even more negative than the normal intracellular potential. Therefore, an increase in negativity beyond the normal resting membrane potential level is called an *inhibitory postsynaptic potential* (IPSP).

Fig. 46.11C shows the effect on the membrane potential caused by activation of inhibitory synapses, allowing chloride influx into the cell and/or potassium efflux out of the cell, with the membrane potential decreasing from its normal value of −65 mV to the more negative value of −70 mV. This membrane potential is 5 mV more negative than normal and is therefore an IPSP of −5 mV, which inhibits transmission of the nerve signal through the synapse.

Presynaptic Inhibition

In addition to *postsynaptic inhibition* caused by inhibitory synapses operating at the neuronal membrane, *presynaptic inhibition* often occurs at the presynaptic terminals before the signal ever reaches the synapse.

Presynaptic inhibition is caused by release of an inhibitory substance onto the outsides of the presynaptic nerve fibrils before their own endings terminate on the postsynaptic neuron. *In most cases, the inhibitory transmitter substance is GABA*, which opens anion channels, allowing large numbers of chloride ions to diffuse into the terminal fibril. The negative charges of these ions inhibit synaptic transmission because they cancel much of the excitatory effect of the positively charged sodium ions that also enter the terminal fibrils when an action potential arrives.

Presynaptic inhibition occurs in many of the sensory pathways in the nervous system. In fact, adjacent sensory nerve fibers often mutually inhibit one another, which minimizes sideways spread and mixing of signals in sensory tracts. We discuss the importance of this phenomenon more fully in subsequent chapters.

Time Course of Postsynaptic Potentials

When an excitatory synapse excites the anterior motor neuron, the neuronal membrane becomes highly permeable to sodium ions for 1 to 2 milliseconds. During this short time, enough sodium ions diffuse to the interior of the postsynaptic motor neuron to increase its intraneuronal potential by a few millivolts, thus creating the EPSP shown by the blue and green curves of **Fig. 46.12**. This potential then slowly declines over the next 15 milliseconds because this is the time required for the excess positive charges to leak out of the excited neuron and reestablish the normal resting membrane potential.

Precisely the opposite effect occurs for an IPSP. That is, the inhibitory synapse increases the permeability of the membrane to potassium or chloride ions, or both, for 1 to 2 milliseconds, and this action decreases the intraneuronal potential to a more negative value than normal, thereby creating the IPSP. This potential also dies away in about 15 milliseconds.

Other types of transmitter substances can excite or inhibit the postsynaptic neuron for much longer periods—for hundreds of milliseconds or even for seconds, minutes, or hours. This is especially true for some of the neuropeptide transmitters.

Spatial Summation in Neurons—Threshold for Firing

Excitation of a single presynaptic terminal on the surface of a neuron almost never excites the neuron. The amount of transmitter released by a single terminal to cause an EPSP

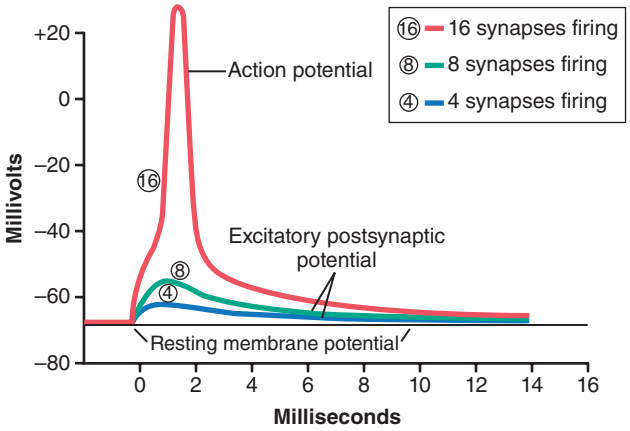

Figure 46.12 Excitatory postsynaptic potentials. This shows that simultaneous firing of only a few synapses will not cause sufficient summated potential to elicit an action potential but that simultaneous firing of many synapses will raise the summated potential to threshold for excitation and cause a superimposed action potential.

is usually no more than 0.5 to 1 mV instead of the 10 to 20 mV normally required to reach threshold for excitation.

However, many presynaptic terminals are usually stimulated at the same time. Even though these terminals are spread over wide areas of the neuron, their effects can still *summate;* that is, they can add to one another until neuronal excitation occurs. We pointed out earlier that a change in potential at any single point within the soma will cause the potential to change almost equally everywhere inside the soma. Therefore, for each excitatory synapse that discharges simultaneously, the total intrasomal potential becomes more positive by 0.5 to 1.0 mV. When the EPSP becomes great enough, the *threshold for firing* will be reached and an action potential will develop spontaneously in the initial segment of the axon, as shown in **Fig. 46.12**. The bottom postsynaptic potential in the figure was caused by simultaneous stimulation of 4 synapses; the next higher potential was caused by stimulation of 8 synapses; finally, a still higher EPSP was caused by stimulation of 16 synapses. In this last case, the firing threshold had been reached, and an action potential was generated in the axon.

This effect of summing simultaneous postsynaptic potentials by activating multiple terminals on widely spaced areas of the neuronal membrane is called *spatial summation*.

"Temporal Summation" Caused By Successive Discharges of a Presynaptic Terminal

Each time a presynaptic terminal fires, the released transmitter substance opens the membrane channels for at most 1 or 2 milliseconds. However, the changed postsynaptic potential lasts up to 15 milliseconds after the synaptic membrane channels have already closed. Therefore, a second opening of the same channels can increase the postsynaptic potential to a still greater level, and the more rapid the rate of stimulation, the greater the postsynaptic potential becomes. Thus, successive discharges from a single presynaptic terminal, if they occur rapidly enough, can add to one another; that is, they can summate. This type of summation is called *temporal summation*.

Simultaneous Summation of Inhibitory and Excitatory Postsynaptic Potentials. If an IPSP tends to *decrease* the membrane potential to a more negative value while an EPSP tends to *increase* the potential at the same time, these two effects can completely or partially nullify each other. Thus, if a neuron is being excited by an EPSP, an inhibitory signal from another source can often reduce the postsynaptic potential to less than threshold value for excitation, thus turning off activity of the neuron.

Facilitation of Neurons

When the summated postsynaptic potential is excitatory but has not risen high enough to reach the threshold for firing by the postsynaptic neuron, the neuron is said to be *facilitated*. That is, its membrane potential is nearer the threshold for firing than normal but is not yet at the firing level. Consequently, another excitatory signal entering the neuron from some other source can then excite the neuron very easily. Diffuse signals in the nervous system often do facilitate large groups of neurons so that they can respond quickly and easily to signals arriving from other sources.

SPECIAL FUNCTIONS OF DENDRITES FOR EXCITING NEURONS

Large Spatial Field of Excitation of Dendrites. The dendrites of the anterior motor neurons often extend 500 to 1000 micrometers in all directions from the neuronal soma, and these dendrites can receive signals from a large spatial area around the motor neuron. This feature provides a vast opportunity for summation of signals from many separate presynaptic nerve fibers.

It is also important that 80% to 95% of all the presynaptic terminals of the anterior motor neuron terminate on dendrites, in contrast to only 5% to 20% terminating on the neuronal soma. Therefore, a large share of the excitation is provided by signals transmitted by way of the dendrites.

Most Dendrites Cannot Transmit Action Potentials But They Can Transmit Signals Within the Same Neuron By Electrotonic Conduction. Most dendrites fail to transmit action potentials because their membranes have relatively few voltage-gated sodium channels, and their thresholds for excitation are too high for action potentials to occur. Yet, they do transmit *electrotonic current* down the dendrites to the soma. Transmission of electrotonic current means direct spread of electrical current by ion conduction in the fluids of the dendrites but without generation of action potentials. Stimulation (or inhibition) of the neuron by this current has special characteristics, as described next.

Decrement of Electrotonic Conduction in the Dendrites Causes Greater Excitatory (or Inhibitory) Effect By Synapses Located Near the Soma. In **Fig. 46.13**, multiple excitatory and inhibitory synapses are shown stimulating the dendrites of a neuron. On the two dendrites to the left, there are excitatory effects near the tip ends. Note the high levels of EPSPs at these ends—that is, note the *less negative* membrane potentials at these points. However, a large share of the EPSP is lost before it reaches the soma. The dendrites are long, and their membranes are thin and at least partially permeable to potassium and chloride ions, making them "leaky" to electric current. Therefore, before the excitatory potentials can reach the soma, a large share of the potential is lost by leakage through the membrane. This decrease in membrane potential as it spreads electrotonically along dendrites toward the soma is called *decremental conduction*.

The farther the excitatory synapse is from the soma of the neuron, the greater will be the decrement and the lesser will be excitatory signal reaching the soma. Therefore, the dendritic synapses that lie near the soma have far more effect in causing neuron excitation or inhibition than those that lie far away from the soma.

Summation of Excitation and Inhibition in Dendrites. The uppermost dendrite of **Fig. 46.13** is shown to be stimulated by both excitatory and inhibitory synapses. At the tip of the dendrite is a strong EPSP, but nearer the soma are two inhibitory synapses acting on the same dendrite. These inhibitory synapses provide a hyperpolarizing voltage that completely nullifies the excitatory effect and, indeed, transmits a small amount of inhibition by electrotonic conduction toward the soma. Thus, dendrites can summate EPSPs and IPSPs in the same way as soma. Also shown in the figure are several inhibitory synapses located directly on the axon hillock and initial axon segment. This location provides especially powerful inhibition because it has the direct effect of increasing the threshold for excitation at the very point where the action potential is normally generated.

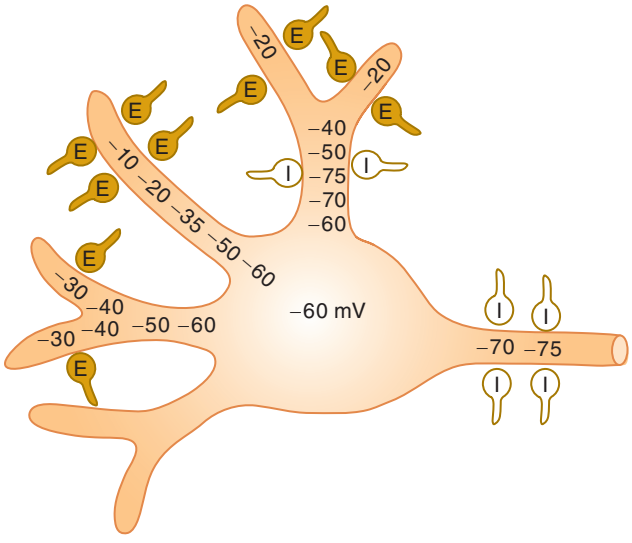

Figure 46.13 Stimulation of a neuron by presynaptic terminals located on dendrites, showing especially decremental conduction of excitatory (E) electrotonic potentials in the two dendrites to the left and inhibition (I) of dendritic excitation in the dendrite that is uppermost. A powerful effect of inhibitory synapses at the initial segment of the axon is also shown.

EXCITATION STATE OF THE NEURON AND RATE OF FIRING

The Summated Excitatory or Inhibitory Drive to the Neuron. If there is a higher degree of excitation than inhibition of the neuron at any given instant, it is in an *excitatory state*. Conversely, if there is more inhibition than excitation, the neuron is in an *inhibitory state*.

When the excitatory state of a neuron rises above the threshold for excitation, the neuron will fire repetitively as long as the excitatory state remains at that level. **Fig. 46.14** shows responses of three types of neurons to varying levels of excitatory state. Note that neuron 1 has a low threshold for excitation, whereas neuron 3 has a high threshold. But, note also that neuron 2 has the lowest maximum frequency of discharge, whereas neuron 3 has the highest maximum frequency.

Some neurons in the central nervous system fire continuously because even the normal excitatory state is above the threshold level. Their frequency of firing can usually be further increased by increasing their excitatory state. The frequency can be decreased, or firing can even be stopped, by superimposing an inhibitory state on the neuron. Thus, different neurons respond differently, have different thresholds for excitation, and have widely differing maximum frequencies of discharge. One can readily understand the importance of having different neurons with these many types of response characteristics to perform the widely varying functions of the nervous system.

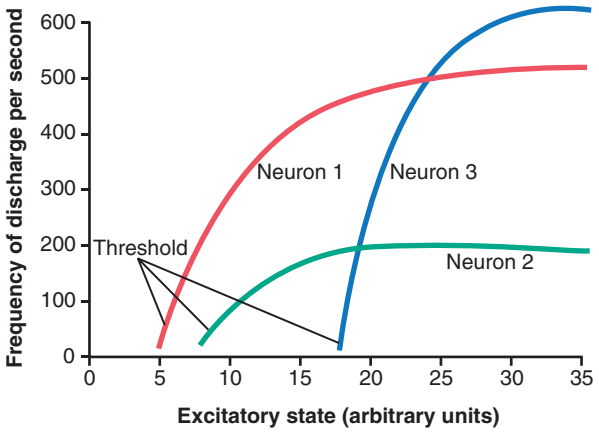

Figure 46.14 Response characteristics of different types of neurons to different levels of excitatory state.

SPECIAL CHARACTERISTICS OF SYNAPTIC TRANSMISSION

Fatigue of Synaptic Transmission. When excitatory synapses are repetitively stimulated at a rapid rate, the number of discharges by the postsynaptic neuron is at first very great, but the firing rate becomes progressively less in succeeding milliseconds or seconds. This phenomenon is called *fatigue of synaptic transmission*.

Fatigue is an exceedingly important characteristic of synaptic function because when areas of the nervous system become overexcited, fatigue causes them to lose this excess excitability after a while. For example, fatigue is probably the most important means whereby the excess excitability of the brain during an epileptic seizure is finally subdued so that the seizure ceases. Thus, the development of fatigue is a protective mechanism against excess neuronal activity. This subject is discussed further in the description of reverberating neuronal circuits in Chapter 47.

The mechanism of fatigue is mainly exhaustion or partial exhaustion of the stores of transmitters in the presynaptic terminals. The excitatory terminals on many neurons can store enough excitatory transmitter to cause only about 10,000 action potentials, and the transmitter can be exhausted in only a few seconds to a few minutes of rapid stimulation. Part of the fatigue process probably results from two other factors as well: (1) progressive inactivation of many of the postsynaptic membrane receptors; and (2) slow development of abnormal concentrations of ions inside the *postsynaptic* neuronal cell.

Effect of Acidosis or Alkalosis on Synaptic Transmission. Most neurons are highly responsive to changes in pH of the surrounding interstitial fluids. *Normally, alkalosis greatly increases neuronal excitability*. For example, a rise in arterial blood pH from the 7.4 norm to 7.8 to 8.0 often causes cerebral epileptic seizures because of increased excitability of some or all of the cerebral neurons. In a person who is predisposed to epileptic seizures, even a short period of hyperventilation, which blows off carbon dioxide and elevates the pH, may precipitate an epileptic attack.

Conversely, *acidosis greatly depresses neuronal activity;* a fall in pH from 7.4 to below 7.0 usually causes a comatose state. For example, in very severe diabetic or uremic acidosis, coma almost always develops.

Effect of Hypoxia on Synaptic Transmission. Neuronal excitability is highly dependent on an adequate supply of oxygen. Cessation of oxygen for only a few seconds can cause complete inexcitability of some neurons. This effect is observed when the brain's blood flow is temporarily interrupted because within 3 to 7 seconds, the person becomes unconscious.

Effect of Drugs on Synaptic Transmission. Many drugs are known to increase the excitability of neurons, and others are known to decrease excitability. For example, *caffeine, theophylline*, and *theobromine*, which are found in coffee, tea, and cocoa, respectively, all *increase* neuronal excitability, presumably by reducing the threshold for excitation of neurons.

Strychnine is one of the best known of all agents that increase excitability of neurons. However, it does not do this by reducing the threshold for excitation of the neurons; instead, it *inhibits the action of some normally inhibitory transmitter substances*, especially the inhibitory effect of glycine in the spinal cord. Therefore, the effects of the excitatory transmitters become overwhelming, and the neurons become so excited that they go into rapidly repetitive discharge, resulting in severe tonic muscle spasms.

Most anesthetics increase the neuronal membrane threshold for excitation and thereby decrease synaptic transmission at many points in the nervous system. Because many of the anesthetics are especially lipid-soluble, some of them might change the physical characteristics of the neuronal membranes, making them less responsive to excitatory agents.

Synaptic Delay. During transmission of a neuronal signal from a presynaptic neuron to a postsynaptic neuron, a certain amount of time is consumed in the process of (1) discharge of the transmitter substance by the presynaptic terminal; (2) diffusion of the transmitter to the postsynaptic neuronal membrane; (3) action of the transmitter on the membrane receptor; (4) action of the receptor to increase the membrane permeability; and (5) inward diffusion of sodium to raise the EPSP to a high enough level to elicit an action potential. The *minimal* period of time required for all these events to take place, even when large numbers of excitatory synapses are stimulated simultaneously, is about 0.5 millisecond and is called the *synaptic delay*. Neurophysiologists can measure the *minimal* delay time between an input volley of impulses into a pool of neurons and the consequent output volley. From the measurement of delay time, one can then estimate the number of series neurons in the circuit.

CHAPTER 47

Sensory Receptors and Neuronal Circuits for Processing Information

Our perceptions of signals within our bodies and of the world around us are mediated by a complex system of sensory receptors that detect such stimuli as touch, sound, light, pain, cold, and warmth. In this chapter, we discuss the basic mechanisms whereby these receptors change sensory stimuli into nerve signals that are then conveyed to and processed in the central nervous system.

TYPES OF SENSORY RECEPTORS AND THE STIMULI THEY DETECT

Table 47.1 lists and classifies five basic types of sensory receptors: (1) *mechanoreceptors*, which detect mechanical compression or stretching of the receptor or of tissues adjacent to the receptor; (2) *thermoreceptors*, which detect changes in temperature, with some receptors detecting cold and others detecting warmth; (3) *nociceptors* (pain receptors), which detect physical or chemical damage occurring in the tissues; (4) *electromagnetic receptors (e.g., photoreceptors)*, which detect light energy on the retina of the eye; and (5) *chemoreceptors*, which detect taste in the mouth, smell in the nose, oxygen level in the arterial blood, osmolality of the body fluids, carbon dioxide concentration, and other factors that make up the chemistry of the body.

We will discuss the function of a few specific types of receptors, primarily peripheral mechanoreceptors, to illustrate some of the principles whereby receptors operate. Other receptors are discussed in the chapters related to the sensory systems that they subserve. **Fig. 47.1** shows some of the types of mechanoreceptors found in the skin or in deep tissues of the body.

DIFFERENTIAL SENSITIVITY OF RECEPTORS

How do two types of sensory receptors detect different types of sensory stimuli? The answer is "by *differential sensitivities*." That is, each type of receptor is highly sensitive to one type of stimulus for which it is designed and yet is almost nonresponsive to other types of sensory stimuli. Thus, the rods and cones of the eyes are highly responsive to light but are almost completely nonresponsive to normal ranges of heat, cold, pressure on the eyeballs, or chemical changes in the blood. The osmoreceptors of the supraoptic nuclei in the hypothalamus detect minute changes in the osmolality of the body fluids but are not known to respond to sound. Finally, pain receptors in the skin are almost never stimulated by usual touch or pressure stimuli but become highly active when tactile stimuli become severe enough to damage the tissues.

Modality of Sensation and Neural Coding

Labeled Line Neural Coding. Each of the principal types of sensation that we can experience—pain, touch, sight, sound, and so forth—is called a *modality* of sensation. Yet, despite the fact that we experience these different modalities of sensation, nerve fibers transmit only impulses. Therefore, how do different nerve fibers transmit different modalities of sensation?

A partial answer is that each nerve tract terminates at a specific point in the central nervous system, and the type of sensation felt when a nerve fiber is stimulated is determined by the point in the nervous system to which the fiber leads. This specificity of afferent nerve fibers for transmitting only one modality of sensation is called *labeled line coding*. For example, if a pain fiber is stimulated, the person perceives pain regardless of what type of stimulus excites the fiber. The stimulus can be electricity, overheating of the fiber, crushing of the fiber, or stimulation of the pain nerve ending by damage to the tissue cells. In all these cases, the person perceives pain. Likewise, if a touch fiber is stimulated by electrical excitation of a touch receptor or in any other way, the person perceives touch because touch fibers lead to specific touch areas in the brain. Similarly, fibers from the retina of the eye terminate in the vision areas of the brain, fibers from the ear terminate in the auditory areas of the brain, and temperature fibers terminate in the temperature areas.

Population Coding. In some cases, one cell can encode more than one sensory modality and a combination of signals from many cells is required for the sensation. An example of this *population coding* is color vision, discussed in Chapter 51. Although each color photoreceptor (cone) is most sensitive to a specific color (blue, green, or red), a range of wavelengths can elicit changes in firing rates in its associated neuron. To perceive the full spectrum of color, the responses from a population of color

Table 47.1 Classification of Sensory Receptors

1. Mechanoreceptors

Skin tactile sensibilities (epidermis and dermis)
- Free nerve endings
- Expanded tip endings
  - Merkel discs
  - Plus several other variants
- Spray endings
- Ruffini endings
- Encapsulated endings
  - Meissner corpuscles
  - Krause corpuscles
- Hair end-organs

Deep tissue sensibilities
- Free nerve endings
- Expanded tip endings
- Spray endings

Ruffini endings
- Encapsulated endings
  - Pacinian corpuscles
  - Plus a few other variants
- Muscle endings
  - Muscle spindles
  - Golgi tendon receptors

Hearing
- Sound receptors of cochlea
  - Equilibrium
- Vestibular receptors

Arterial pressure
- Baroreceptors of carotid sinuses and aorta

2. Thermoreceptors

Cold
- Cold receptors

Warmth
- Warm receptors

3. Nociceptors

Pain
- Free nerve endings

4. Electromagnetic Receptors

Vision
- Rods
- Cones

5. Chemoreceptors

Taste
- Receptors of taste buds

Smell
- Receptors of olfactory epithelium

Arterial oxygen
- Receptors of aortic and carotid bodies

Osmolality
- Neurons in or near supraoptic nuclei

Blood CO_2
- Receptors in or on surface of medulla and in aortic and carotid bodies

Blood glucose, amino acids, fatty acids
- Receptors in hypothalamus

photoreceptors must be combined. Even more complex is the neural representation of an object, which results from a complex mosaic of individual receptors that collectively signal colors, size, contours, and texture.

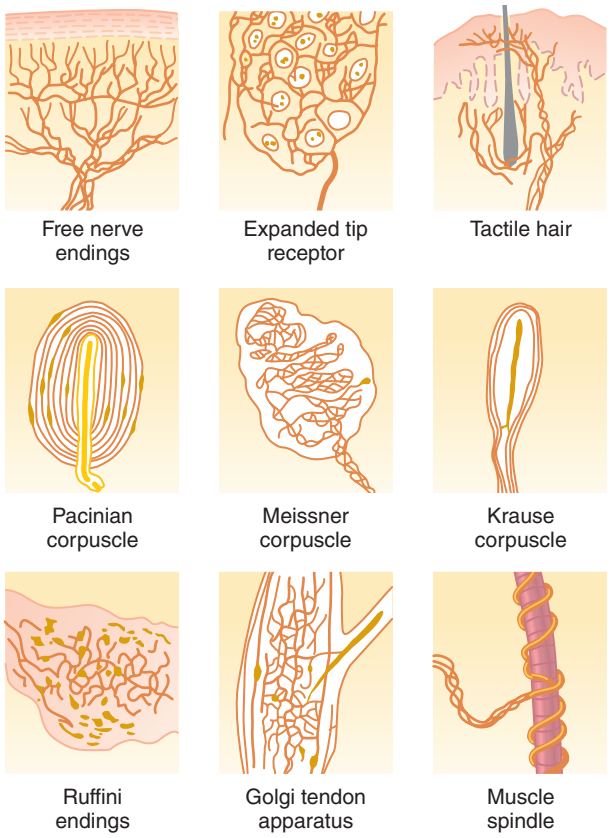

Figure 47.1 Several types of somatic sensory nerve endings.

Each of our sensory modalities is represented by an ensemble of central neurons connected to a specific class of receptors. These different ensembles of neurons are referred to as *sensory systems* and include the somatosensory, visual, auditory, vestibular, olfactory, and taste systems discussed in subsequent chapters. The richness of our perceptions requires activation of large ensembles of receptors acting in parallel, as well as sequential relay and processing of their signals by the central nervous system.

TRANSDUCTION OF SENSORY STIMULI INTO NERVE IMPULSES

LOCAL ELECTRICAL CURRENTS AT NERVE ENDINGS—RECEPTOR POTENTIALS

All sensory receptors have one feature in common. Whatever the type of stimulus that excites the receptor, its immediate effect is to change the membrane electrical potential of the receptor. This change in potential is called a *receptor potential*.

Mechanisms of Receptor Potentials. Different receptors can be excited in one of several ways to cause receptor potentials: (1) by mechanical deformation of the receptor, which stretches the receptor membrane and opens stretch-sensitive ion channels; (2) by application of a chemical to the membrane, which also opens ion channels or binds to membrane receptors and activates second messenger systems; (3) by change of the temperature of the membrane,

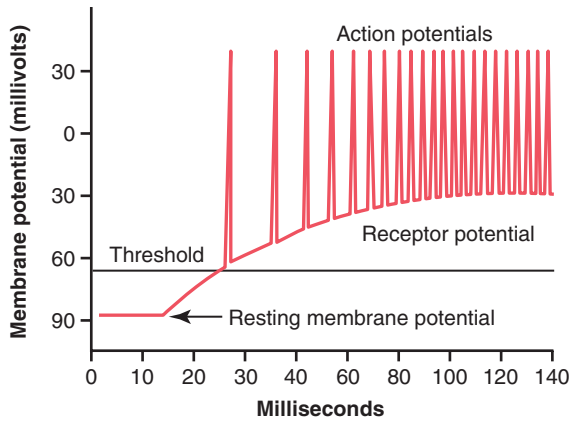

Figure 47.2 Typical relation between receptor potential and action potentials when the receptor potential rises above threshold level.

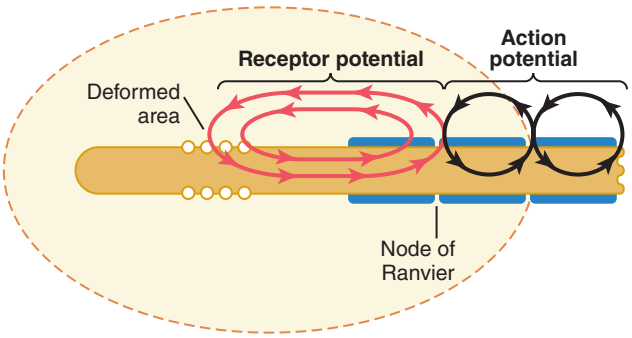

Figure 47.3 Excitation of a sensory nerve fiber by a receptor potential produced in a Pacinian corpuscle.

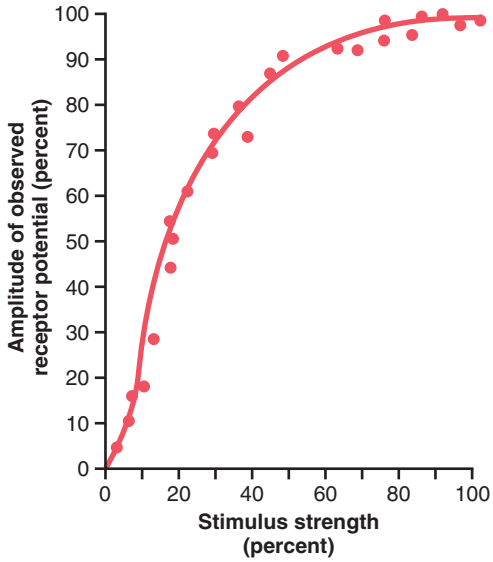

Figure 47.4 Relation of amplitude of receptor potential to strength of a mechanical stimulus applied to a Pacinian corpuscle. *(Data from Loëwenstein WR. Excitation and inactivation in a receptor membrane.* Ann N Y Acad Sci. *1961;94:510.)*

which alters activity of temperature-sensing ion channels and metabotropic receptors in the membrane; or (4) by the effects of electromagnetic radiation, such as light on a retinal visual receptor, which either directly or indirectly changes the receptor membrane characteristics and allows ions to flow through membrane channels.

These four means of exciting receptors correspond in general to the different types of known sensory receptors. In all cases, the basic cause of the change in membrane potential is a change in membrane permeability of the receptor, which allows ions to diffuse more or less readily through the membrane and thereby to change the *transmembrane potential*.

Maximum Receptor Potential Amplitude. The maximum amplitude of most sensory receptor potentials is about 100 mV, but this level occurs only at an extremely high intensity of sensory stimulus. This is about the same maximum voltage recorded in action potentials and is also the change in voltage when the membrane becomes maximally permeable to sodium ions.

Receptor Potentials Above a Threshold Elicit Action Potentials. When the receptor potential rises above the *threshold* for eliciting action potentials in the nerve fiber attached to the receptor, then action potentials occur, as illustrated in **Fig. 47.2**. Note also that the more the receptor potential rises above the threshold level, the greater becomes the *action potential frequency*.

Receptor Potential of the Pacinian Corpuscle—an Example of Receptor Function

Note in **Fig. 47.1** that the Pacinian corpuscle has a central nerve fiber extending through its core. Surrounding this central nerve fiber are multiple concentric capsule layers; thus, compression anywhere on the outside of the corpuscle will elongate, indent, or otherwise deform the central fiber.

Fig. 47.3 shows only the central fiber of the Pacinian corpuscle after all capsule layers but one have been removed. The tip of the central fiber inside the capsule is unmyelinated, but the fiber does become myelinated (the blue sheath shown in the figure) shortly before leaving the corpuscle to enter a peripheral sensory nerve.

Fig. 47.3 also shows the mechanism whereby a receptor potential is produced in the Pacinian corpuscle. Observe the small area of the terminal fiber that has been deformed by compression of the corpuscle, and note that ion channels have opened in the membrane, allowing positively charged sodium ions to diffuse to the interior of the fiber. This action creates increased positivity inside the fiber, initiating the receptor potential, which induces a *local circuit* of current flow, shown by the arrows, that spreads along the nerve fiber. At the first node of Ranvier, which lies inside the capsule of the Pacinian corpuscle, the local current flow depolarizes the fiber membrane at this node, which then sets off typical action potentials that are transmitted along the nerve fiber toward the central nervous system.

Relation Between Stimulus Intensity and the Receptor Potential. **Fig. 47.4** shows the changing amplitude of the receptor potential caused by progressively stronger

mechanical compression (increasing "stimulus strength") applied experimentally to the central core of a Pacinian corpuscle. Note that the amplitude increases rapidly at first but then progressively less rapidly at high stimulus strength.

In turn, the *frequency of repetitive action potentials* transmitted from sensory receptors increases approximately in proportion to the increase in receptor potential. Putting this principle together with the data in **Fig. 47.4**, one can see that very intense stimulation of the receptor causes progressively less and less additional increase in numbers of action potentials. This exceedingly important principle is applicable to almost all sensory receptors. It allows the receptor to be sensitive to very weak sensory experience and yet not reach a maximum firing rate until the sensory experience is extreme. This feature allows the receptor to have an extreme range of response—from very weak to very intense.

ADAPTATION OF RECEPTORS

Another characteristic of sensory receptors is that they generally *adapt* either partially or completely to any constant stimulus after a period of time. That is, when a continuous sensory stimulus is applied, the receptor responds at a high impulse rate at first and then at a progressively slower rate until, finally, the rate of action potentials decreases to very few or to none at all.

Fig. 47.5 shows typical adaptation of certain types of receptors. Note that the Pacinian corpuscle adapts very rapidly, hair receptors adapt within a second or so, and some joint capsule and muscle spindle receptors adapt slowly.

Furthermore, some sensory receptors adapt to a far greater extent than others. For example, the Pacinian corpuscles adapt to "extinction" within a few hundredths of a second, and the receptors at the bases of the hairs adapt to extinction within a second or more. Most *mechanoreceptors* appear to eventually adapt almost completely, but some require hours or days to do so, and they are called "nonadapting" receptors. The longest measured time for almost complete adaptation of a mechanoreceptor is about 2 days, which is the adaptation time for many carotid and aortic baroreceptors; however, some physiologists believe that these specialized baroreceptors never fully adapt. Some of the nonmechanoreceptors—the chemoreceptors and pain receptors, for example—probably never adapt completely.

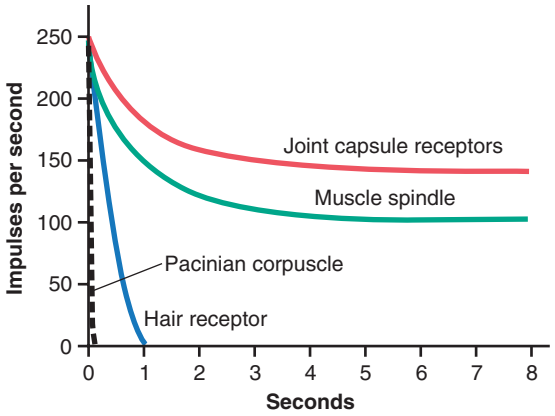

Figure 47.5 Adaptation of different types of receptors showing rapid adaptation of some receptors and slow adaptation of others.

Mechanisms By Which Receptors Adapt. The mechanism of receptor adaptation is different for each type of receptor in much the same way that development of a receptor potential is an individual property. For example, in the eye, the rods and cones adapt by changing the concentrations of their light-sensitive chemicals (discussed in Chapter 51).

Adaptation of the Pacinian corpuscle mechanoreceptor occurs in two ways. First, the Pacinian corpuscle is a viscoelastic structure so that when a distorting force is suddenly applied to one side of the corpuscle, this force is instantly transmitted by the viscous component of the corpuscle directly to the same side of the central nerve fiber, thus eliciting a receptor potential. However, within a few hundredths of a second, the fluid within the corpuscle redistributes, and the receptor potential is no longer elicited. Thus, the receptor potential appears at the onset of compression but disappears within a small fraction of a second, even though the compression continues.

The second, much slower mechanism of adaptation of the Pacinian corpuscle results from a process called *accommodation*, which occurs in the nerve fiber itself. That is, even if by chance the central core fiber should continue to be distorted, the tip of the nerve fiber gradually becomes accommodated to the stimulus. This probably results from progressive "inactivation" of the sodium channels in the nerve fiber membrane, which means that sodium current flow through the channels causes them to close gradually, an effect that seems to occur for all or most cell membrane sodium channels, as was explained in Chapter 5.

Presumably, these same two general mechanisms of adaptation also apply to the other types of mechanoreceptors. That is, part of the adaptation results from readjustments in the structure of the receptor, and part results from an electrical type of accommodation in the terminal nerve fibril.

Slowly Adapting Receptors Detect Continuous Stimulus Strength—the "Tonic" Receptors. Slowly adapting receptors continue to transmit impulses to the brain as long as the stimulus is present (or at least for many minutes or hours). Therefore, they keep the brain constantly apprised of the status of the body and its relation to its surroundings. For example, impulses from the muscle spindles and Golgi tendon apparatuses allow the nervous system to know the status of muscle contraction and load on the muscle tendon at each instant.

Other slowly adapting receptors include the following: (1) receptors of the macula in the vestibular apparatus;

(2) pain receptors; (3) arterial baroreceptors; and (4) chemoreceptors of the carotid and aortic bodies.

Because the slowly adapting receptors can continue to transmit information for many hours, or even days, they are called *tonic receptors*.

Rapidly Adapting Receptors Detect Change in Stimulus Strength—the "Rate Receptors," "Movement Receptors," or "Phasic Receptors." Receptors that adapt rapidly cannot be used to transmit a continuous signal because they are stimulated only when the stimulus strength changes. Yet, they react strongly *while a change is actually taking place*. Therefore, these receptors are called *rate receptors, movement receptors*, or *phasic receptors*. Thus, sudden pressure applied to the Pacinian corpuscle excites this receptor for a few milliseconds, and then its excitation is over, even though the pressure continues. Later, however, it transmits a signal again when the pressure is released. In other words, the Pacinian corpuscle is exceedingly important in apprising the nervous system of rapid tissue deformations, but it is useless for transmitting information about constant conditions in the body.

Predictive Function of the Rate Receptors. If the rate at which some change in the body's status is taking place is known, the state of the body a few seconds or even a few minutes later can be predicted. For example, the receptors of the semicircular canals in the vestibular apparatus of the ear detect the rate at which the head begins to turn when a person runs around a curve. Using this information, a person can predict how much they will turn within the next 2 seconds and can adjust the motion of the legs *ahead of time* to keep from losing balance. Likewise, receptors located in or near the joints help detect the rates of movement of the different parts of the body. For example, when a person is running, information from the joint rate receptors allows the nervous system to predict where the feet will be during any precise fraction of the next second. Therefore, appropriate motor signals can be transmitted to the muscles of the legs to make any necessary anticipatory corrections in position so that the person will not fall. Loss of this predictive function makes it impossible for the person to run.

Nerve Fibers That Transmit Different Types of Signals and Their Physiological Classification

Some signals need to be transmitted to or from the central nervous system extremely rapidly; otherwise, the information would be useless. An example of this is the sensory signals that apprise the brain of the momentary positions of the legs at each fraction of a second during running. At the other extreme, some types of sensory information, such as that depicting prolonged aching pain, do not need to be transmitted rapidly, and thus slowly conducting fibers will suffice. As shown in **Fig. 47.6**, nerve fibers come in all sizes, from 0.5 to 20 micrometers in diameter; the larger the diameter, the greater the conducting velocity. The range of conducting velocities is between 0.5 and 120 m/sec.

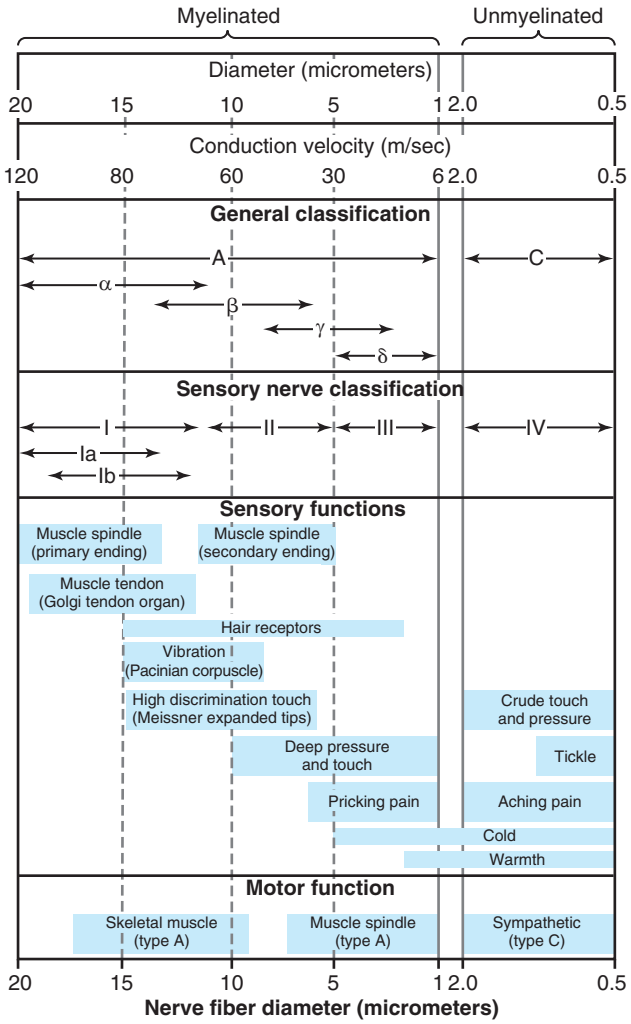

Figure 47.6 Physiological classifications and functions of nerve fibers.

General Classification of Nerve Fibers. Shown in **Fig. 47.6** is a "general classification" and a "sensory nerve classification" of the different types of nerve fibers. In the general classification, the fibers are divided into types A and C; the type A fibers are further subdivided into α, β, γ, and δ fibers.

Type A fibers are the typical large and medium-sized *myelinated* fibers of spinal nerves. Type C fibers are the small *unmyelinated* nerve fibers that conduct impulses at low velocities. The C fibers constitute more than half of the sensory fibers in most peripheral nerves, as well as all the postganglionic autonomic fibers.

The sizes, velocities of conduction, and functions of the different nerve fiber types are also given in **Fig. 47.6**. Note that a few large myelinated fibers can transmit impulses at velocities as great as 120 m/sec, covering a distance that is longer than a football field in 1 second. Conversely, the smallest fibers transmit impulses as slowly as 0.5 m/sec, requiring about 2 seconds to go from the big toe to the spinal cord.

Alternative Classification Used By Sensory Physiologists. Certain recording techniques have made it possible to separate the type Aα fibers into two subgroups, yet these same recording techniques cannot distinguish easily

between Aβ and Aγ fibers. Therefore, the following classification is frequently used by sensory physiologists.

Group Ia. Fibers from the annulospiral endings of muscle spindles (~17 microns in diameter on average; these fibers are α-type A fibers in the general classification).

Group Ib. Fibers from the Golgi tendon organs (~16 micrometers in diameter on average; these fibers also are α-type A fibers).

Group II. Fibers from most discrete cutaneous tactile receptors and from the flower-spray endings of the muscle spindles (~8 micrometers in diameter on average; these fibers are β- and γ-type A fibers in the general classification).

Group III. Fibers carrying temperature, crude touch, and pricking pain sensations (~3 micrometers in diameter on average; they are δ-type A fibers in the general classification).

Group IV. Unmyelinated fibers carrying pain, itch, temperature, and crude touch sensations (0.5–2 micrometers in diameter; they are type C fibers in the general classification).

SIGNAL INTENSITY TRANSMISSION IN NERVE TRACTS—SPATIAL AND TEMPORAL SUMMATION

One of the characteristics of each signal that always must be conveyed is signal intensity—for example, the intensity of pain. The different gradations of intensity can be transmitted either by using increasing numbers of parallel fibers or by sending more action potentials along a single fiber. These two mechanisms are called, respectively, *spatial summation* and *temporal summation*.

Spatial Summation. **Fig. 47.7** shows the phenomenon of *spatial summation*, whereby increasing signal strength is transmitted by using progressively greater numbers of fibers. This figure shows a section of skin innervated by a large number of parallel pain fibers. Each of these fibers arborizes into hundreds of minute *free nerve endings* that serve as pain receptors. The entire cluster of fibers from one pain fiber frequently covers an area of skin as large as 5 centimeters in diameter. This area is called the *receptor field* of that fiber. The number of endings is large in the center of the field but diminishes toward the periphery.

One can also see from the figure that the arborizing fibrils overlap those from other pain fibers. Therefore, a pinprick of the skin usually stimulates endings from many different pain fibers simultaneously. When the pinprick is in the center of the receptive field of a particular pain fiber, the degree of stimulation of that fiber is far greater than when it is in the periphery of the field because of the greater number of free nerve endings in the middle of the field.

The lower part of **Fig. 47.7** shows three views of the cross section of the nerve bundle leading from the skin area. To the left is the effect of a weak stimulus, with only a single nerve fiber in the middle of the bundle stimulated strongly (represented by the red-colored fiber), whereas several adjacent fibers are stimulated weakly (half-red fibers). The other two views of the nerve cross section show the effect of a moderate stimulus and a strong stimulus, with progressively more fibers being stimulated. Thus, the stronger signals spread to more and more fibers, a phenomenon called *spatial summation*.

Temporal Summation. A second means for transmitting signals of increasing strength is by increasing the *frequency* of nerve impulses in each fiber, called *temporal summation*. **Fig. 47.8** demonstrates this phenomenon,

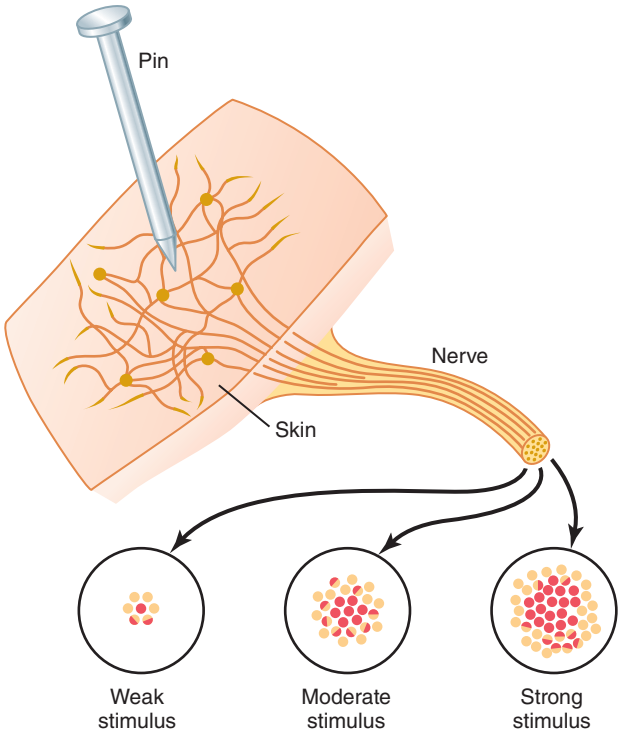

Figure 47.7 Pattern of stimulation of pain fibers in a nerve leading from an area of skin pricked by a pin. This pattern of stimulation is an example of *spatial summation*.

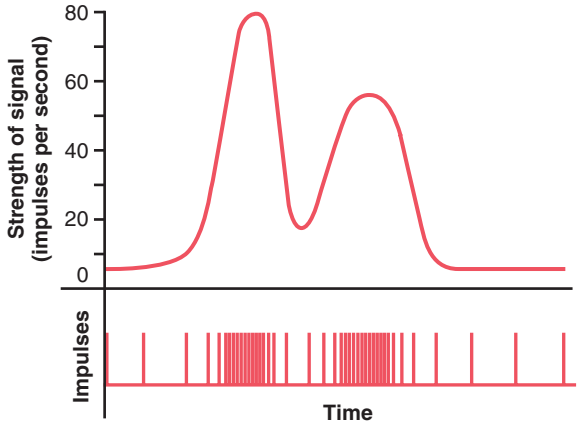

Figure 47.8 Translation of signal strength into a frequency-modulated series of nerve impulses, showing the strength of signal *(above)* and the separate nerve impulses *(below)*. This illustration is an example of *temporal summation*.

showing a changing strength of signal in the upper part and the actual impulses transmitted by the nerve fiber in the lower part.

TRANSMISSION AND PROCESSING OF SIGNALS IN NEURONAL POOLS

The central nervous system is composed of thousands to millions of neuronal pools; some of these pools contain few neurons, whereas others have vast numbers. For example, the entire cerebral cortex could be considered to be a single large neuronal pool. Other neuronal pools include the different basal ganglia and the specific nuclei in the thalamus, cerebellum, mesencephalon, pons, and medulla. Also, the entire dorsal gray matter of the spinal cord could be considered one long pool of neurons.

Each neuronal pool has its own special organization that causes it to process signals in its own unique way, thus allowing the total consortium of pools to achieve the multitude of functions of the nervous system. Yet, despite their differences in function, the pools also have many similar principles of function, described in the following sections.

RELAYING OF SIGNALS THROUGH NEURONAL POOLS

Organization of Neurons for Relaying Signals. **Fig. 47.9** is a schematic diagram of several neurons in a neuronal pool, showing input fibers to the left and "output" fibers to the right. Each input fiber divides hundreds to thousands of times, providing a thousand or more terminal fibrils that spread into a large area in the pool to synapse with dendrites or cell bodies of neurons in the pool. The dendrites usually also arborize and spread hundreds to thousands of micrometers in the pool.

The neuronal area stimulated by each incoming nerve fiber is called its *stimulatory field*. Note that large numbers of the terminals from each input fiber lie on the nearest neuron in its "field," but progressively fewer terminals lie on the neurons farther away.

Threshold and Subthreshold Stimuli—Excitation or Facilitation. As discussed in Chapter 46, discharge of a single excitatory presynaptic terminal almost never causes an action potential in a postsynaptic neuron. Instead, large numbers of input terminals must discharge on the same neuron either simultaneously or in rapid succession to cause excitation. For example, in **Fig. 47.9**, let us assume that six terminals must discharge almost simultaneously to excite any one of the neurons. Note that *input fiber 1* has more than enough terminals to cause *neuron a* to discharge. The stimulus from input fiber 1 to this neuron is said to be an *excitatory stimulus;* it is also called a *suprathreshold stimulus* because it is above the threshold required for excitation.

Input fiber 1 also contributes terminals to neurons b and c, but not enough to cause excitation. Nevertheless, discharge of these terminals makes both these neurons more likely to be excited by signals arriving through other incoming nerve fibers. Therefore, the stimuli to these neurons are said to be *subthreshold*, and the neurons are said to be *facilitated*.

Similarly, for *input fiber 2*, the stimulus to *neuron d* is a suprathreshold stimulus, and the stimuli to *neurons b* and *c* are subthreshold, but facilitating, stimuli.

Fig. 47.9 represents a highly condensed version of a neuronal pool because each input nerve fiber usually provides massive numbers of branching terminals to hundreds or thousands of neurons in its distribution "field," as shown in **Fig. 47.10**. In the central portion of the field in this figure, designated by the circled area, all the neurons are stimulated by the incoming fiber. Therefore, this is said to be the *discharge zone* of the incoming fiber, also called the *excited zone* or *liminal zone*. To each

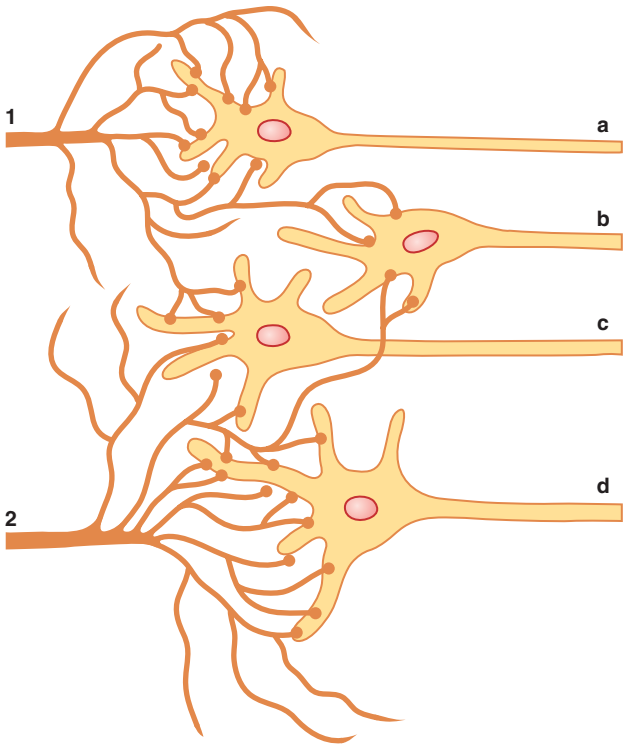

Figure 47.9 Basic organization of a neuronal pool. See text for details.

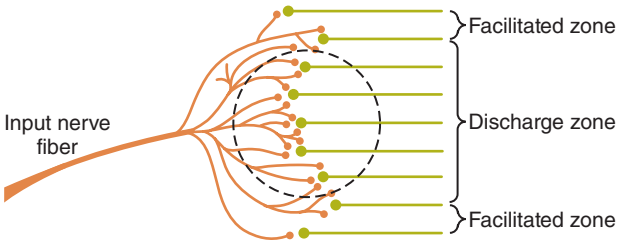

Figure 47.10 "Discharge" and "facilitated" zones of a neuronal pool.

side, the neurons are facilitated but not excited; these areas are called the *facilitated zone*, also called the *subthreshold zone* or *subliminal zone*.

Inhibition of a Neuronal Pool. Some incoming fibers inhibit neurons, rather than exciting them. This mechanism is the opposite of facilitation, and the entire field of the inhibitory branches is called the *inhibitory zone*. The degree of inhibition in the center of this zone is great because of large numbers of endings in the center and becomes progressively less toward its edges.

Divergence of Signals Passing Through Neuronal Pools

Often, it is important for weak signals entering a neuronal pool to excite far greater numbers of nerve fibers leaving the pool. This phenomenon is called *divergence*. Two major types of divergence occur and have entirely different purposes.

An *amplifying* type of divergence is shown in **Fig. 47.11A**. Amplifying divergence means simply that an input signal spreads to an increasing number of neurons as it passes through successive orders of neurons in its path. This type of divergence is characteristic of the corticospinal pathway in its control of skeletal muscles, with a single large pyramidal cell in the motor cortex capable, under highly facilitated conditions, of exciting as many as 10,000 muscle fibers.

The second type of divergence, shown in **Fig. 47.11B**, is *divergence into multiple tracts*. In this case, the signal is transmitted in two directions from the pool. For example, information transmitted up the dorsal columns of the spinal cord takes two courses in the lower part of the brain: (1) into the cerebellum; and (2) on through the lower regions of the brain to the thalamus and cerebral cortex. Likewise, in the thalamus, almost all sensory information is relayed into still deeper structures of the thalamus and, at the same time, to discrete regions of the cerebral cortex.

Convergence of Signals

Convergence means signals from multiple inputs uniting to excite a single neuron. **Fig. 47.12A** shows *convergence from a single source*—that is, multiple terminals each from a single incoming fiber tract terminate on the same neuron. The importance of this type of convergence is that neurons are almost never excited by an action potential from a single input terminal. However, action potentials converging on the neuron from multiple terminals provide enough spatial summation to bring the neuron to the threshold required for discharge.

Convergence can also result from input signals (excitatory or inhibitory) *from multiple sources*, as shown in **Fig. 47.12B**. For example, the interneurons of the spinal cord receive converging signals from the following: (1) peripheral nerve fibers entering the cord; (2) propriospinal fibers passing from one segment of the cord to another; (3) corticospinal fibers from the cerebral cortex; and (4) several other long pathways descending from the brain into the spinal cord. Then, the signals from the interneurons converge on the anterior motor neurons to control muscle function.

Such convergence allows *summation* of information from different sources, and the resulting response is a summated effect of all the different types of information. Convergence is one of the important means whereby the central nervous system correlates, summates, and sorts different types of information.

Neuronal Circuits With Both Excitatory and Inhibitory Output Signals

Sometimes an incoming signal to a neuronal pool causes an output excitatory signal going in one direction and, at the same time, an inhibitory signal going elsewhere. For example, at the same time that an excitatory signal is transmitted by one set of neurons in the spinal cord to cause forward movement of a leg, an inhibitory signal is transmitted through a separate set of neurons to inhibit the muscles on the back of the leg so that they will

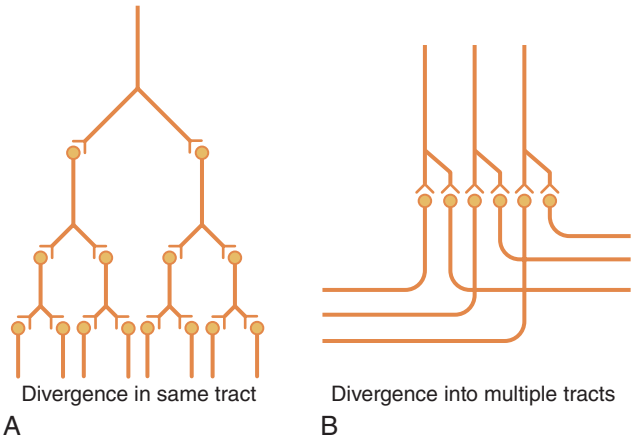

Figure 47.11 "Divergence" in neuronal pathways. (A) Divergence within a pathway to cause "amplification" of the signal. (B) Divergence into multiple tracts to transmit the signal to separate areas.

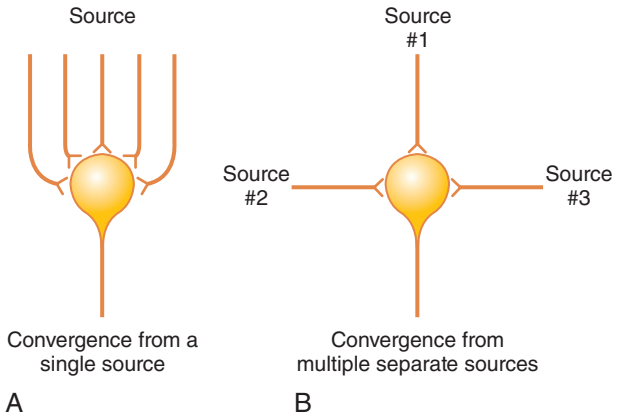

Figure 47.12 Convergence of multiple input fibers onto a single neuron. (A) Multiple input fibers from a single source. (B) Input fibers from multiple separate sources.

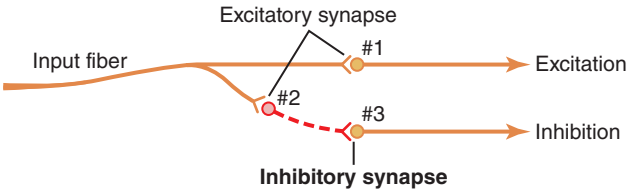

Figure 47.13 Inhibitory circuit. Neuron 2 is an inhibitory neuron.

not oppose the forward movement. This type of circuit is characteristic for controlling all antagonistic pairs of muscles; it is called the *reciprocal inhibition circuit*.

Fig. 47.13 shows the means whereby the inhibition is achieved. The input fiber directly excites the excitatory output pathway, but it stimulates an intermediate *inhibitory neuron* (neuron 2), which secretes a different type of transmitter substance to inhibit the second output pathway from the pool. This type of circuit is also important in preventing overactivity in many parts of the brain.

PROLONGATION OF A SIGNAL BY A NEURONAL POOL—AFTERDISCHARGE

Thus far, we have considered signals that are merely relayed through neuronal pools. However, in many cases, a signal entering a pool causes a prolonged output discharge, called *afterdischarge*, lasting a few milliseconds to as long as many minutes after the incoming signal is over. The most important mechanisms whereby afterdischarge occurs are described in the following sections.

Synaptic Afterdischarge. When excitatory synapses discharge on the surfaces of dendrites or soma of a neuron, a postsynaptic electrical potential develops in the neuron and lasts for many milliseconds, especially when some of the long-acting synaptic transmitter substances are involved. As long as this potential lasts, it can continue to excite the neuron, causing it to transmit a continuous train of output impulses, as explained in Chapter 46. Thus, as a result of this synaptic afterdischarge alone, it is possible for a single instantaneous input signal to cause a sustained signal output (a series of repetitive discharges) lasting for many milliseconds.

Reverberatory (Oscillatory) Circuit as a Cause of Signal Prolongation. One of the most important circuits in the entire nervous system is the *reverberatory* or *oscillatory circuit*. Such circuits are caused by positive feedback within the neuronal circuit that feeds back to reexcite the input of the same circuit. Consequently, once stimulated, the circuit may discharge repetitively for a long time.

Several possible varieties of reverberatory circuits are shown in **Fig. 47.14**. The simplest, shown in **Fig. 47.14A**, involves only a single neuron. In this case, the output neuron sends a collateral nerve fiber back to its own dendrites or soma to restimulate itself. Although the importance of this type of circuit is not clear, once the neuron discharges, the feedback stimuli could keep the neuron discharging for a protracted time thereafter.

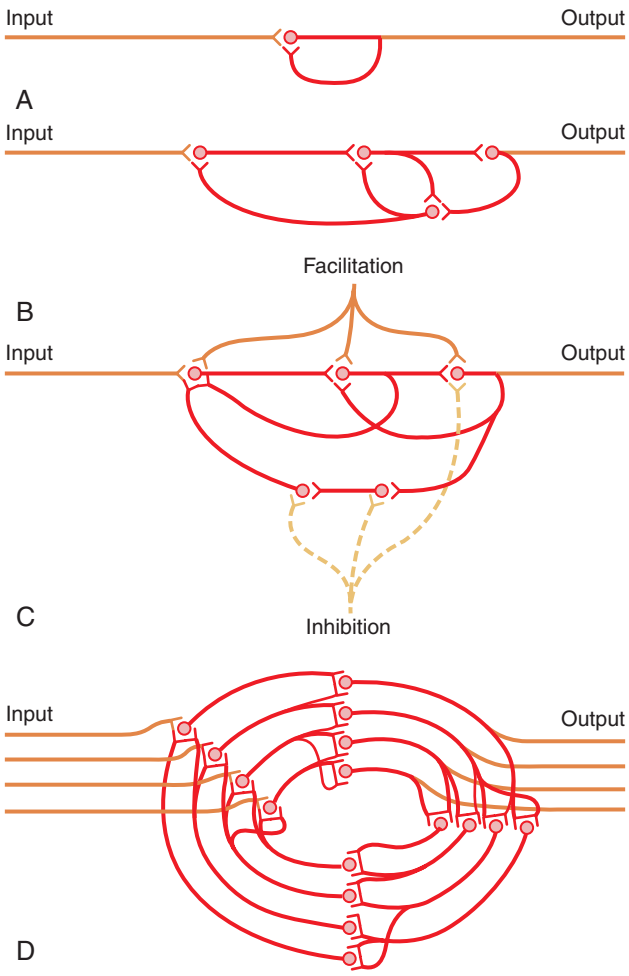

Figure 47.14 (A–D) Reverberatory circuits of increasing complexity.

Fig. 47.14B shows a few additional neurons in the feedback circuit, which causes a longer delay between initial discharge and the feedback signal. **Fig. 47.14C** shows a more complex system in which both facilitatory and inhibitory fibers impinge on the reverberating circuit. A facilitatory signal enhances the intensity and frequency of reverberation, whereas an inhibitory signal depresses or stops the reverberation.

Fig. 47.14D shows that most reverberating pathways are constituted of many parallel fibers. At each cell station, the terminal fibrils spread widely. In such a system, the total reverberating signal can be either weak or strong, depending on how many parallel nerve fibers are momentarily involved in the reverberation.

Signal Prolongation of a Reverberatory Circuit. **Fig. 47.15** shows output signals from a typical reverberatory circuit. The input stimulus may last only 1 millisecond or so, and yet the output can last for many milliseconds or even minutes. The figure demonstrates that the intensity of the output signal usually increases to a high value early in reverberation and then decreases to a critical point where it suddenly ceases entirely. The cause of this sudden cessation of reverberation is fatigue of synaptic junctions

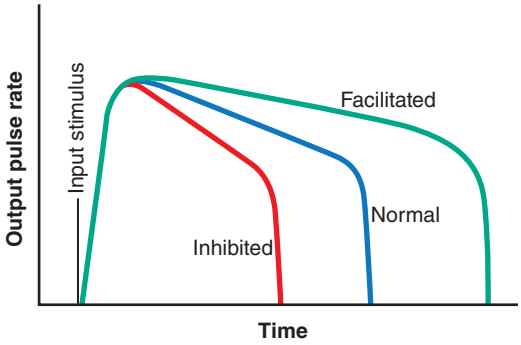

Figure 47.15 Typical pattern of the output signal from a reverberatory circuit after a single input stimulus, showing the effects of facilitation and inhibition.

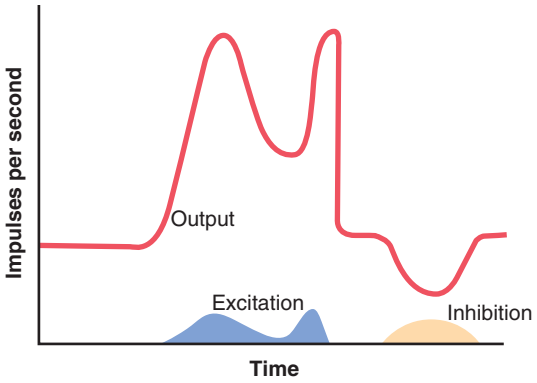

Figure 47.16 Continuous output from either a reverberating circuit or a pool of intrinsically discharging neurons. This figure also shows the effect of excitatory or inhibitory input signals.

in the circuit. Fatigue beyond a certain critical level lowers the stimulation of the next neuron in the circuit below threshold level so that the circuit feedback is suddenly broken.

The duration of the total signal before cessation can also be controlled by signals from other parts of the brain that inhibit or facilitate the circuit. These patterns of output signals are recorded from motor nerves exciting a muscle involved in a flexor reflex after pain stimulation of the foot (as shown later in **Fig. 47.18**).

Continuous Signal Output From Some Neuronal Circuits

Some neuronal circuits emit output signals continuously, even without excitatory input signals. At least two mechanisms can cause this effect: (1) continuous intrinsic neuronal discharge; and (2) continuous reverberatory signals.

Continuous Discharge Caused By Intrinsic Neuronal Excitability. Neurons, like other excitable tissues, discharge repetitively if their level of excitatory membrane potential rises above a certain threshold level. The membrane potentials of many neurons, even normally, are high enough to cause them to emit impulses continually. This phenomenon occurs especially in many of the neurons of the cerebellum, as well as in most of the interneurons of the spinal cord. The rates at which these cells emit impulses can be increased by excitatory signals or decreased by inhibitory signals; inhibitory signals often can decrease the rate of firing to zero.

Continuous Signals Emitted From Reverberating Circuits as a Means for Transmitting Information. A reverberating circuit that does not fatigue enough to stop reverberation is a source of continuous impulses. Furthermore, excitatory impulses entering the reverberating pool can increase the output signal, whereas inhibition can decrease or even extinguish the signal.

Fig. 47.16 illustrates a continuous output signal from a pool of neurons. The pool may be emitting impulses because of intrinsic neuronal excitability or as a result of reverberation. Note that an excitatory input signal greatly increases the output signal, whereas an inhibitory input signal greatly decreases the output. Students who are familiar with radio transmitters will recognize this to be a *carrier wave* type of information transmission. That is, the excitatory and inhibitory control signals are not the *cause* of the output signal, but they do *control* its changing level of intensity. Note that *this carrier wave system allows a decrease in signal intensity, as well as an increase*, whereas up to this point, the types of information transmission we have discussed have been mainly positive information rather than negative information.

This type of information transmission is used by the autonomic nervous system to control such functions as vascular tone, gut tone, degree of constriction of the iris in the eye, and heart rate. That is, the nerve excitatory signal to each of these areas can be either increased or decreased by accessory input signals into the reverberating neuronal pathway.

Rhythmical Signal Output

Many neuronal circuits emit rhythmical output signals—for example, a rhythmical respiratory signal originates in the respiratory centers of the medulla and pons. This respiratory rhythmical signal continues throughout life. Other rhythmical signals, such as those that cause scratching movements by the hind leg of a dog or the walking movements of any animal, require input stimuli into the respective circuits to initiate the rhythmical signals.

All or almost all rhythmical signals that have been studied experimentally have been found to result from reverberating circuits or a succession of sequential reverberating circuits that feed excitatory or inhibitory signals in a circular pathway from one neuronal pool to the next.

Excitatory or inhibitory signals can also increase or decrease the amplitude of the rhythmical signal output. **Fig. 47.17**, for example, shows changes in the respiratory signal output in the phrenic nerve. When the carotid body is stimulated by arterial oxygen deficiency, both the frequency and the amplitude of the respiratory rhythmical output signal increase progressively.

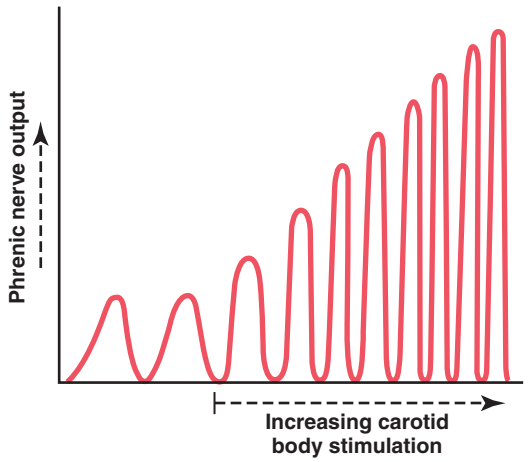

Figure 47.17 The rhythmical output of summated nerve impulses from the respiratory center, showing that progressively increasing stimulation of the carotid body increases both the intensity and the frequency of the phrenic nerve signal to the diaphragm to increase respiration.

INSTABILITY AND STABILITY OF NEURONAL CIRCUITS

Almost every part of the brain connects either directly or indirectly with every other part, which creates a serious challenge. If the first part excites the second, the second the third, the third the fourth, and so on until finally the signal reexcites the first part, then an excitatory signal entering any part of the brain would set off a continuous cycle of reexcitation of all parts. If this cycle should occur, the brain would be inundated by a mass of uncontrolled reverberating signals—signals that would be transmitting no information but, nevertheless, would be consuming the circuits of the brain so that none of the informational signals could be transmitted.

Such an effect occurs in widespread areas of the brain during *epileptic seizures*. How does the central nervous system prevent this effect from happening all the time? The answer lies mainly in two basic mechanisms that function throughout the central nervous system: (1) inhibitory circuits; and (2) fatigue of synapses.

INHIBITORY CIRCUITS AS A MECHANISM FOR STABILIZING NERVOUS SYSTEM FUNCTION

Two types of inhibitory circuits in widespread areas of the brain help prevent excessive spread of signals: (1) inhibitory feedback circuits that return from the termini of pathways back to the initial excitatory neurons of the same pathways occur in virtually all sensory nervous pathways and inhibit either the input neurons or the intermediate neurons in the sensory pathway when the termini become overly excited; and (2) some neuronal pools exert gross inhibitory control over widespread areas of the brain (e.g., many of the basal ganglia exert inhibitory influences throughout the muscle control system).

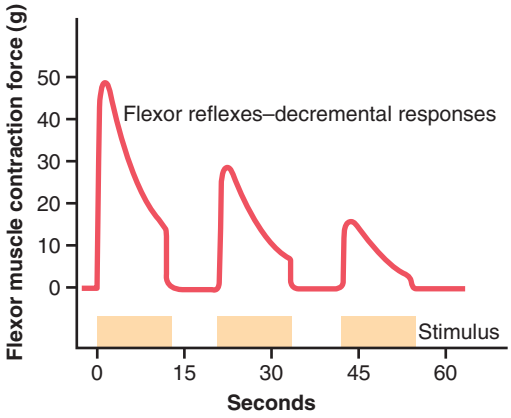

Figure 47.18 Successive flexor reflexes showing fatigue of conduction through the reflex pathway.

SYNAPTIC FATIGUE AS A MEANS OF STABILIZING THE NERVOUS SYSTEM

Synaptic fatigue means simply that synaptic transmission becomes progressively weaker the more prolonged and more intense the period of excitation. **Fig. 47.18** shows three successive records of a flexor reflex elicited in an animal caused by pain stimuli in the footpad. Note in each record that the strength of contraction progressively "decrements"—that is, its strength diminishes. Much of this effect is caused by *fatigue* of synapses in the flexor reflex circuit. Furthermore, the shorter the interval between successive flexor reflexes, the less the intensity of the subsequent reflex response.

Automatic Short-Term Adjustment of Pathway Sensitivity By the Fatigue Mechanism. Those neuronal pathways that are overused usually become rapidly fatigued, so their sensitivities decrease. Conversely, those that are underused become rested, and their sensitivities increase. Thus, fatigue and recovery from fatigue constitute an important short-term means of moderating the sensitivities of the different nervous system circuits. These functions help keep the circuits operating in a range of sensitivity that allows effective function.

Long-Term Changes in Synaptic Sensitivity Caused By Automatic Downregulation or Upregulation of Synaptic Receptors. The long-term sensitivities of synapses can be changed tremendously by upregulating the number of receptor proteins at the synaptic sites when there is underactivity and downregulating the receptors when there is overactivity. The mechanism for this process is as follows. Receptor proteins are being formed constantly by the endoplasmic reticular–Golgi apparatus system and are constantly being inserted into the receptor neuron synaptic membrane. However, when the synapses are overused so that excesses of transmitter substance combine with the receptor proteins, many of these receptors are inactivated and removed from the synaptic membrane.

It is indeed fortunate that upregulation and downregulation of receptors, as well as other control mechanisms for adjusting synaptic sensitivity, continually adjust the sensitivity in each circuit to the level required for proper function. Consider for a moment how serious it would be if the sensitivities of only a few of these circuits were abnormally high; one might then expect almost continual muscle cramps, seizures, psychotic disturbances, hallucinations, mental tension, or other nervous disorders. Fortunately, the automatic controls normally readjust the sensitivities of the circuits back to controllable ranges of reactivity any time the circuits begin to be too active or too depressed.

CHAPTER 48

Somatic Sensations: I. General Organization, Tactile and Position Senses

The *somatic senses* are the nervous mechanisms that collect sensory information from all over the body. These senses are in contradistinction to the *special senses*, which include vision, hearing, smell, taste, and equilibrium.

CLASSIFICATION OF SOMATIC SENSES

The somatic senses can be classified into three physiological types: (1) the *mechanoreceptive somatic senses*, which include both *tactile* and *position* sensations that are stimulated by mechanical displacement of some tissue of the body; (2) the *thermoreceptive senses*, which detect heat and cold; and (3) the *pain sense*, which is activated by factors that damage the tissues.

This chapter deals with the mechanoreceptive tactile and position senses. In Chapter 49, the thermoreceptive and pain senses are discussed. The tactile senses include *touch, pressure, vibration*, and *tickle* senses, and the position senses include *static position* and *rate of movement* senses.

Other Classifications of Somatic Sensations. Somatic sensations are also often grouped together in other classes, as follows:

Exteroreceptive sensations are those from the surface of the body. *Proprioceptive sensations* are those relating to the physical state of the body, including position sensations, tendon and muscle sensations, pressure sensations from the bottom of the feet, and even the sensation of equilibrium, which is often considered a "special" sensation rather than a somatic sensation.

Visceral sensations are those from the viscera of the body. When using this term, one usually refers specifically to sensations from the internal organs.

Deep sensations are those that come from deep tissues, such as from fasciae, muscles, and bone. They include mainly "deep" pressure, pain, and vibration.

DETECTION AND TRANSMISSION OF TACTILE SENSATIONS

Interrelations Among the Tactile Sensations of Touch, Pressure, and Vibration. Although touch, pressure, and vibration are frequently classified as separate sensations, they are all detected by the same types of receptors. There are three principal differences among them: (1) touch sensation generally results from stimulation of tactile receptors in the skin or in tissues immediately beneath the skin; (2) pressure sensation generally results from deformation of deeper tissues; and (3) vibration sensation results from rapidly repetitive sensory signals; however, some of the same types of receptors as those for touch and pressure are used.

Tactile Receptors. There are at least six entirely different types of tactile receptors, but many more similar to these also exist. Some were shown in Fig. 47.1 (previous chapter); their special characteristics are as follows.

First, some *free nerve endings*, which are found everywhere in the skin and in many other tissues, can detect touch and pressure. For example, even light contact with the cornea of the eye, which contains no other type of nerve ending besides free nerve endings, can nevertheless elicit touch and pressure sensations.

Second, a touch receptor with great sensitivity is the *Meissner corpuscle* (illustrated in Fig. 47.1 and **Fig. 48.1**), an elongated encapsulated nerve ending of a large (type Aβ) myelinated sensory nerve fiber. Inside the capsulation are many branching terminal nerve filaments. These corpuscles are present in the nonhairy parts of the skin and are particularly abundant in the fingertips, lips, and other areas of the skin where a person's ability to discern spatial locations of touch sensations is highly developed. Meissner corpuscles adapt in a fraction of a second after they are stimulated, which means that they are particularly sensitive to movement of objects over the surface of the skin, as well as to low-frequency vibration.

Third, the fingertips and other areas that contain large numbers of Meissner corpuscles usually also contain large numbers of *expanded tip tactile receptors*, one type of which is *Merkel discs*, shown in **Fig. 48.1**. The hairy parts of the skin also contain moderate numbers of expanded tip receptors, even though they have almost no Meissner corpuscles. These receptors differ from Meissner corpuscles in that they transmit an initially strong but partially adapting signal and then a continuing weaker signal that slowly adapts. Therefore, they are responsible for giving out steady-state signals that allow one to determine continuous touch of objects against the skin.

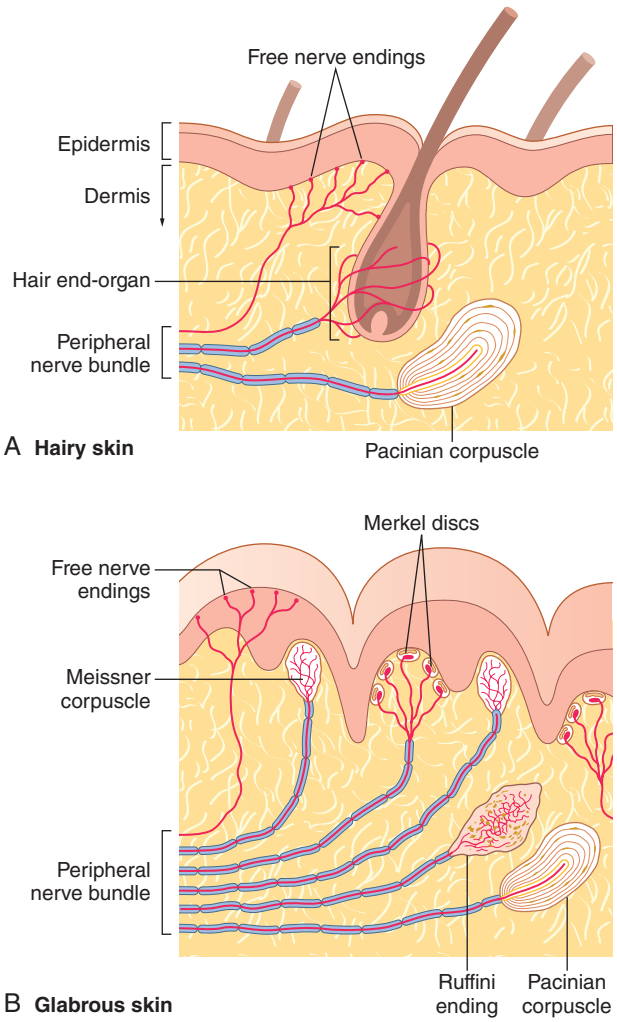

Figure 48.1 Mechanoreceptors in the hairy skin (A) and glaborous skin (B). Note the clusters of Merkel discs located in the basal epidermis and connecting to a single large myelinated fiber. The Meissner cells also lie in the basal epidermis, bordering the edges of the papillary ridges, whereas the Pacinian corpuscles and Ruffini endings are found in the dermis; one myelinated fiber innervates each of these receptor organs.

Merkel discs are often grouped together in a receptor organ called *touch domes*, which project upward against the underside of the epithelium of the skin. This upward projection causes the epithelium at this point to protrude outward, thus creating a dome and constituting an extremely sensitive receptor. Also note in **Fig. 48.1** that the entire group of Merkel discs is innervated by a single large myelinated nerve fiber (type Aβ). These receptors, along with the Meissner corpuscles discussed earlier, play extremely important roles in localizing touch sensations to specific surface areas of the body and in determining the texture of what is felt.

Fourth, slight movement of any hair on the body stimulates a nerve fiber entwining its base. Thus, each hair and its basal nerve fiber, called the *hair end-organ* (**Fig. 48.1**), are also touch receptors. These receptors adapt readily and, like Meissner corpuscles, detect mainly the following: (1) movement of objects on the surface of the body; or (2) initial contact with the body.

Fifth, located in the deeper layers of the skin and also in still deeper internal tissues are many *Ruffini endings*, which are multibranched encapsulated endings, as shown in Fig. 47.1 and **Fig. 48.1**. These endings adapt very slowly and are important for signaling continuous states of deformation of the tissues, such as heavy prolonged touch and pressure signals. They are also found in joint capsules and help to signal the degree of joint rotation.

Sixth, *Pacinian corpuscles*, which were discussed in detail in Chapter 47, lie both immediately beneath the skin and deep in the fascial tissues of the body. They are stimulated only by rapid local compression of the tissues because they adapt in a few hundredths of a second. Therefore, they are particularly important for detecting tissue vibration or other rapid changes in the mechanical state of the tissues.

Transmission of Tactile Signals in Peripheral Nerve Fibers. Almost all specialized sensory receptors, such as Meissner corpuscles, Iggo dome receptors, hair receptors, Pacinian corpuscles, and Ruffini endings, transmit their signals in type Aβ nerve fibers that have transmission velocities ranging from 30 to 70 m/sec. Conversely, free nerve ending tactile receptors transmit signals mainly via the small type Aδ myelinated fibers that conduct at velocities of only 5 to 30 m/sec.

Some tactile free nerve endings transmit via type C unmyelinated fibers at velocities from a fraction of a meter up to 2 m/sec. These nerve endings send signals into the spinal cord and lower brain stem, probably subserving mainly the sensation of tickle.

Thus, the more critical types of sensory signals—those that help to determine precise localization on the skin, minute gradations of intensity, or rapid changes in sensory signal intensity—are all transmitted in more rapidly conducting types of sensory nerve fibers. Conversely, the cruder types of signals, such as pressure, poorly localized touch, and especially tickle, are transmitted via much slower, very small nerve fibers that require much less space in the *peripheral nerve bundle* than the fast fibers.

Detection of Vibration. All tactile receptors are involved in detection of vibration, although different receptors detect different frequencies of vibration. Pacinian corpuscles can detect signal vibrations from 30 to 800 cycles/sec because they respond extremely rapidly to minute and rapid deformations of the tissues. They also transmit their signals over type Aβ nerve fibers, which can transmit as many as 1000 impulses/sec. Low-frequency vibrations from 2 up to 80 cycles/sec, in contrast, stimulate other tactile receptors, especially Meissner corpuscles, which adapt less rapidly than do Pacinian corpuscles.

Detection of Tickle and Itch By Mechanoreceptive Free Nerve Endings. Neurophysiological studies have demonstrated the existence of very sensitive, rapidly adapting mechanoreceptive free nerve endings that elicit

only the tickle and itch sensations. Furthermore, these endings are found almost exclusively in superficial layers of the skin, which is also the only tissue from which the tickle and itch sensations usually can be elicited. These sensations are transmitted by very small type C, unmyelinated fibers similar to those that transmit the aching slow type of pain.

The purpose of the itch sensation is presumably to call attention to mild surface stimuli such as a flea crawling on the skin or a fly about to bite; the signals elicited then activate the scratch reflex or other maneuvers that rid the host of the irritant. Itch can be relieved by scratching if this action removes the irritant or if the scratch is strong enough to elicit pain. The pain signals are believed to suppress the itch signals in the cord by *lateral inhibition*, as described in Chapter 49.

SENSORY PATHWAYS FOR TRANSMITTING SOMATIC SIGNALS INTO THE CENTRAL NERVOUS SYSTEM

Almost all sensory information from the somatic segments of the body enters the spinal cord through the *dorsal roots of the spinal nerves*. However, from the entry point into the cord and then to the brain, the sensory signals are carried through one of two alternative sensory pathways: (1) the *dorsal column–medial lemniscal system;* or (2) the *anterolateral system*. These two systems come back together partially at the level of the thalamus.

The dorsal column–medial lemniscal system, as its name implies, carries signals upward to the medulla of the brain mainly in the *dorsal columns* of the cord. Then, after the signals synapse and cross to the opposite side in the medulla, they continue upward through the brain stem to the thalamus via the *medial lemniscus*.

Conversely, signals in the anterolateral system, immediately after entering the spinal cord from the dorsal spinal nerve roots, synapse in the dorsal horns of the spinal gray matter and then cross to the opposite side of the cord and ascend through the anterior and lateral white columns of the cord. They terminate at all levels of the lower brain stem and in the thalamus.

The dorsal column–medial lemniscal system is composed of large myelinated nerve fibers that transmit signals to the brain at velocities of 30 to 110 m/sec, whereas the anterolateral system is composed of smaller myelinated fibers that transmit signals at velocities ranging from a few meters per second up to 40 m/sec.

Another difference between the two systems is that the dorsal column–medial lemniscal system has a high degree of spatial orientation of the nerve fibers with respect to their origin, whereas the anterolateral system has much less spatial orientation. These differences immediately characterize the types of sensory information that can be transmitted by the two systems. That is, sensory information that must be transmitted rapidly with temporal and spatial fidelity is transmitted mainly in the dorsal column–medial lemniscal system; that which does not need to be transmitted rapidly or with great spatial fidelity is transmitted mainly in the anterolateral system.

The anterolateral system has a special capability that the dorsal system does not have—the ability to transmit a broad spectrum of sensory modalities, such as pain, warmth, cold, and crude tactile sensations. Most of these sensory modalities are discussed in detail in Chapter 49. The dorsal system is limited to discrete types of mechanoreceptive sensations.

With this differentiation in mind, we can now list the types of sensations transmitted in the two systems.

Dorsal Column–Medial Lemniscal System.

1. Touch sensations requiring a high degree of localization of the stimulus
2. Touch sensations requiring transmission of fine gradations of intensity
3. Phasic sensations, such as vibratory sensations
4. Sensations that signal movement against the skin
5. Position sensations from the joints
6. Pressure sensations related to fine degrees of judgment of pressure intensity

Anterolateral System.

1. Pain
2. Thermal sensations, including both warm and cold sensations
3. Crude touch and pressure sensations capable only of crude localizing ability on the surface of the body
4. Tickle and itch sensations
5. Sexual sensations

TRANSMISSION IN THE DORSAL COLUMN–MEDIAL LEMNISCAL SYSTEM

ANATOMY OF THE DORSAL COLUMN–MEDIAL LEMNISCAL SYSTEM

On entering the spinal cord through the spinal nerve dorsal roots, the large myelinated fibers from the specialized mechanoreceptors divide almost immediately to form a *medial branch* and a *lateral branch*, shown by the right-hand fiber entering through the spinal root in **Fig. 48.2** (**Video 48.1**). The medial branch turns medially first and then upward in the dorsal column, proceeding via the dorsal column pathway all the way to the brain.

The lateral branch enters the dorsal horn of the cord gray matter and then divides many times to provide terminals that synapse with local neurons in the intermediate and anterior portions of the cord gray matter. These local neurons in turn serve three functions:

1. A major share of them give off fibers that enter the dorsal columns of the cord and then travel upward to the brain.

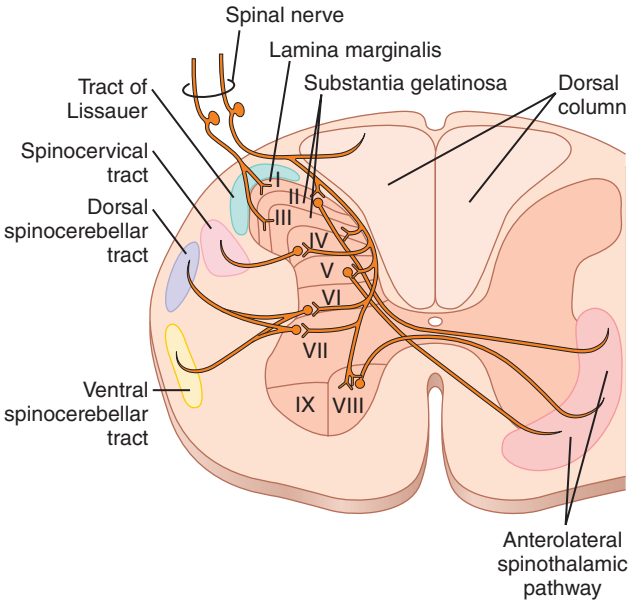

Figure 48.2 Cross section of the spinal cord, showing the anatomy of the cord gray matter and of ascending sensory tracts in the white columns of the spinal cord.

2. Many of the fibers are very short and terminate locally in the spinal cord gray matter to elicit local spinal cord reflexes, which are discussed in Chapter 55.
3. Others give rise to the spinocerebellar tracts, which are discussed in Chapter 57 in relation to the function of the cerebellum.

Dorsal Column–Medial Lemniscal Pathway. Note in **Fig. 48.3** that nerve fibers entering the dorsal columns pass uninterrupted up to the dorsal medulla, where they synapse in the *dorsal column nuclei* (the *cuneate* and *gracile nuclei*). From there, *second-order neurons* cross immediately to the opposite side of the brain stem and continue upward through the *medial lemnisci* to the *thalamus*. In this pathway through the brain stem, each medial lemniscus is joined by additional fibers from the *sensory nuclei of the trigeminal nerve;* these fibers subserve the same sensory functions for the head that the dorsal column fibers subserve for the body.

In the thalamus, the medial lemniscal fibers terminate in the thalamic sensory relay area, called the *ventrobasal complex*. From the ventrobasal complex, *third-order nerve fibers* project, as shown in **Fig. 48.4**, mainly to the *postcentral gyrus* of the *cerebral cortex*, called *somatic sensory area I* (as shown in **Fig. 48.6**, these fibers also project to a smaller area in the lateral parietal cortex called *somatic sensory area II*).

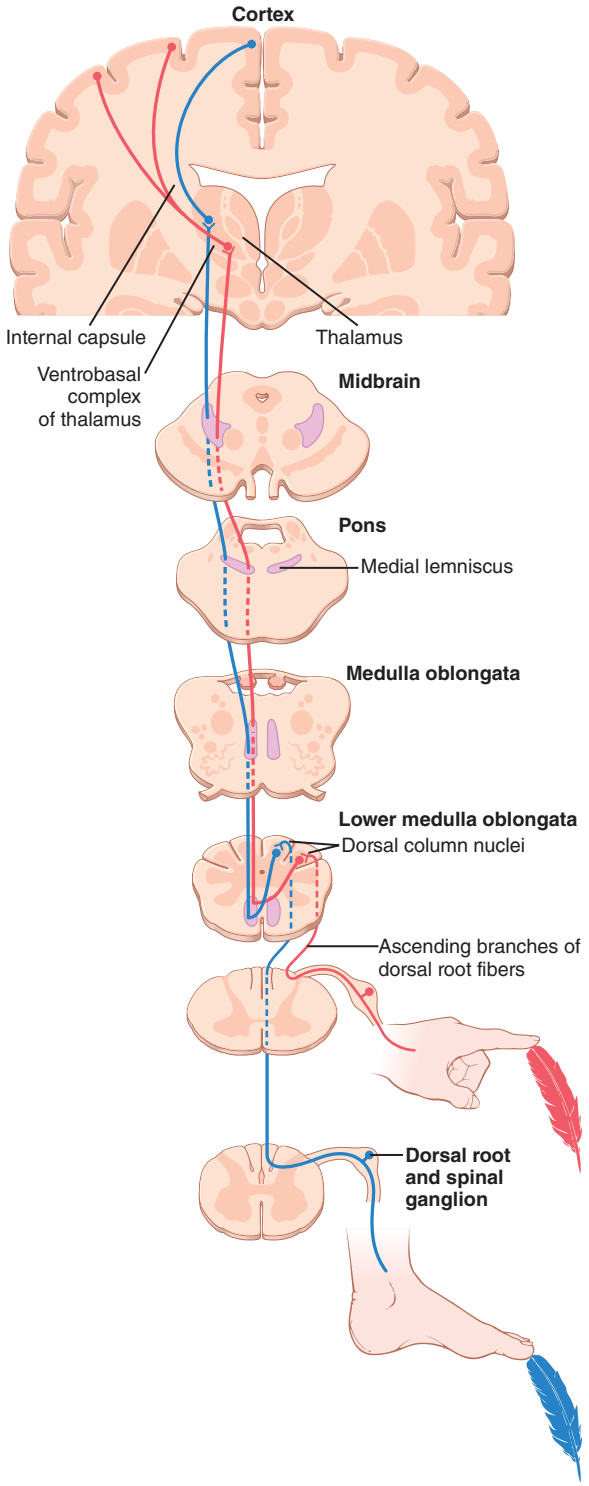

Figure 48.3 Dorsal column–medial lemniscal pathway for transmitting critical types of tactile signals.

Spatial Orientation of Nerve Fibers in the Dorsal Column–Medial Lemniscal System

One of the distinguishing features of the dorsal column–medial lemniscal system is a distinct spatial orientation of nerve fibers from the individual parts of the body that is maintained throughout. For example, in the dorsal columns of the spinal cord, the fibers from the lower parts of the body lie toward the center of the cord, whereas those that enter the cord at progressively higher segmental levels form successive layers laterally.

In the thalamus, distinct spatial orientation is still maintained, with the tail end of the body represented by the most lateral portions of the ventrobasal complex and the head and face represented by the medial areas of the

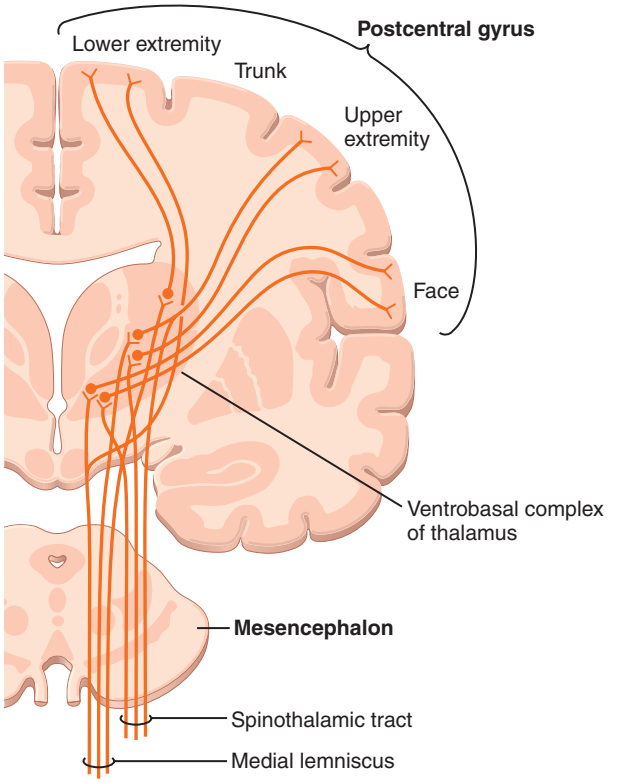

Figure 48.4 Projection of the dorsal column–medial lemniscal system through the thalamus to the somatosensory cortex.

complex. Because of the crossing of the medial lemnisci in the medulla, the left side of the body is represented in the right side of the thalamus, and the right side of the body is represented in the left side of the thalamus.

SOMATOSENSORY CORTEX

Fig. 48.5 shows a map of the human cerebral cortex that has been divided into about 52 distinct areas, called *Brodmann areas*, based on histological structural differences found in the brains of humans and other primates. A few of the Brodmann areas mapped in nonhuman primates differ from those found in humans, and the precise functions of some areas are still obscure. However, this map is important because most neurophysiologists and neurologists use it to refer to many of the different functional areas of the human cortex by number.

Note in **Fig. 48.5** the large *central fissure* (also called *central sulcus*) that extends horizontally across the brain. Sensory signals from most modalities of sensation terminate in the cerebral cortex immediately posterior to the central fissure. Generally, the anterior half of the *parietal lobe* is concerned almost entirely with reception and interpretation of *somatosensory signals*, but the posterior half of the parietal lobe provides still higher levels of interpretation.

Visual signals terminate in the *occipital lobe*, and *auditory signals* terminate in the *temporal lobe* (**Fig. 48.6**).

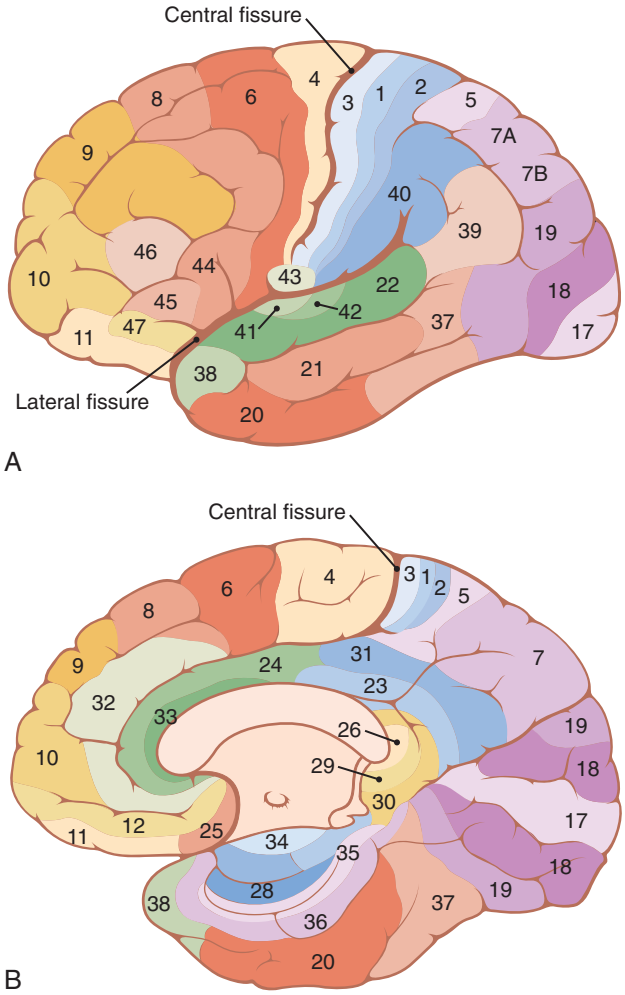

Figure 48.5 Structurally distinct areas, called *Brodmann areas*, of the human cerebral cortex. (A) Lateral surface. (B) Medial view. Note specifically areas 1, 2, and 3, which constitute *primary somatosensory area I*, and areas 5 and 7A, which constitute the *somatosensory association area*.

Conversely, the portion of the cerebral cortex anterior to the central fissure and constituting the posterior half of the frontal lobe is called the *motor cortex;* it is devoted almost entirely to control of muscle contractions and body movements. A major share of this motor control is in response to somatosensory signals received from the sensory portions of the cortex, which keep the motor cortex informed about the positions and motions of the different body parts.

Somatosensory Areas I and II. **Fig. 48.6** shows two separate sensory areas in the anterior parietal lobe, called *somatosensory area I* and *somatosensory area II.* The reason for this division into two areas is that a distinct and separate spatial orientation of the different parts of the body is found in each of these two areas. However, somatosensory area I is so much more extensive than somatosensory area II that in popular usage, the term "somatosensory cortex" almost always means area I.

Somatosensory area I has a high degree of localization of the different parts of the body, as shown by the names of many parts of the body in **Fig. 48.6**. By contrast,

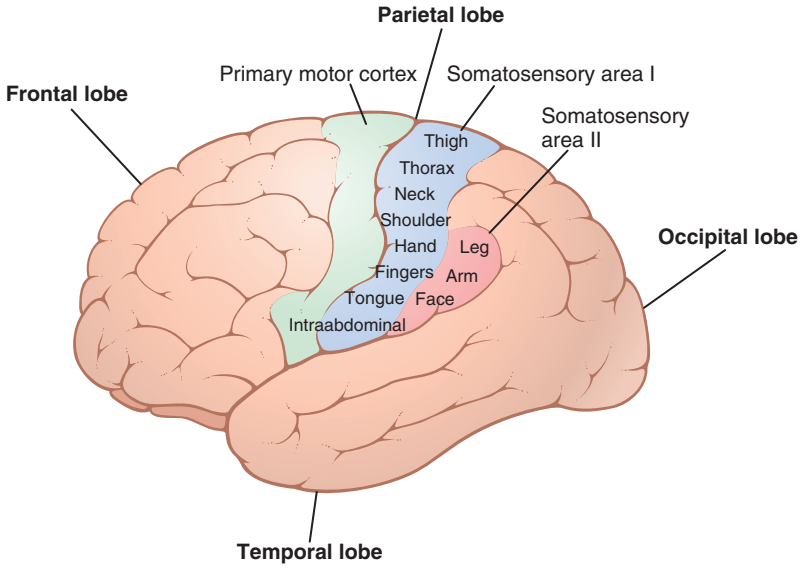

Figure 48.6 Two somatosensory cortical areas, somatosensory areas I and II.

localization is poor in somatosensory area II, although, roughly, the face is represented anteriorly, the arms centrally, and the legs posteriorly.

Much less is known about the function of somatosensory area II. It is known that signals enter this area from the brain stem, transmitted upward from both sides of the body. Also, many signals come secondarily from somatosensory area I and from other sensory areas of the brain, even from the visual and auditory areas. Projections from somatosensory area I are required for function of somatosensory area II. However, removal of parts of somatosensory area II has no apparent effect on the response of neurons in somatosensory area I. Thus, much of what we know about somatic sensation appears to be explained by the functions of somatosensory area I.

Spatial Orientation of Signals From Different Parts of the Body in Somatosensory Area I. Somatosensory area I lies immediately behind the central fissure. It is located in the postcentral gyrus of the human cerebral cortex (in Brodmann areas 3, 1, and 2).

Fig. 48.7 shows a cross section through the brain at the level of the *postcentral gyrus*, demonstrating representations of the different parts of the body in separate regions of somatosensory area I. Note, however, that each lateral side of the cortex receives sensory information almost exclusively from the opposite side of the body.

Some areas of the body are represented by large areas in the somatic cortex—the lips the greatest of all, followed by the face and thumb—whereas the trunk and lower part of the body are represented by relatively small areas. The sizes of these areas are directly proportional to the number of specialized sensory receptors in each respective peripheral area of the body. For example, a great number of specialized nerve endings are found in the lips and thumb, whereas only a few are present in the skin of the body trunk.

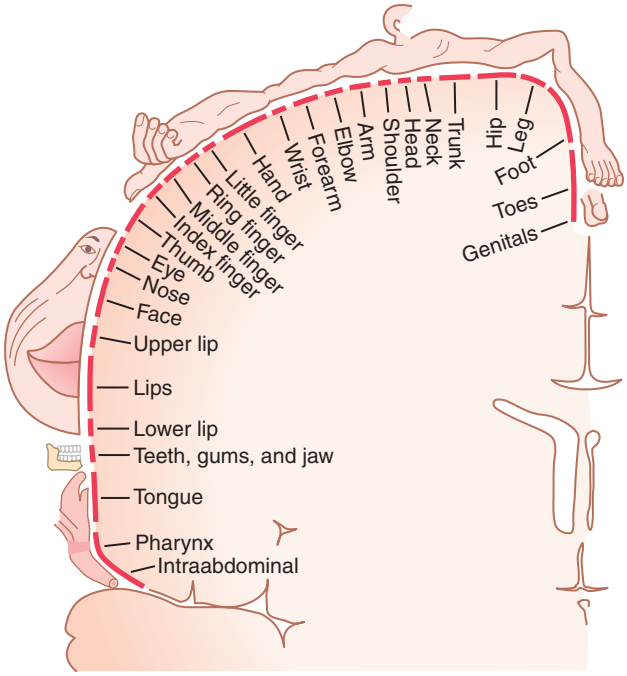

Figure 48.7 Representation of the different areas of the body in somatosensory area I of the cortex. *(From Penfield W, Rasmussen T.* Cerebral Cortex of Man: A Clinical Study of Localization of Function. *New York: Hafner; 1968.)*

Note also that the nose, lips, mouth and face are represented in the most lateral portion of somatosensory area I, and the head, neck, shoulders, and lower part of the body are represented medially.

Layers of the Somatosensory Cortex and Their Function

The cerebral cortex contains *six* fundamental layers of neurons, beginning with layer I next to the brain surface and extending progressively deeper to layer VI, shown in **Fig. 48.8**. As would be expected, each layer is endowed

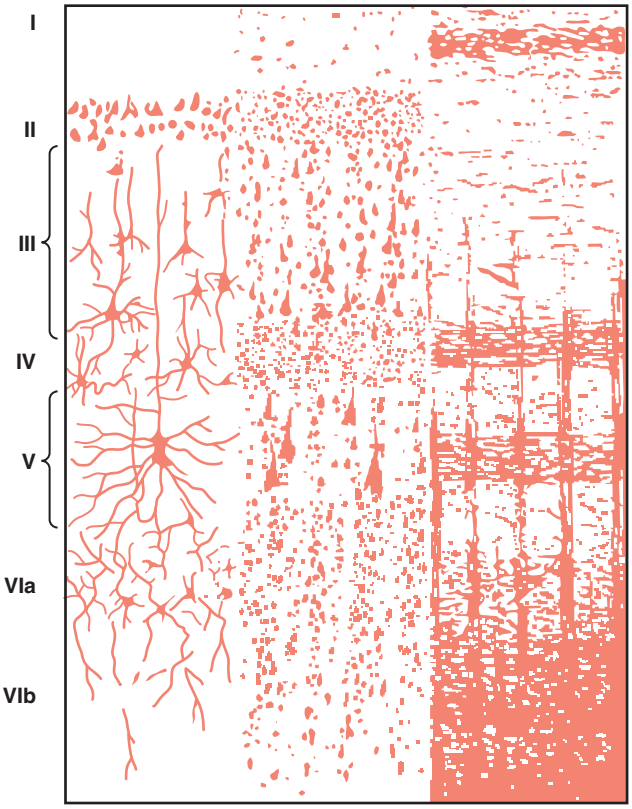

Figure 48.8 Structure of the cerebral cortex—I, molecular layer; II, external granular layer; III, layer of small pyramidal cells; IV, internal granular layer; V, large pyramidal cell layer; and VIa and VIb, layers of fusiform or polymorphic cells. *(From Ranson SW, Clark SL.* Anatomy of the Nervous System. *Philadelphia: WB Saunders; 1959.)*

with unique combinations of cell types and interlaminar connections, and the neurons in each layer perform functions different from those in other layers. Some of these functions are the following:

1. The incoming sensory signal excites neuronal layer IV first; the signal then spreads toward the surface of the cortex and also toward deeper layers.
2. Layers I and II receive diffuse, nonspecific input signals from lower brain centers that facilitate specific regions of the cortex; this system is described in Chapter 58. This input mainly controls the overall level of excitability of the respective regions stimulated.
3. The neurons in layers II and III send axons to related portions of the cerebral cortex on the opposite side of the brain through the *corpus callosum*.
4. The neurons in layers V and VI send axons to the deeper parts of the nervous system. Those in layer V are generally larger and project to more distant areas, such as to the basal ganglia, brain stem, and spinal cord, where they control signal transmission. From layer VI, especially large numbers of axons extend to the thalamus, providing signals from the cerebral cortex that interact with and help to control the excitatory levels of incoming sensory signals entering the thalamus.

The Sensory Cortex Is Organized in Vertical Columns of Neurons; Each Column Detects a Different Sensory Spot on the Body With a Specific Sensory Modality

Functionally, the neurons of the somatosensory cortex are arranged in vertical columns extending all the way through the six layers of the cortex, with each column having a diameter of 0.3 to 0.5 millimeter and containing perhaps 10,000 neuronal cell bodies. Each of these columns serves a single specific sensory modality; some columns respond to stretch receptors around joints, some to stimulation of tactile hairs, others to discrete localized pressure points on the skin, and so forth. At layer IV, where the input sensory signals first enter the cortex, the columns of neurons function almost entirely separately from one another. At other levels of the columns, interactions occur that initiate analysis of the meanings of the sensory signals.

In the most anterior 5 to 10 millimeters of the postcentral gyrus, located deep in the central fissure in Brodmann area 3 A, an especially large share of the vertical columns responds to muscle, tendon, and joint stretch receptors. Many of the signals from these sensory columns then spread anteriorly, directly to the motor cortex located immediately forward of the central fissure. These signals play a major role in controlling the outgoing motor signals that activate sequences of muscle contraction.

Moving posteriorly in somatosensory area I, more and more of the vertical columns respond to slowly adapting cutaneous receptors; still farther posteriorly, greater numbers of the columns are sensitive to deep pressure.

In the most posterior portion of somatosensory area I, about 6% of the vertical columns respond only when a stimulus moves across the skin in a particular direction. Thus, this is a still higher order of interpretation of sensory signals; the process becomes even more complex as the signals spread farther backward from somatosensory area I into the parietal cortex, an area called the *somatosensory association area*, as we discuss subsequently.

Functions of Somatosensory Area I

Widespread bilateral excision of somatosensory area I causes loss of the following types of sensory judgment:

1. The person is unable to localize discretely the different sensations in different parts of the body. However, they can localize these sensations crudely, such as to a particular hand, to a major level of the body trunk, or to one of the legs. Thus, it is clear that the brain stem, thalamus, or parts of the cerebral cortex not normally considered to be concerned with somatic sensations can perform some degree of localization.
2. The person is unable to judge critical degrees of pressure against the body.
3. The person is unable to judge the weights of objects.

4. The person is unable to judge shapes or forms of objects. This condition is called *astereognosis*.
5. The person is unable to judge texture of materials because this type of judgment depends on highly critical sensations caused by movement of the fingers over the surface to be judged.

Note that in this list nothing has been said about loss of pain and temperature sense. In the specific absence of only somatosensory area I, appreciation of these sensory modalities is still preserved both in quality and intensity. However, the sensations are poorly localized, indicating that pain and temperature *localization* depend greatly on the topographic map of the body in somatosensory area I to localize the source.

SOMATOSENSORY ASSOCIATION AREAS

Brodmann areas 5 and 7 of the cerebral cortex, located in the parietal cortex behind somatosensory area I (see **Fig. 48.5**), play important roles in deciphering deeper meanings of the sensory information in the somatosensory areas. Therefore, these areas are called *somatosensory association areas*.

Electrical stimulation in a somatosensory association area can occasionally cause an awake person to experience a complex body sensation, sometimes even the "feeling" of an object such as a knife or a ball. Therefore, it seems clear that the somatosensory association area combines information arriving from multiple points in the primary somatosensory area to decipher its meaning. This occurrence also fits with the anatomical arrangement of the neuronal tracts that enter the somatosensory association area because it receives signals from the following: (1) somatosensory area I; (2) the ventrobasal nuclei of the thalamus; (3) other areas of the thalamus; (4) the visual cortex; and (5) the auditory cortex.

Amorphosynthesis Effect of Removing the Somatosensory Association Area. When the somatosensory association area is removed on one side of the brain, the person loses the ability to recognize complex objects and complex forms felt on the opposite side of the body. In addition, the person loses most of the sense of form of their own body or body parts on the opposite side. In fact, the person is mainly oblivious to the opposite side of the body—that is, forgets that it is there. Therefore, the person also often forgets to use the other side for motor functions as well. Likewise, when feeling objects, the person tends to recognize only one side of the object and forgets that the other side even exists. This complex sensory deficit is called *amorphosynthesis*.

CHARACTERISTICS OF DORSAL COLUMN–MEDIAL LEMNISCAL SIGNAL TRANSMISSION AND ANALYSIS

Basic Neuronal Circuit in the Dorsal Column–Medial Lemniscal System. The lower part of **Fig. 48.9** shows the basic organization of the neuronal circuit of the spinal cord dorsal column pathway, demonstrating that at each synaptic stage, divergence occurs. The upper curves of the figure show that the cortical neurons that discharge to the greatest extent are those in a central part of the cortical "field" for each respective receptor. Thus, a weak stimulus causes only the most central neurons to fire. A stronger stimulus causes still more neurons to fire, but those in the center discharge at a considerably more rapid rate than do those farther away from the center.

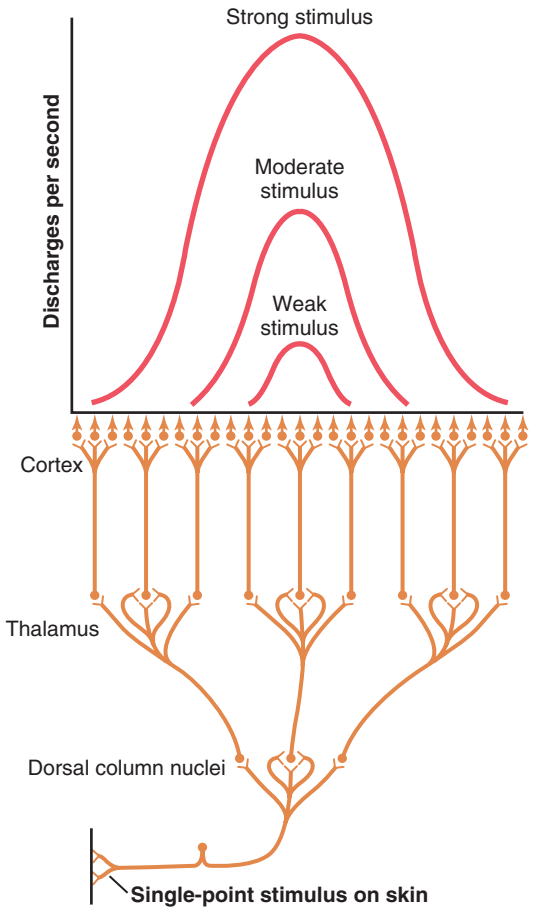

Figure 48.9 Transmission of a pinpoint stimulus signal to the cerebral cortex.

Two-Point Discrimination. A method frequently used to test tactile discrimination is to determine a person's so-called "*two-point*" *discriminatory ability*. In this test, two needles are pressed lightly against the skin at the same time, and the person determines whether one point or two points of stimulus is (are) felt. On the tips of the fingers, a person can normally distinguish two separate points, even when the needles are as close together as 1 to 2 millimeters. However, on someone's back, the needles usually must be as far apart as 30 to 70 millimeters before two separate points can be detected. The reason for this difference is the different numbers of specialized tactile receptors in the two areas.

Fig. 48.10 shows the mechanism whereby the dorsal column pathway (as well as all other sensory pathways) transmits two-point discriminatory information. This figure

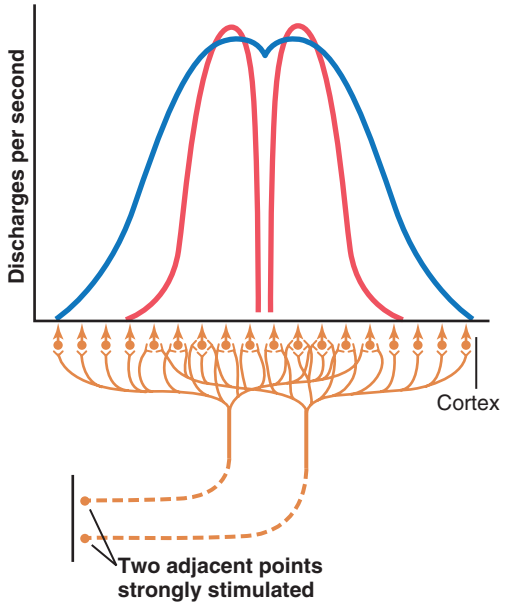

Figure 48.10 Transmission of signals to the cortex from two adjacent pinpoint stimuli. The *blue curve* represents the pattern of cortical stimulation without "surround" inhibition, and the two *red curves* represent the pattern when "surround" inhibition does occur.

shows two adjacent points on the skin that are strongly stimulated, as well as the areas of the somatosensory cortex (greatly enlarged) that are excited by signals from the two stimulated points. The blue curve shows the spatial pattern of cortical excitation when both skin points are stimulated simultaneously. Note that the resultant zone of excitation has two separate peaks. These two peaks, separated by a valley, allow the sensory cortex to detect the presence of two stimulatory points, rather than a single point. The capability of the sensorium to distinguish this presence of two points of stimulation is strongly influenced by another mechanism, *lateral inhibition*, as explained in the next section.

Effect of Lateral Inhibition to Increase the Degree of Contrast in the Perceived Spatial Pattern. As noted in Chapter 47, virtually every sensory pathway, when excited, gives rise simultaneously to lateral *inhibitory* signals; these inhibitory signals spread to the sides of the excitatory signal and inhibit adjacent neurons. For example, consider an excited neuron in a dorsal column nucleus. Aside from the central excitatory signal, short lateral pathways transmit inhibitory signals to the surrounding neurons—that is, these signals pass through additional interneurons that secrete an inhibitory transmitter.

The importance of *lateral inhibition*, also called *surround inhibition*, is that it blocks lateral spread of the excitatory signals and, therefore, increases the degree of contrast in the sensory pattern perceived in the cerebral cortex.

In the case of the dorsal column system, lateral inhibitory signals occur at each synaptic level—for example, in the following: (1) the dorsal column nuclei of the medulla; (2) the ventrobasal nuclei of the thalamus; and (3) the cortex itself. At each of these levels, the lateral inhibition helps to block lateral spread of the excitatory signal. As a result, the peaks of excitation stand out, and much of the surrounding diffuse stimulation is blocked. This effect is demonstrated by the two red curves in **Fig. 48.10**, showing complete separation of the peaks when the intensity of lateral inhibition is great.

Transmission of Rapidly Changing and Repetitive Sensations. The dorsal column system is also of particular importance in apprising the sensorium of rapidly changing peripheral conditions. Based on recorded action potentials, this system can recognize changing stimuli that occur in as little as $\frac{1}{400}$ of a second.

Vibratory Sensation. Vibratory signals are rapidly repetitive and can be detected as vibration up to 700 cycles/sec. The higher frequency vibratory signals originate from the Pacinian corpuscles in the skin and deeper tissues, but lower frequency signals (<~200 cycles/sec) can also originate from Meissner corpuscles. These signals are transmitted only in the dorsal column pathway. For this reason, application of vibration (e.g., from a "tuning fork") to different peripheral parts of the body is an important tool used by neurologists for testing functional integrity of the dorsal columns.

Interpretation of Sensory Stimulus Intensity

The ultimate goal of most sensory stimulation is to apprise the mind of the state of the body and its surroundings. Therefore, it is important that we discuss briefly some of the principles related to transmission of sensory *stimulus intensity* to the higher levels of the nervous system.

How is it possible for the sensory system to transmit sensory experiences of tremendously varying intensities? For example, the auditory system can detect the weakest possible whisper but can also discern the meanings of an explosive sound, even though the sound intensities of these two experiences can vary by more than 10 billion times; the eyes can see visual images with light intensities that vary as much as a half-million times, and the skin can detect pressure differences of 10,000 to 100,000 times.

As a partial explanation of these effects, **Fig. 47.4** in the previous chapter shows the relation of the receptor potential produced by the Pacinian corpuscle to the intensity of the sensory stimulus. At low stimulus intensity, slight changes in intensity increase the potential markedly, whereas at high levels of stimulus intensity, further increases in receptor potential are slight. Thus, the Pacinian corpuscle is capable of accurately measuring extremely minute *changes* in stimulus at low-intensity levels but at high-intensity levels the change in stimulus must be much greater to cause the same amount of *change* in receptor potential.

The transduction mechanism for detecting sound by the cochlea of the ear demonstrates an additional method for separating gradations of stimulus intensity. When sound stimulates a specific point on the basilar membrane, weak sound stimulates only those hair cells at the point of maximum sound vibration. However, as the sound intensity increases, many more hair cells in each direction farther away from the maximum vibratory point are also

stimulated. Thus, signals are transmitted over progressively increasing numbers of nerve fibers, which is another mechanism whereby stimulus intensity is transmitted to the central nervous system. This mechanism, plus the direct effect of stimulus intensity on impulse rate in each nerve fiber, as well as several other mechanisms, make it possible for some sensory systems to operate effectively at stimulus intensity levels changing as much as millions of times.

Importance of the Tremendous Intensity Range of Sensory Reception. Were it not for the tremendous intensity range of sensory reception that people can experience, the various sensory systems would often be operating in the wrong range. This principle is demonstrated by the attempts of most people, when taking photographs with a camera, to adjust the light exposure without using a light meter. Left to intuitive judgment of light intensity, a person almost always overexposes the film on bright days and greatly underexposes the film at twilight. Yet, that person's own eyes are capable of discriminating visual objects in bright sunlight or at twilight with great detail; the camera cannot perform this discrimination without very special manipulation because of the narrow critical range of light intensity required for proper exposure of film.

Judgment of Stimulus Intensity.

Weber-Fechner Principle—Detection of "Ratio" of Stimulus Strength. In the mid-1800s, Weber first, and Fechner later, proposed the principle that *gradations of stimulus strength are discriminated approximately in proportion to the logarithm of stimulus strength*. That is, a person already holding 30 grams of weight in the hand can barely detect an additional 1-gram increase in weight and, when already holding 300 grams, can barely detect a 10-gram increase in weight. Thus, in this case, the *ratio* of the change in stimulus strength required for detection remains essentially constant, about 1 to 30, which is what the logarithmic principle means. To express this principle mathematically,

$$\text{Interpreted signal strength} = \text{Log(Stimulus)} + \text{Constant}$$

More recently, it has become evident that the Weber-Fechner principle is quantitatively accurate only for higher intensities of visual, auditory, and cutaneous sensory experiences and applies only poorly to most other types of sensory experiences. Yet, the Weber-Fechner principle is still helpful to remember because it emphasizes that the greater the background sensory intensity, the greater an additional change must be for the psyche to detect the change.

Power Law. Another attempt by physiopsychologists to find a good mathematical relation is the following formula, known as the *power law:*

$$\text{Interpreted signal strength} = K \times (\text{Stimulus} - k)^y$$

In this formula, the exponent y and the constants K and k are different for each type of sensation.

When this power law relation is plotted on a graph using double logarithmic coordinates, as shown in **Fig. 48.11**, and when appropriate quantitative values for y, K, and k are found, a linear relation can be attained between interpreted stimulus strength and actual stimulus strength over a large range for almost any type of sensory perception.

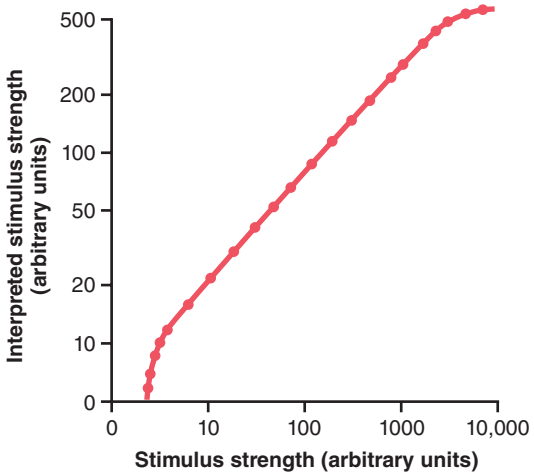

Figure 48.11 Graphic demonstration of the "power law" relationship between actual stimulus strength and strength that the mind interprets it to be. Note that the power law does not hold at either very weak or very strong stimulus strengths.

POSITION SENSES

The *position senses* are frequently also called *proprioceptive senses*. They can be divided into two subtypes: (1) *static position sense*, which means conscious perception of the orientation of the different parts of the body with respect to one another; and (2) *rate of movement sense*, also called *kinesthesia* or *dynamic proprioception*.

Position Sensory Receptors. Knowledge of position, both static and dynamic, depends on knowing the degrees of angulation of all joints in all planes and their rates of change. Therefore, multiple different types of receptors help to determine joint angulation and are used together for position sense. Both skin tactile receptors and deep receptors near the joints are used. In the case of the fingers, where skin receptors are in great abundance, as much as half of position recognition is believed to be detected through the skin receptors. Conversely, for most of the larger joints of the body, deep receptors are more important.

For determining joint angulation in midranges of motion, the *muscle spindles* are among the most important receptors. They are also exceedingly important in helping to control muscle movement, as discussed in Chapter 55. When the angle of a joint is changing, some muscles are being stretched while others are loosened, and the net stretch information from the spindles is transmitted into the computational system of the spinal cord and higher regions of the dorsal column system for deciphering joint angulations.

At the extremes of joint angulation, stretch of the ligaments and deep tissues around the joints is an additional important factor in determining position. Types of sensory endings used for this are the Pacinian corpuscles, Ruffini endings, and receptors similar to the Golgi tendon receptors found in muscle tendons.

The Pacinian corpuscles and muscle spindles are especially adapted for detecting rapid rates of change. It is

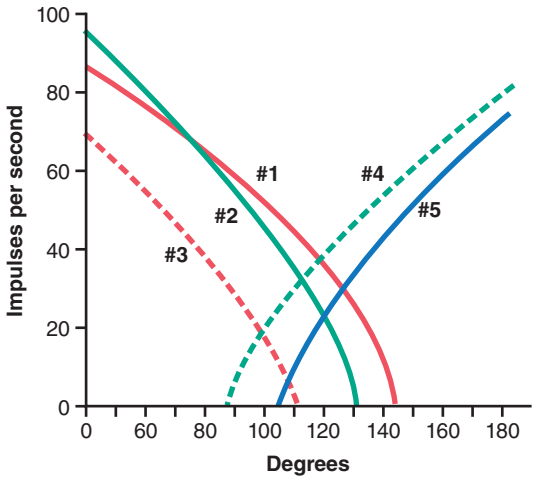

Figure 48.12 Typical responses of five different thalamic neurons (1–5) in the thalamic ventrobasal complex when the knee joint is moved through its range of motion. *(Data from Mountcastle VB, Poggie GF, Werner G. The relation of thalamic cell response to peripheral stimuli varied over an intensive continuum.* J Neurophysiol. *1963;26:807.)*

likely that these are the receptors most responsible for detecting rate of movement.

Processing of Position Sense Information in the Dorsal Column–Medial Lemniscal Pathway. Referring to **Fig. 48.12**, one sees that *thalamic neurons* responding to joint rotation are of two categories: (1) those maximally stimulated when the joint is at full rotation; and (2) those maximally stimulated when the joint is at minimal rotation. Thus, the signals from the individual joint receptors are used to tell the psyche how much each joint is rotated.

TRANSMISSION OF SENSORY SIGNALS IN THE ANTEROLATERAL PATHWAY

The anterolateral pathway for transmitting sensory signals up the spinal cord and into the brain, in contrast to the dorsal column pathway, transmits sensory signals that do not require highly discrete localization of the signal source and do not require discrimination of fine gradations of intensity. These types of signals include pain, heat, cold, crude tactile, tickle, itch, and sexual sensations (**Video 48.2**). In Chapter 49, pain and temperature sensations are discussed specifically.

Anatomy of the Anterolateral Pathway

The *spinal cord anterolateral fibers* originate mainly in dorsal horn laminae I, IV, V, and VI (see **Fig. 48.2**). These laminae are where many of the dorsal root sensory nerve fibers terminate after entering the cord.

As shown in **Fig. 48.13**, the anterolateral fibers cross immediately in the *anterior commissure* of the cord to the opposite *anterior* and *lateral white columns*, where they turn upward toward the brain via the *anterior spinothalamic* and *lateral spinothalamic tracts*.

The upper terminus of the two spinothalamic tracts is mainly 2-fold: (1) throughout the *reticular nuclei of the brain stem;* and (2) in two different nuclear complexes of the thalamus, the *ventrobasal complex* and the *intralaminar nuclei*. In general, the tactile signals are transmitted mainly into the ventrobasal complex, terminating in some of the same thalamic nuclei where the dorsal column tactile signals terminate. From

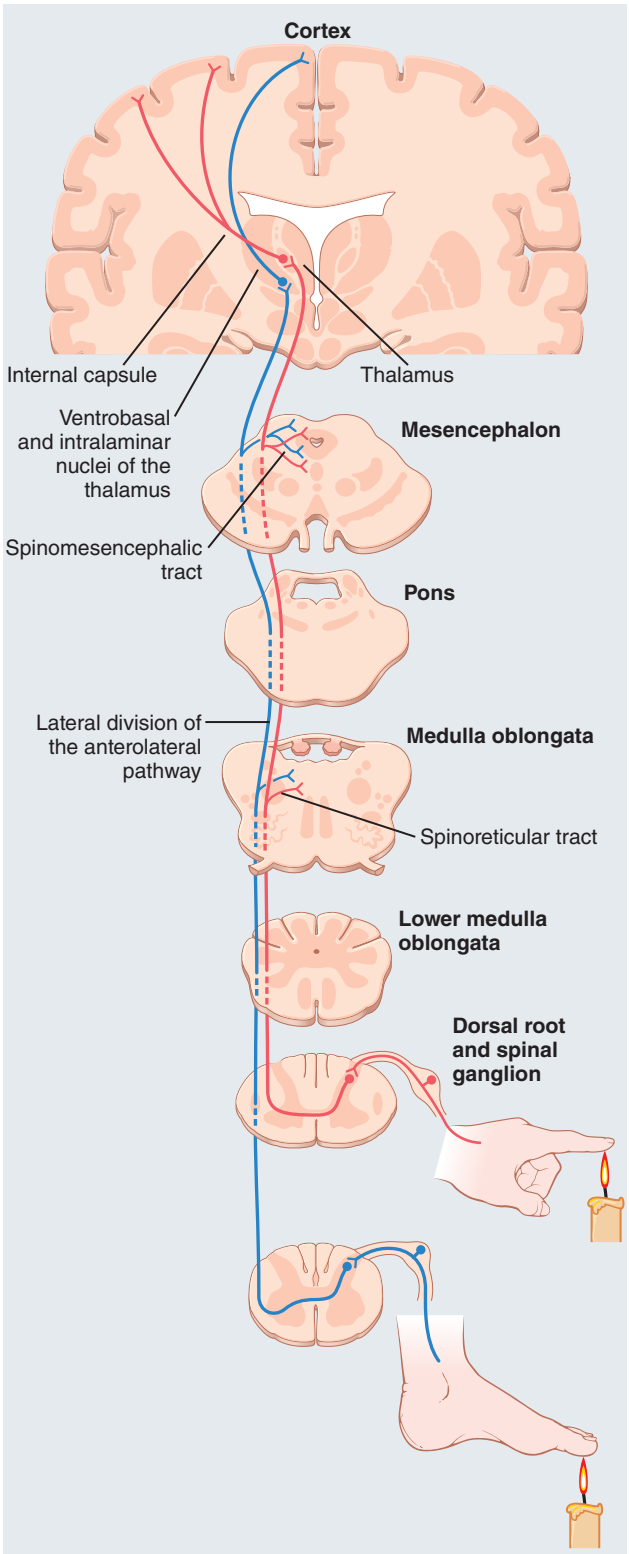

Figure 48.13 Anterior and lateral divisions of the anterolateral sensory pathway.

here, the signals are transmitted to the somatosensory cortex, along with the signals from the dorsal columns.

Conversely, only a small fraction of the pain signals project directly to the ventrobasal complex of the thalamus. Instead, most pain signals terminate in the reticular nuclei of the brain stem and from there are relayed to the intralaminar nuclei of the thalamus, where the pain signals are further processed, as discussed in greater detail in Chapter 49.

CHARACTERISTICS OF TRANSMISSION IN THE ANTEROLATERAL PATHWAY

In general, the same principles apply to transmission in the anterolateral pathway as in the dorsal column–medial lemniscal system, except for the following differences: (1) the velocities of transmission are only a third to half those in the dorsal column–medial lemniscal system, ranging from 8 to 40 m/sec; (2) the degree of spatial localization of signals is poor; (3) the gradations of intensities are also far less accurate, with most of the sensations being recognized in 10 to 20 gradations of strength, rather than as many as 100 gradations for the dorsal column system; and (4) the ability to transmit rapidly changing or rapidly repetitive signals is poor.

Thus, it is evident that the anterolateral system is a cruder type of transmission system than the dorsal column–medial lemniscal system. Even so, certain modalities of sensation are transmitted only in this system and not at all in the dorsal column–medial lemniscal system. These are pain, temperature, tickle, itch, and sexual sensations, in addition to crude touch and pressure.

Function of the Thalamus in Somatic Sensation

When the somatosensory cortex of a human being is destroyed, that person loses most critical tactile sensibilities, but a slight degree of crude tactile sensibility does return. Therefore, the thalamus (and other lower centers) apparently has a slight ability to discriminate tactile sensation, even though the thalamus normally functions mainly to relay this type of information to the cortex.

Conversely, loss of the somatosensory cortex has little effect on one's perception of pain sensation and only a moderate effect on the perception of temperature. Therefore, the lower brain stem, the thalamus, and other associated basal regions of the brain are believed to play dominant roles in discrimination of these sensibilities. It is interesting that these sensibilities appeared very early in the phylogenetic development of animals, whereas the critical tactile sensibilities and the somatosensory cortex were late developments.

Cortical Control of Sensory Sensitivity—"Corticofugal" Signals

In addition to somatosensory signals transmitted from the periphery to the brain, *corticofugal* signals are transmitted in the backward direction from the cerebral cortex to the lower sensory relay stations of the thalamus, medulla, and spinal cord. They control the intensity of sensitivity of the sensory input.

Corticofugal signals are almost entirely inhibitory, so when sensory input intensity becomes too great, the corticofugal signals automatically decrease transmission in the relay nuclei. This action does two things: First, it decreases lateral spread of the sensory signals into adjacent neurons and, therefore, increases the degree of sharpness in the signal pattern. Second, it keeps the sensory system operating in a range of sensitivity that is not so low that the signals are ineffectual nor so high that the system is swamped beyond its capacity to differentiate sensory patterns. This principle of corticofugal sensory control is used by all sensory systems, not only the somatic system, as explained in subsequent chapters.

Segmental Fields of Sensation—Dermatomes

Each spinal nerve innervates a "segmental field" of the skin called a *dermatome*. The different dermatomes are shown in **Fig. 48.14**. They are shown in the figure as if there were

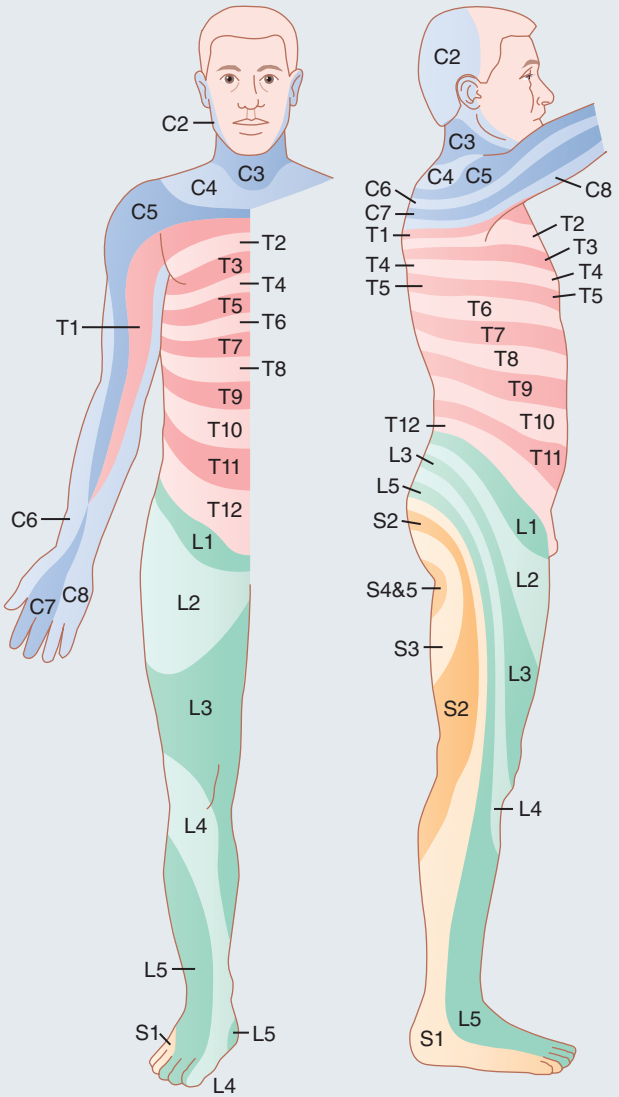

Figure 48.14 Dermatomes. *(Modified from Grinker RR, Sahs AL.* Neurology. *6th ed. Springfield, IL: 1966. Courtesy of Charles C Thomas Publisher, Ltd., Springfield, IL.)*

distinct borders between the adjacent dermatomes, which is far from true because much overlap exists from segment to segment.

Fig. 48.14 shows that the anal region of the body lies in the dermatome of the most distal cord segment, dermatome S5. In the embryo, this is the tail region and the most distal portion of the body. The legs originate embryologically from the lumbar and upper sacral segments (L2 to S3), rather than from the distal sacral segments. One can use a dermatomal map, as shown in **Fig. 48.14**, to determine the level in the spinal cord at which a cord injury has occurred when peripheral sensations are disturbed by the injury.

Somatic Sensations: II. Pain, Headache, and Thermal Sensations

Many ailments of the body cause pain. Furthermore, the ability to diagnose different diseases depends to a great extent on a physician's knowledge of the different qualities of pain. For these reasons, the first part of this chapter is devoted mainly to pain and to the physiological bases of some associated clinical phenomena.

Pain occurs whenever tissues are being damaged and causes the individual to react to remove the pain stimulus. Even such simple activities as sitting for a long time can cause tissue damage because of lack of blood flow to the skin where it is compressed by the weight of the body. When the skin becomes painful as a result of the ischemia, the person normally shifts weight subconsciously. However, a person who has lost the pain sense—for example, after a spinal cord injury—fails to feel the pain and, therefore, fails to shift. This situation soon results in total breakdown and desquamation of the skin at the areas of pressure.

FAST PAIN AND SLOW PAIN AND THEIR QUALITIES

Pain has been classified into two major types, *fast pain* and *slow pain*. Fast pain is felt within about 0.1 second after a pain stimulus is applied, whereas slow pain begins only after 1 second or more and then increases slowly over many seconds and sometimes even minutes. As discussed in this chapter, the conduction pathways for these two types of pain are different, and each of them has specific qualities.

Fast pain is also described by many alternative names, such as *sharp pain, pricking pain, acute pain*, and *electric pain*. This type of pain is felt when a needle is stuck into the skin, when the skin is cut with a knife, when the skin is burned acutely, or when the skin is subjected to electric shock. Fast-sharp pain is not felt in most deep tissues of the body.

Slow pain also goes by many names, such as *slow burning pain, aching pain, throbbing pain, nauseous pain*, and *chronic pain*. This type of pain is usually associated with *tissue destruction*. It can lead to prolonged, almost unbearable suffering. Slow pain can occur both in the skin and in deep tissues or organs.

PAIN RECEPTORS (NOCICEPTORS) AND THEIR STIMULATION

Pain Receptors Are Free Nerve Endings. The pain receptors (also called *nociceptors*) in the skin and other tissues are all free nerve endings. They are widespread in the superficial layers of the *skin*, as well as in certain internal tissues, such as the *periosteum*, the *arterial walls*, the *joint surfaces*, and the *falx* and *tentorium* in the cranial vault. Most other deep tissues are only sparsely supplied with pain endings; nevertheless, any widespread tissue damage can summate to cause the slow, chronic, aching type of pain in most of these areas.

Mechanical, Thermal, and Chemical Stimuli Excite Pain Receptors. Pain can be elicited by multiple types of stimuli, classified as *mechanical, thermal*, and *chemical pain stimuli*. In general, fast pain is elicited by the mechanical and thermal types of stimuli, whereas slow pain can be elicited by all three types.

Some of the chemicals that excite pain receptors are *bradykinin, serotonin, histamine, potassium ions, acids, acetylcholine*, and *proteolytic enzymes*. In addition, *prostaglandins* and *substance P* enhance the sensitivity of pain endings but do not directly excite them. The chemical substances are especially important in stimulating the slow, suffering type of pain that occurs after tissue injury.

Nonadapting Nature of Pain Receptors. In contrast to most other sensory receptors of the body, pain receptors adapt very little and sometimes not at all. In fact, under some conditions, excitation of pain fibers becomes progressively greater, especially for slow, aching, nauseous pain, as the pain stimulus continues. This increase in sensitivity of the pain receptors is called *hyperalgesia*. One can readily understand the importance of this failure of pain receptors to adapt because it allows the pain to keep the person apprised of a tissue-damaging stimulus as long as it persists.

Rate of Tissue Damage as a Stimulus for Pain. The average person begins to perceive pain when the skin is heated above 45°C, as shown in **Fig. 49.1**. This is also the temperature at which the tissues begin to be damaged by

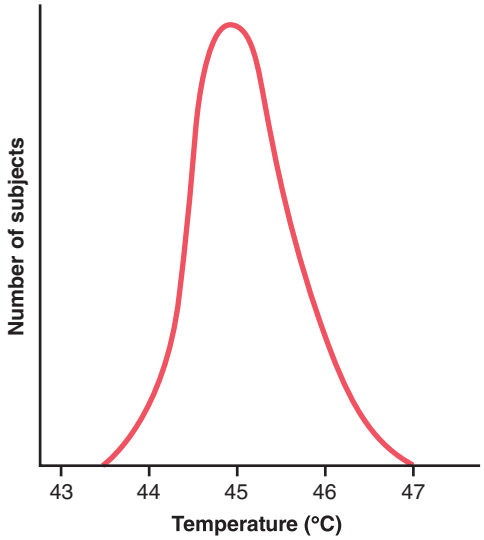

Figure 49.1 Distribution curve obtained from a large number of persons showing the minimal skin temperature that will cause pain. *(Modified from Hardy JD. Nature of pain.* J Clin Epidemiol. *1956;4:22.)*

heat; indeed, the tissues are eventually destroyed if the temperature remains above this level indefinitely. Therefore, it is immediately apparent that pain resulting from heat is closely correlated with the *rate at which damage to the tissues is occurring* and not with the total damage that has already occurred.

The intensity of pain is also closely correlated with the *rate of tissue damage* from causes other than heat, such as bacterial infection, tissue ischemia, tissue contusion, and so forth.

Special Importance of Chemical Pain Stimuli During Tissue Damage. Extracts from damaged tissue cause intense pain when injected beneath the normal skin. Most of the chemicals listed earlier that excite the chemical pain receptors can be found in these extracts. One chemical that seems to be especially painful is *bradykinin*. Also, the intensity of the pain felt after tissue injury correlates with local increases in potassium ion concentration or increases in proteolytic enzymes that directly attack the nerve endings and excite pain by making the nerve membranes more permeable to ions.

Tissue Ischemia as a Cause of Pain. When blood flow to a tissue is blocked, the tissue often becomes very painful within a few minutes. The greater the rate of metabolism of the tissue, the more rapidly the pain appears. For example, if a blood pressure cuff is placed around the upper arm and inflated until the arterial blood flow ceases, exercise of the forearm muscles sometimes can cause muscle pain within 15 to 20 seconds. In the absence of muscle exercise, the pain may not appear for 3 to 4 minutes, even though the muscle blood flow remains zero.

One of the suggested causes of pain during ischemia is accumulation of large amounts of *lactic acid* in the tissues, formed as a consequence of anaerobic metabolism (i.e., metabolism without oxygen). It is also probable that other chemical agents, such as bradykinin and proteolytic enzymes, are formed in the tissues because of cell damage and that these agents, in addition to lactic acid, stimulate the pain nerve endings.

Muscle Spasm as a Cause of Pain. Muscle spasm is also a common cause of pain and is the basis of many clinical pain syndromes. This pain probably results partially from the direct effect of muscle spasm in stimulating mechanosensitive pain receptors, but it might also result from the indirect effect of muscle spasm to compress the blood vessels and cause ischemia. The spasm also increases the rate of metabolism in the muscle tissue, thus making the relative ischemia even greater, creating ideal conditions for the release of chemical pain-inducing substances.

DUAL PATHWAYS FOR TRANSMISSION OF PAIN SIGNALS INTO THE CENTRAL NERVOUS SYSTEM

Even though all pain receptors are free nerve endings, these endings use two separate pathways for transmitting pain signals into the central nervous system. The two pathways mainly correspond to the two types of pain—a *fast-sharp pain pathway* and a *slow-chronic pain pathway*.

PERIPHERAL PAIN FIBERS—"FAST" AND "SLOW" FIBERS

The fast-sharp pain signals are elicited by either mechanical or thermal pain stimuli. They are transmitted in the peripheral nerves to the spinal cord by small type Aδ fibers at velocities between 6 and 30 m/sec. Conversely, the slow-chronic type of pain is elicited mostly by chemical types of pain stimuli but sometimes by persisting mechanical or thermal stimuli. This slow-chronic pain is transmitted to the spinal cord by type C fibers at velocities between 0.5 and 2 m/sec.

Because of this double system of pain innervation, a sudden painful stimulus often gives a "double" pain sensation: a fast-sharp pain that is transmitted to the brain by the Aδ fiber pathway, followed a second or so later by a slow pain that is transmitted by the C fiber pathway. The sharp pain plays an important role in making the person react immediately to move away from the stimulus. The slow pain tends to become greater over time, eventually producing intolerable pain and making the person keep trying to relieve the cause of the pain.

On entering the spinal cord from the dorsal spinal roots, the pain fibers terminate on relay neurons in the dorsal horns. Here again, there are two systems for processing the pain signals on their way to the brain, as shown in **Figs. 49.2 and 49.3**.

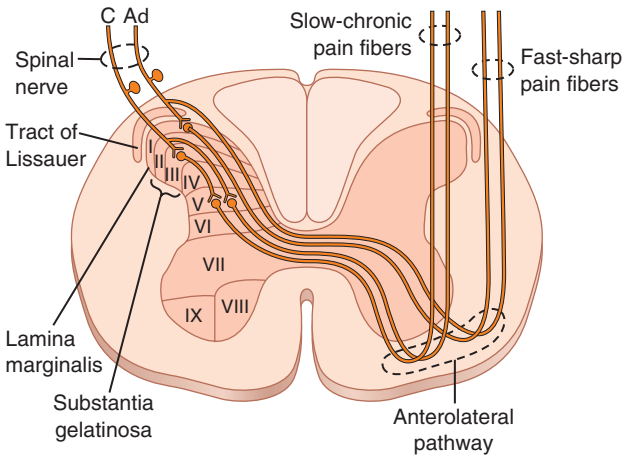

Figure 49.2 Transmission of both fast-sharp and slow-chronic pain signals into and through the spinal cord on their way to the brain. Aδ fibers transmit fast-sharp pain, and C fibers transmit slow-chronic pain.

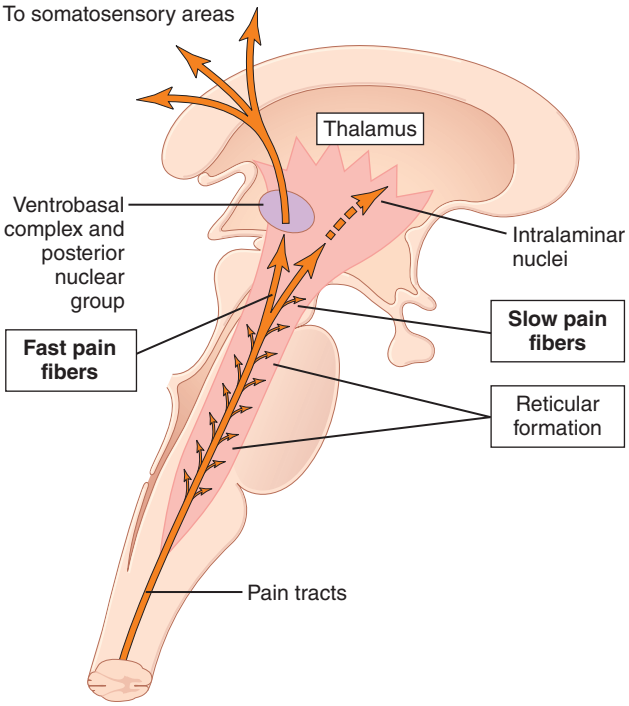

Figure 49.3 Transmission of pain signals into the brain stem, thalamus, and cerebral cortex via the *fast pricking pain pathway* and the *slow burning pain pathway*.

DUAL PAIN PATHWAYS IN THE CORD AND BRAIN STEM—THE NEOSPINOTHALAMIC TRACT AND THE PALEOSPINOTHALAMIC TRACT

On entering the spinal cord, the pain signals take two pathways to the brain, through (1) the *neospinothalamic tract* and (2) the *paleospinothalamic tract*.

Neospinothalamic Tract for Fast Pain

The fast type Aδ pain fibers transmit mainly mechanical and acute thermal pain. They terminate mainly in lamina I (lamina marginalis) of the dorsal horns, as shown in **Fig. 49.2**, and there they excite second-order neurons of the neospinothalamic tract. These second-order neurons give rise to long fibers that cross immediately to the opposite side of the cord through the anterior commissure and then turn upward, passing to the brain in the *anterolateral columns*.

Termination of the Neospinothalamic Tract in the Brain Stem and Thalamus. A few fibers of the neospinothalamic tract terminate in the reticular areas of the brain stem, but most pass all the way to the thalamus without interruption, terminating in the *ventrobasal complex* along with the dorsal column–medial lemniscal tract for tactile sensations, as discussed in Chapter 48. A few fibers also terminate in the posterior nuclear group of the thalamus. From these thalamic areas, the signals are transmitted to other basal areas of the brain, as well as to the somatosensory cortex.

The Nervous System Can Localize Fast Pain in the Body. Fast-sharp pain can be localized much more exactly in different parts of the body than can slow-chronic pain. However, when only pain receptors are stimulated, without simultaneous stimulation of tactile receptors, even fast pain may be poorly localized, often only within 10 centimeters or so of the stimulated area. Yet, when tactile receptors that excite the dorsal column–medial lemniscal system are simultaneously stimulated, the localization can be nearly exact.

Glutamate Is the Probable Neurotransmitter of the Type Aδ Fast Pain Fibers. *Glutamate* is believed to be the neurotransmitter substance secreted in the spinal cord at the type Aδ pain nerve fiber endings. Glutamate is one of the most widely used excitatory transmitters in the central nervous system, usually having a duration of action lasting only a few milliseconds.

Paleospinothalamic Pathway for Transmitting Slow-Chronic Pain

The paleospinothalamic pathway is a much older system and transmits pain mainly from the peripheral slow-chronic type C pain fibers, although it also transmits some signals from type Aδ fibers. In this pathway, the peripheral fibers terminate in the spinal cord almost entirely in laminae II and III of the dorsal horns, which together are called the *substantia gelatinosa*, as shown by the lateral-most dorsal root type C fiber in **Fig. 49.2**. Most of the signals then pass through one or more additional short fiber neurons within the dorsal horns before entering mainly lamina V, also in the dorsal horn. Here, the last neurons in the series give rise to long axons that mostly join the fibers from the fast pain pathway, passing first through the anterior commissure to the opposite side of the cord and then upward to the brain in the anterolateral pathway.

Substance P is the Probable Slow-Chronic Neurotransmitter of Type C Nerve Endings. Type C pain fiber terminals entering the spinal cord release both

glutamate transmitter and substance P transmitter. The glutamate transmitter acts instantaneously and lasts for only a few milliseconds. Substance P is released much more slowly, building up in concentration over a period of seconds or even minutes. In fact, it has been suggested that the "double" pain sensation one feels after a pinprick might result partly from the fact that the glutamate transmitter gives a faster pain sensation, whereas the substance P transmitter gives a more lagging sensation. Regardless of the yet unknown details, it seems clear that glutamate is the neurotransmitter most involved in transmitting fast pain into the central nervous system, and substance P is concerned with slow-chronic pain.

Projection of Paleospinothalamic Pathway (Slow-Chronic Pain Signals) Into the Brain Stem and Thalamus. The slow-chronic paleospinothalamic pathway terminates widely in the brain stem, in the large shaded area shown in **Fig. 49.3**. Only 10% to 25% of the fibers pass all the way to the thalamus. Instead, most terminate in one of three areas: (1) the *reticular nuclei* of the medulla, pons, and mesencephalon; (2) the *tectal area* of the mesencephalon deep to the superior and inferior colliculi; or (3) the *periaqueductal gray region* surrounding the aqueduct of Sylvius. These lower regions of the brain appear to be important for feeling the suffering types of pain. From the brain stem pain areas, multiple short-fiber neurons relay the pain signals upward into the intralaminar and ventrolateral nuclei of the thalamus and into certain portions of the hypothalamus and other basal regions of the brain.

Imprecise Localization of Pain Source Transmitted in the Slow-Chronic Pathway. Localization of pain transmitted via the paleospinothalamic pathway is imprecise. For example, slow-chronic pain can usually be localized only to a major part of the body, such as to one arm or leg but not to a specific point on the arm or leg. This phenomenon is in keeping with the multisynaptic, diffuse connectivity of this pathway. It explains why patients often have serious difficulty in localizing the source of some chronic types of pain.

Role of the Reticular Formation, Thalamus, and Cerebral Cortex in Appreciation of Pain. Complete removal of the somatic sensory areas of the cerebral cortex does not prevent pain perception. Therefore, it is likely that pain impulses entering the brain stem reticular formation, the thalamus, and other lower brain centers contribute to conscious perception of pain. This does not mean that the cerebral cortex has nothing to do with normal pain appreciation; electrical stimulation of cortical somatosensory areas does cause a person to perceive mild pain from about 3% of the points stimulated. However, it is believed that the cortex plays an especially important role in interpreting pain quality, even though pain perception might be principally the function of lower centers.

Special Capability of Pain Signals to Arouse Overall Brain Excitability. Electrical stimulation in the *reticular areas of the brain stem* and in the *intralaminar nuclei of the thalamus*, the areas where the slow-suffering type of pain terminates, has a strong arousal effect on nervous activity throughout the entire brain. These two areas constitute part of the brain's principal arousal system, discussed in Chapter 60. This explains why it is almost impossible for a person to sleep when in severe pain.

Surgical Interruption of Pain Pathways. When a person has severe and intractable pain (e.g., pain resulting from rapidly spreading cancer), it is necessary to relieve the pain. To provide pain relief, the pain nervous pathways can be cut at any one of several points. If the pain is in the lower part of the body, a *cordotomy* in the thoracic region of the spinal cord often relieves the pain for a few weeks to a few months. To perform a cordotomy, the pain-conducting tracts of the spinal cord on the side opposite to the pain are cut in its *anterolateral quadrant* to interrupt the anterolateral sensory pathway.

A cordotomy is not always successful in relieving pain for two reasons. First, many pain fibers from the upper part of the body do not cross to the opposite side of the spinal cord until they have reached the brain, and the cordotomy does not transect these fibers. Second, pain frequently returns several months later, partly as a result of sensitization of other pathways that normally are too weak to be effectual (e.g., sparse pathways in the dorsolateral cord).

PAIN SUPPRESSION (ANALGESIA) SYSTEM IN THE BRAIN AND SPINAL CORD

The degree to which different people react to pain varies tremendously. This variation results partly from a capability of the brain to suppress input of pain signals to the nervous system by activating a pain control system, called an *analgesia system*.

The analgesia system, shown in **Fig. 49.4**, consists of three major components:

1. The *periaqueductal gray* and *periventricular areas* of the mesencephalon and upper pons surround the aqueduct of Sylvius and portions of the third and fourth ventricles.
2. Neurons from these areas send signals to the *raphe magnus nucleus*, a thin midline nucleus located in the lower pons and upper medulla, and the *nucleus reticularis paragigantocellularis*, located laterally in the medulla.
3. From these nuclei, second-order signals are transmitted down the dorsolateral columns in the spinal cord to a *pain inhibitory complex located in the dorsal horns of the spinal cord*. At this point, the analgesia signals can block the pain before it is relayed to the brain.

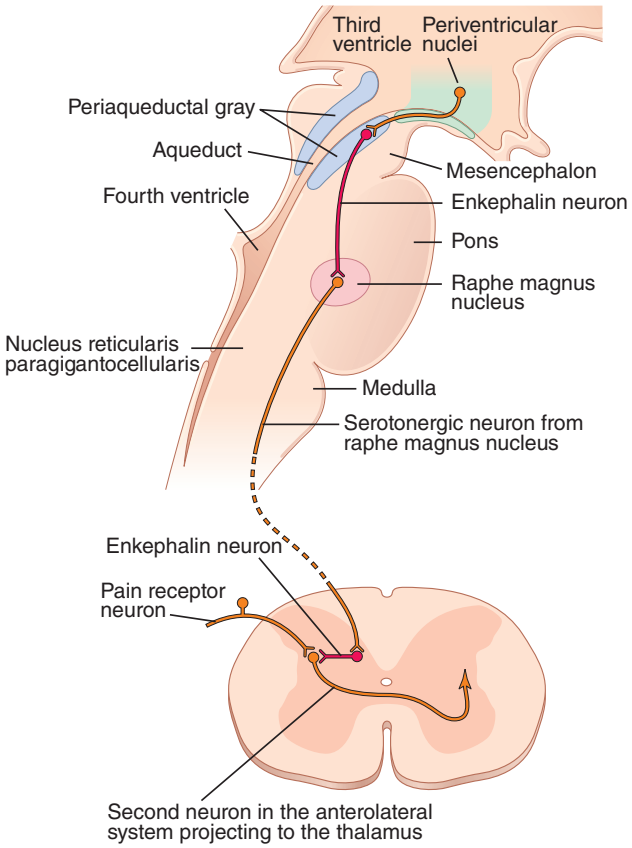

Figure 49.4 Analgesia system of the brain and spinal cord, showing (1) inhibition of incoming pain signals at the cord level and (2) presence of *enkephalin-secreting neurons* that suppress pain signals in both the cord and the brain stem.

Electrical stimulation either in the periaqueductal gray area or in the raphe magnus nucleus can suppress many strong pain signals entering via the dorsal spinal roots. Also, stimulation of areas at higher levels of the brain that excite the periaqueductal gray area can also suppress pain. Some of these areas are the following: (1) the *periventricular nuclei in the hypothalamus*, lying adjacent to the third ventricle; and, to a lesser extent, (2) the *medial forebrain bundle*, also in the hypothalamus.

Several transmitter substances, especially *enkephalin* and *serotonin*, are involved in the analgesia system. Many nerve fibers derived from the periventricular nuclei and from the periaqueductal gray area secrete enkephalin at their endings. Thus, as shown in **Fig. 49.4**, the endings of many fibers in the raphe magnus nucleus release enkephalin when stimulated.

Fibers originating in this area send signals to the dorsal horns of the spinal cord to secrete serotonin at their endings. The serotonin causes local cord neurons to secrete enkephalin as well. The enkephalin is believed to cause both *presynaptic* and *postsynaptic inhibition* of incoming type C and type Aδ pain fibers where they synapse in the dorsal horns.

Thus, the analgesia system can block pain signals at the initial entry point to the spinal cord. It can also block many local cord reflexes that result from pain signals, especially withdrawal reflexes described in Chapter 55.

THE BRAIN'S OPIATE SYSTEM—ENDORPHINS AND ENKEPHALINS

Experimental studies conducted more than 55 years ago revealed that injection of minute quantities of morphine either into the periventricular nucleus around the third ventricle or into the periaqueductal gray area of the brain stem causes an extreme degree of analgesia. Subsequent studies demonstrated that morphine-like agents, mainly the opiates, act at many other points in the analgesia system, including the dorsal horns of the spinal cord. Because most drugs that alter excitability of neurons do so by acting on synaptic receptors, it was assumed that the "morphine receptors" of the analgesia system must be receptors for some morphine-like neurotransmitter that is naturally secreted in the brain. Therefore, an extensive search was undertaken for the natural opiate of the brain. About a dozen such opiate-like substances have now been found at different points of the nervous system. All are breakdown products of three large protein molecules—*pro-opiomelanocortin, proenkephalin*, and *prodynorphin*. Among the more important of these opiate-like substances are *β-endorphin, met-enkephalin, leu-enkephalin*, and *dynorphin*.

The two enkephalins are found in the brain stem and spinal cord, in the portions of the analgesia system described earlier, and β-endorphin is present in the hypothalamus and pituitary gland. Dynorphin is found mainly in the same areas as the enkephalins, but in much lower quantities.

Although the details of the brain's opiate system are not completely understood, *activation of the analgesia system* by nervous signals entering the periaqueductal gray and periventricular areas, or *inactivation of pain pathways* by morphine-like drugs, can almost totally suppress many pain signals entering through the peripheral nerves.

Inhibition of Pain Transmission By Simultaneous Tactile Sensory Signals

Another important event in the saga of pain control was the discovery that stimulation of large-type Aβ sensory fibers from peripheral tactile receptors can depress transmission of pain signals from the same body area. This effect presumably results from local lateral inhibition in the spinal cord. It explains why such simple maneuvers as rubbing the skin near painful areas is often effective in relieving pain, and it probably also explains why liniments are often useful for pain relief.

This mechanism and the simultaneous psychogenic excitation of the central analgesia system are probably also the basis of pain relief by *acupuncture.*

Treatment of Pain By Electrical Stimulation

Several clinical procedures using electrical stimulation have been developed for suppressing pain. Stimulating electrodes are placed on selected areas of the skin or, on occasion, implanted over the spinal cord, supposedly to stimulate the dorsal sensory columns.

In some patients, electrodes have been placed stereotactically in appropriate intralaminar nuclei of the thalamus or in the periventricular or periaqueductal area of the diencephalon. The patient can then personally control the degree of stimulation. Dramatic relief has been reported in some cases. Also, pain relief has been reported to last for as long as 24 hours after only a few minutes of stimulation.

REFERRED PAIN

Sometimes, a person feels pain in a part of the body that is fairly remote from the tissue causing the pain. This phenomenon is called *referred pain*. For example, pain in one of the visceral organs often is referred to an area on the body surface. Knowledge of the different types of referred pain is important in clinical diagnosis because, in many visceral ailments, the only clinical sign is referred pain.

Mechanism of Referred Pain. **Fig. 49.5** shows the probable mechanism whereby most pain is referred. In this figure, branches of visceral pain fibers are shown to synapse in the spinal cord on the same second-order neurons (1 and 2) that receive pain signals from the skin. When the visceral pain fibers are stimulated, pain signals from the viscera are conducted through at least some of the same neurons that conduct pain signals from the skin, and the person has the feeling that the sensations originate in the skin.

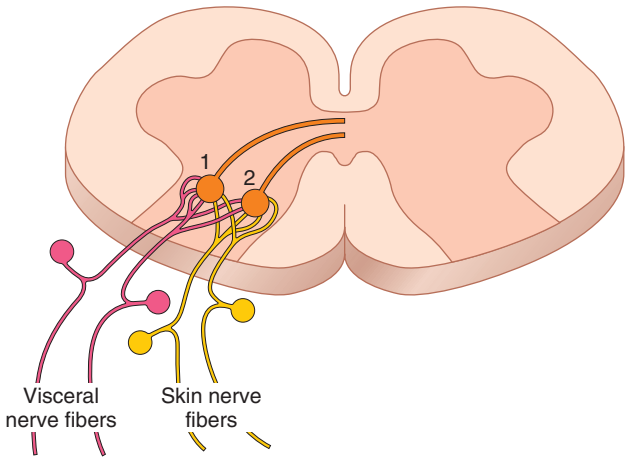

Figure 49.5 Mechanism of referred pain and referred hyperalgesia. Neurons 1 and 2 receive pain signals from the skin, as well as from the viscera.

VISCERAL PAIN

Pain from the different viscera of the abdomen and chest is one of the few criteria that can be used for diagnosing visceral inflammation, visceral infectious disease, and other visceral ailments. Often, the viscera have sensory receptors for no other modalities of sensation besides pain. Also, visceral pain differs from surface pain in several important aspects.

One of the most important differences between surface pain and visceral pain is that highly localized types of damage to the viscera seldom cause severe pain. For example, a surgeon can cut the gut entirely in two in a patient who is awake without causing significant pain. Conversely, any stimulus that causes *diffuse stimulation of pain nerve endings* throughout a viscus causes pain that can be severe. For example, ischemia caused by occluding the blood supply to a large area of gut stimulates many diffuse pain fibers at the same time and can result in extreme pain.

Causes of True Visceral Pain

Any stimulus that excites pain nerve endings in diffuse areas of the viscera can cause visceral pain. Such stimuli include ischemia of visceral tissue, chemical damage to the surfaces of the viscera, spasm of the smooth muscle of a hollow viscus, excess distention of a hollow viscus, and stretching of the connective tissue surrounding or within the viscus. Essentially all visceral pain that originates in the thoracic and abdominal cavities is transmitted through small type C pain fibers and, therefore, can transmit only the chronic, aching, suffering type of pain.

Ischemia. Ischemia causes visceral pain in the same way as in other tissues, presumably because of the formation of acidic metabolic end products or tissue-degenerative products such as bradykinin, proteolytic enzymes, or others that stimulate pain nerve endings.

Chemical Stimuli. If damaging substances leak from the gastrointestinal tract into the peritoneal cavity, the pain is usually excruciatingly severe. For example, proteolytic acidic gastric juice may leak through a ruptured gastric or duodenal ulcer. This juice causes widespread digestion of the visceral peritoneum, thus stimulating broad areas of pain fibers and causing severe pain.

Spasm of a Hollow Viscus. Spasm of a portion of the gut, the gallbladder, a bile duct, a ureter, or any other hollow viscus can cause pain, possibly by mechanical stimulation of the pain nerve endings. Another possibility is that the spasm may cause diminished blood flow to the muscle, combined with the muscle's increased metabolic need for nutrients, thus causing severe pain.

Often, pain from a spastic viscus occurs in the form of *cramps*, with the pain increasing to a high degree of severity and then subsiding. This process continues intermittently once every few minutes. The intermittent cycles result from periods of smooth muscle contraction. For example, each time a peristaltic wave travels along an overly excitable spastic gut, a cramp occurs. The cramping type of pain

frequently occurs in persons with appendicitis, gastroenteritis, constipation, menstruation, parturition, gallbladder disease, or ureteral obstruction.

Overdistention of a Hollow Viscus. Extreme overfilling of a hollow viscus also can result in pain, presumably because of overstretch of the tissues. Overdistention can also collapse the blood vessels that encircle the viscus or that pass into its wall, thus perhaps promoting ischemic pain.

Insensitive Viscera. A few visceral areas are almost completely insensitive to pain of any type. These areas include the parenchyma of the liver and the alveoli of the lungs. Yet, the liver *capsule* is extremely sensitive to both direct trauma and stretch, and the *bile ducts* are also sensitive to pain. In the lungs, even though the alveoli are insensitive, the *bronchi* and the *parietal pleura* are very sensitive to pain.

"PARIETAL PAIN" CAUSED BY VISCERAL DISEASE

When a disease affects a viscus, the disease process often spreads to the parietal peritoneum, pleura, or pericardium. These parietal surfaces, like the skin, are supplied with extensive pain innervation from the peripheral spinal nerves. Therefore, pain from the parietal wall overlying a viscus is frequently sharp. An example here can emphasize the difference between this pain and true visceral pain—a knife incision through the *parietal* peritoneum is very painful, whereas a similar cut through the visceral peritoneum or through a gut wall is not very painful, if it is painful at all.

LOCALIZATION OF VISCERAL PAIN—VISCERAL AND PARIETAL PAIN TRANSMISSION PATHWAYS

Pain from the different viscera is frequently difficult to localize, for several reasons. First, the patient's brain does not know from firsthand experience that the different internal organs exist; therefore, any pain that originates internally can be localized only generally. Second, sensations from the abdomen and thorax are transmitted through two pathways to the central nervous system, the *true visceral pathway* and the *parietal pathway*. True visceral pain is transmitted via pain sensory fibers in the autonomic nerve bundles, and the sensations are *referred* to surface areas of the body that are often far from the painful organ. Conversely, parietal sensations are conducted *directly* into local spinal nerves from the parietal peritoneum, pleura, or pericardium, and these sensations are usually *localized directly over the painful area*.

Localization of Referred Pain Transmitted via Visceral Pathways. When visceral pain is referred to the surface of the body, the person generally localizes it in the dermatomal segment from which the visceral organ originated in the embryo, not necessarily where the visceral organ now lies. For example, the heart originated in the neck and upper thorax, so the heart's visceral pain fibers pass upward along the sympathetic sensory nerves and enter the spinal cord between segments C3 and T5. Therefore, as shown in **Fig. 49.6**, pain from the heart is referred to the side of the neck, over the shoulder, over the pectoral muscles, down the arm, and into the substernal area of the upper chest. These are the areas of the body surface that send their own somatosensory nerve fibers into the C3 to T5 cord segments. Usually, the pain is on the left side rather than on the right because the left side of the heart is much more frequently involved in coronary disease than is the right side.

The stomach originated approximately from the seventh to ninth thoracic segments of the embryo. Therefore, stomach pain is referred to the anterior epigastrium above the umbilicus, which is the surface area of the body subserved by the seventh through ninth thoracic segments. **Fig. 49.6** shows several other surface areas to which visceral pain is referred from other organs, in general representing the areas in the embryo from which the respective organs originated.

Parietal Pathway for Transmission of Abdominal and Thoracic Pain. Pain from the viscera is frequently localized to two surface areas of the body at the same time because of the dual transmission of pain through the referred visceral pathway and the direct parietal pathway. Thus, **Fig. 49.7** shows dual transmission from an inflamed appendix. Pain impulses pass first from the appendix through visceral pain fibers located within sympathetic nerve bundles and then into the spinal cord at about T10 or T11; this pain is referred to an area around the umbilicus and is of the aching, cramping type. Pain impulses also often originate in the parietal peritoneum

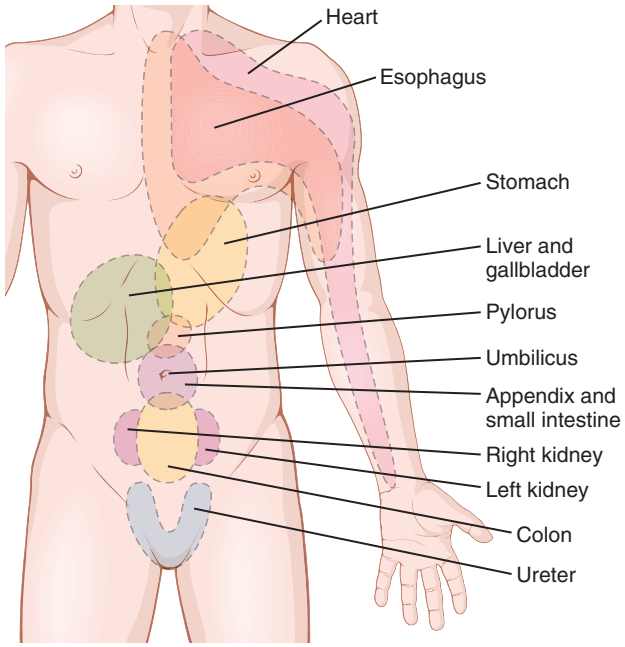

Figure 49.6 Surface areas of referred pain from different visceral organs.

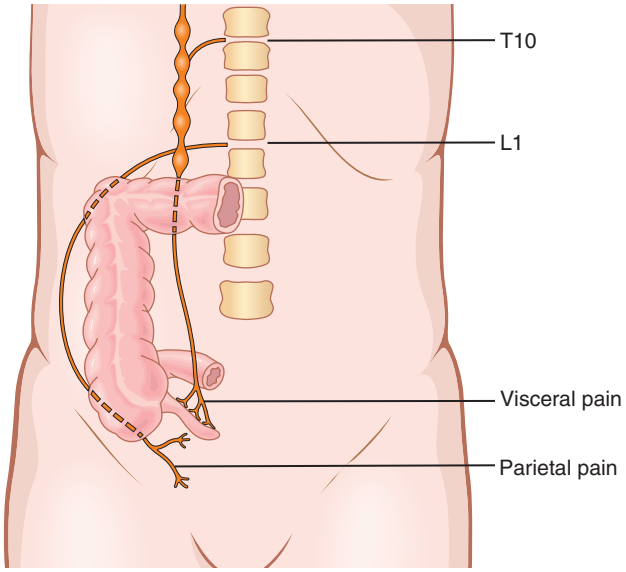

Figure 49.7 Visceral and parietal transmission of pain signals from the appendix.

where the inflamed appendix touches or is adherent to the abdominal wall. These impulses cause pain of the sharp type directly over the irritated peritoneum in the right lower quadrant of the abdomen.

Some Clinical Abnormalities of Pain and Other Somatic Sensations

Hyperalgesia—Hypersensitivity to Pain

A pain nervous pathway sometimes becomes excessively excitable, which gives rise to *hyperalgesia*. Possible causes of hyperalgesia are the following: (1) excessive sensitivity of the pain receptors, called *primary hyperalgesia;* and (2) facilitation of sensory transmission, called *secondary hyperalgesia*.

An example of primary hyperalgesia is the extreme sensitivity of sunburned skin, which results from sensitization of the skin pain endings by local tissue products from the burn—perhaps histamine, prostaglandins, and others. Secondary hyperalgesia frequently results from lesions in the spinal cord or the thalamus. Several of these lesions are discussed in subsequent sections.

Herpes Zoster (Shingles)

Occasionally, *herpesvirus* infects a dorsal root ganglion. This infection causes severe pain in the dermatomal segment subserved by the ganglion, thus eliciting a segmental type of pain that circles halfway around the body. The disease is called *herpes zoster*, or *shingles*, because of a skin eruption that often ensues.

The cause of the pain is presumably infection of the pain neuronal cells in the dorsal root ganglion by the virus. In addition to causing pain, the virus is carried by neuronal cytoplasmic flow outward through the neuronal peripheral axons to their cutaneous origins. Here the virus causes a rash that vesiculates within a few days and then crusts over within another few days, all occurring within the dermatomal area served by the infected dorsal root.

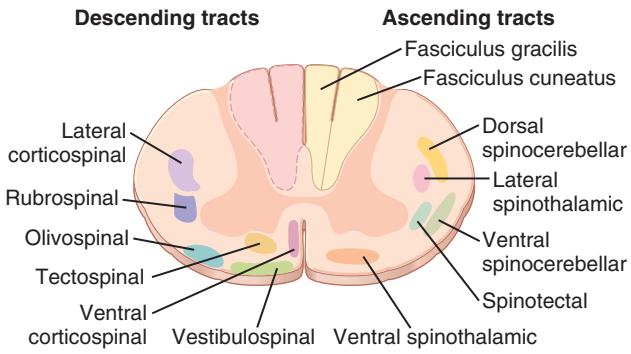

Figure 49.8 Cross section of the spinal cord showing principal ascending tracts on the *right* and principal descending tracts on the *left*.

Tic Douloureux

A lancinating or stabbing type of pain occasionally occurs in some people over one side of the face in the sensory distribution area (or part of the area) of the fifth or ninth nerves; this phenomenon is called *tic douloureux* (or *trigeminal neuralgia* or *glossopharyngeal neuralgia*). The pain feels like sudden electrical shocks, and it may appear for only a few seconds at a time or may be almost continuous. Often, it is set off by exceedingly sensitive trigger areas on the surface of the face, in the mouth, or inside the throat—almost always by a mechanoreceptive stimulus rather than a pain stimulus. For example, when the patient swallows a bolus of food and the food touches a tonsil, it might set off a severe lancinating pain in the mandibular portion of the fifth nerve.

The pain of tic douloureux can usually be blocked by surgically cutting the peripheral nerve from the hypersensitive area. The sensory portion of the fifth nerve may be sectioned immediately inside the cranium, where the motor and sensory roots of the fifth nerve separate from each other so that the motor portions, which are necessary for many jaw movements, can be spared while the sensory elements are destroyed. This operation leaves the side of the face anesthetic, which may be annoying. Furthermore, sometimes the operation is unsuccessful, indicating that the lesion that causes the pain might be in the sensory nucleus in the brain stem and not in the peripheral nerves.

Brown-Séquard Syndrome

If the spinal cord is transected entirely, all sensations and motor functions distal to the segment of transection are blocked, but if the spinal cord is transected on only one side, the *Brown-Séquard syndrome* occurs. The effects of such transection can be predicted from knowledge of the cord fiber tracts shown in **Fig. 49.8**. All motor functions are blocked on the side of the transection in all segments below the level of the transection. Yet, only some of the modalities of sensation are lost on the transected side, and others are lost on the opposite side. The sensations of pain, heat, and cold—sensations served by the spinothalamic pathway—are lost *on the opposite side of the body* in all dermatomes two to six segments below the level of the transection. By contrast, sensations that are transmitted only in

the dorsal and dorsolateral columns—kinesthetic and position sensations, vibration sensation, discrete localization, and two-point discrimination—are lost *on the side of the transection* in all dermatomes below the level of the transection. Discrete "light touch" is impaired on the side of the transection because the principal pathway for transmission of light touch, the dorsal column, is transected. That is, the fibers in this column do not cross to the opposite side until they reach the medulla of the brain. "Crude touch," which is poorly localized, still persists because of partial transmission in the opposite spinothalamic tract.

Headache

Headaches often represent a type of pain referred to the surface of the head from deep head structures. Some headaches result from pain stimuli arising inside the cranium, but others result from pain arising outside the cranium, such as from the nasal sinuses.

Headache of Intracranial Origin

Pain-Sensitive Areas in the Cranial Vault. The brain tissues are almost totally insensitive to pain. Even cutting or electrically stimulating the sensory areas of the cerebral cortex only occasionally causes pain; instead, it causes prickly types of paresthesias on the area of the body represented by the portion of the sensory cortex stimulated. Therefore, it is likely that much or most of the pain of headache is not caused by damage in the brain itself.

Conversely, *tugging on the venous sinuses around the brain, damaging the tentorium*, or *stretching the dura at the base of the brain* can cause intense pain that is recognized as headache. Also, almost any type of traumatizing, crushing, or stretching stimulus to the *blood vessels of the meninges* can cause headache. An especially sensitive structure is the middle meningeal artery; neurosurgeons are careful to anesthetize this artery specifically when performing brain operations with use of local anesthesia.

Areas of the Head to Which Intracranial Headache Is Referred. Stimulation of pain receptors in the cerebral vault above the tentorium, including the upper surface of the tentorium itself, initiates pain impulses in the cerebral portion of the fifth nerve and, therefore, causes referred headache to the front half of the head in the surface areas supplied by this somatosensory portion of the fifth cranial nerve, as shown in **Fig. 49.9**.

Conversely, pain impulses from beneath the tentorium enter the central nervous system mainly through the glossopharyngeal, vagal, and second cervical nerves, which also supply the scalp above, behind, and slightly below the ear. Subtentorial pain stimuli cause "occipital headache" referred to the posterior part of the head.

Types of Intracranial Headache

Headache of Meningitis. One of the most severe headaches of all is that resulting from meningitis, which causes inflammation of the meninges, including the sensitive areas of the dura and the sensitive areas around the venous sinuses. Such intense damage can cause extreme headache pain referred over the entire head.

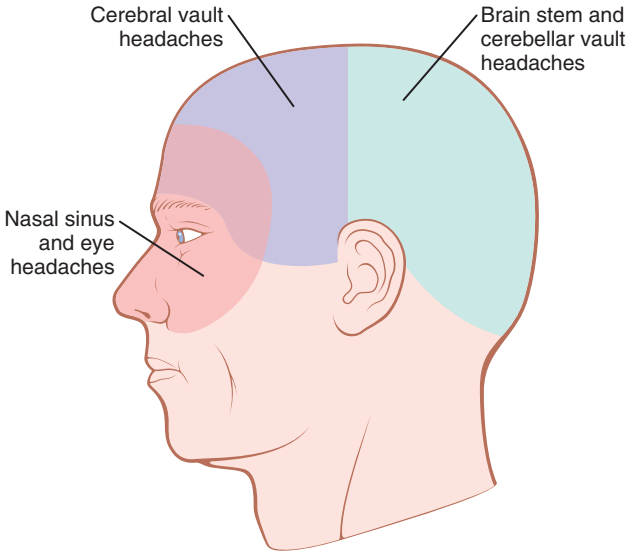

Figure 49.9 Areas of headache resulting from different causes.

Headache Caused By Low Cerebrospinal Fluid Pressure. Removing as little as 20 milliliters of fluid from the spinal canal, particularly if the person remains in an upright position, often causes intense intracranial headache. Removing this quantity of fluid removes part of the flotation for the brain that is normally provided by the cerebrospinal fluid. The weight of the brain stretches and otherwise distorts the various dural surfaces and thereby elicits the headache pain.

Migraine Headache. Migraine headache is a special type of recurrent headache of moderate to severe intensity that may last from 4 to 72 hours and is the second most prevalent neurological disorder (after tension-type headache), affecting about 15% of the population. Migraine headaches often begin with various prodromal sensations, such as nausea, loss of vision in part of the field of vision, visual aura, and other types of sensory hallucinations. The prodromal symptoms usually begin 30 to 60 minutes before the headache phase and are associated with *cortical spreading depression*, a slowly propagated wave of depolarization across the cerebral cortex that disrupts ionic gradients and is initially followed by cerebral hypoperfusion. Cortical spreading depression likely contributes to the prodromal symptoms of migraine, but its role in the headache phase is uncertain.

Considerable research suggests that activation of the *trigeminal nerve* and its axonal projections to intracranial blood vessels (termed the *trigeminovascular system*) play a key role in migraine headache. Activation of these neurons releases nitric oxide and vasoactive peptides, such as *calcitonin gene–related peptide (CGRP)* and *substance P*, which then dilate intracranial blood vessels and induce local inflammatory reactions. Nociceptive signals originating from activation and sensitization of the trigeminovascular neurons are relayed to somatosensory cortex and other cortical areas, ultimately resulting in the perception of migraine pain.

There may be a genetic predisposition to migraine headaches because a positive family history for migraine has

been reported in 65% to 90% of cases. Migraine headaches also occur about three times as frequently in women as in men.

Alcoholic Headache. As many people have experienced, a headache often follows excessive alcohol consumption. It is likely that alcohol, because it is toxic to tissues, directly irritates the meninges and causes the intracranial pain. Dehydration may also play a role in the hangover that follows an alcoholic binge; hydration usually attenuates but does not abolish headache and other symptoms of hangover.

Extracranial Types of Headache

Headache Resulting From Muscle Spasm. Emotional tension often causes many of the muscles of the head, especially the muscles attached to the scalp and the neck muscles attached to the occiput, to become spastic; this mechanism is postulated as a common cause of headache. The pain of the spastic head muscles supposedly is referred to the overlying areas of the head and gives one the same type of headache as do intracranial lesions.

Headache Caused By Irritation of Nasal and Accessory Nasal Structures. The mucous membranes of the nose and nasal sinuses are sensitive to pain, but not intensely so. Nevertheless, infection or other irritative processes in widespread areas of the nasal structures often summate and cause headache that is referred behind the eyes or, in the case of frontal sinus infection, to the frontal surfaces of the forehead and scalp, as shown in **Fig. 49.9**. Also, pain from the lower sinuses, such as from the maxillary sinuses, can be felt in the face.

Headache Caused By Eye Disorders. Difficulty in focusing one's eyes clearly may cause excessive contraction of the eye ciliary muscles in an attempt to gain clear vision. Even though these muscles are extremely small, their tonic contraction is believed to cause retro-orbital headache. Also, excessive attempts to focus the eyes can result in reflex spasm in various facial and extraocular muscles, which is a possible cause of headache.

A second type of headache that originates in the eyes occurs when the eyes are exposed to excessive irradiation by light rays, especially ultraviolet light. Looking at the sun or the arc of an arc welder for even a few seconds may result in headache that lasts from 24 to 48 hours. The headache sometimes results from "actinic" irritation of the conjunctivae, and the pain is referred to the surface of the head or retro-orbitally. However, focusing intense light from an arc or the sun on the retina can also burn the retina, which could be a cause of headache.

THERMAL SENSATIONS

THERMAL RECEPTORS AND THEIR EXCITATION

People can perceive different gradations of cold and heat, from *freezing cold* to *cold* to *cool* to *indifferent* to *warm* to *hot* to *burning hot*.

Thermal gradations are discriminated by at least three types of sensory receptors—cold receptors, warmth receptors, and pain receptors. The pain receptors are stimulated only by extreme degrees of heat or cold and are responsible, along with the cold and warmth receptors, for "freezing cold" and "burning hot" sensations.

The cold and warmth receptors are located immediately under the skin at discrete separated *spots*. Most areas of the body have 3 to 10 times as many cold spots as warmth spots; the number in different areas of the body varies from 15 to 25 cold spots/cm^2 in the lips to 3 to 5 cold spots/cm^2 in the finger to less than 1 cold spot/cm^2 in some broad surface areas of the trunk.

Warmth receptors are believed to be free nerve endings. This is because warmth signals are transmitted mainly over unmyelinated type C nerve fibers at transmission velocities of only 0.4 to 2 m/sec.

A definitive cold receptor has been identified. It is a special, small, type Aδ myelinated nerve ending that branches several times, the tips of which protrude into the bottom surfaces of basal epidermal cells. Signals are transmitted from these receptors via thinly myelinated type Aδ nerve fibers at velocities of about 20 m/sec. Some cold sensations are believed to be transmitted in type C nerve fibers as well, which suggests that some free nerve endings also might function as cold receptors.

Stimulation of Thermal Receptors—Sensations of Cold, Cool, Indifferent, Warm, and Hot. **Fig. 49.10** shows the effects of different temperatures on the responses of four types of nerve fibers: (1) a pain fiber stimulated by cold; (2) a cold fiber; (3) a warmth fiber; and (4) a pain fiber stimulated by heat. Note especially that these fibers respond differently at different levels of temperature. For example, in the *freezing cold* region, only the cold-pain fibers are stimulated (if the skin becomes even colder so that it nearly freezes or actually does freeze, these fibers cannot be stimulated). As the temperature rises to +10°C to 15°C, the cold-pain impulses cease, but the cold receptors begin to be stimulated, reaching peak stimulation at about 24°C and fading out slightly above 40°C. Above about 30°C, the warmth receptors begin to be stimulated, but these also fade out at about 49°C. Finally, at around 45°C, the heat-pain fibers begin to be stimulated by heat and, paradoxically, some of the cold fibers begin to be stimulated again, possibly because of damage to the cold endings caused by the excessive heat.

One can understand from **Fig. 49.10** that a person determines the different gradations of thermal sensations by the relative degrees of stimulation of the different types of endings. One can also understand why extreme degrees of both cold and heat can be painful and why both these sensations, when intense enough, may give almost the same quality of sensation—that is, freezing cold and burning hot sensations feel almost alike.

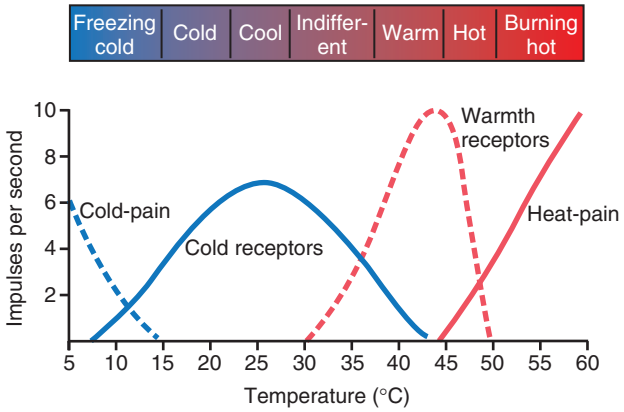

Figure 49.10 Discharge frequencies at different skin temperatures of a *cold-pain fiber*, a *cold fiber*, a *warmth fiber*, and a *heat-pain fiber*.

Stimulatory Effects of Rising and Falling Temperature—Adaptation of Thermal Receptors. When a cold receptor is suddenly subjected to an abrupt fall in temperature, it becomes strongly stimulated at first, but this stimulation fades rapidly during the first few seconds and progressively more slowly during the next 30 minutes or more. In other words, the receptor "adapts" to a great extent, but never 100%.

Thus, it is evident that the thermal senses respond markedly to *changes in temperature* in addition to being able to respond to steady states of temperature. This means that when the temperature of the skin is actively falling, a person feels much colder than when the temperature remains cold at the same level. Conversely, if the temperature is actively rising, the person feels much warmer than they would at the same temperature if it were constant. The response to changes in temperature explains the extreme degree of heat one feels on first entering a tub of hot water and the extreme degree of cold felt on going from a heated room to outdoors on a cold day.

MECHANISM OF STIMULATION OF THERMAL RECEPTORS

It is believed that the cold and warmth receptors are stimulated by changes in their metabolic rates and that these changes result from the fact that temperature alters the rate of intracellular chemical reactions more than 2-fold for each 10°C change. In other words, thermal detection probably results not from direct physical effects of heat or cold on the nerve endings but from chemical stimulation of the endings as modified by temperature.

Spatial Summation of Thermal Sensations. Because the number of cold or warmth endings in any one surface area of the body is slight, it is difficult to judge gradations of temperature when small skin areas are stimulated. However, when a large skin area is stimulated all at once, the thermal signals from the entire area are cumulative. For example, rapid changes in temperature as little as 0.01°C can be detected if this change affects the entire surface of the body simultaneously. Conversely, temperature changes 100 times as great often will not be detected when the affected skin area is only 1 square centimeter in size.

TRANSMISSION OF THERMAL SIGNALS IN THE NERVOUS SYSTEM

In general, thermal signals are transmitted in pathways parallel to those for pain signals. On entering the spinal cord, the signals travel for a few segments upward or downward in the *tract of Lissauer* and then terminate mainly in laminae I, II, and III of the dorsal horns—the same as for pain. After a small amount of processing by one or more cord neurons, the signals enter long, ascending thermal fibers that cross to the opposite anterolateral sensory tract and terminate in (1) the reticular areas of the brain stem and (2) the ventrobasal complex of the thalamus.

A few thermal signals are also relayed to the cerebral somatic sensory cortex from the ventrobasal complex. Occasionally, a neuron in cortical somatic sensory area I has been found by microelectrode studies to be directly responsive to either cold or warm stimuli on a specific area of the skin. However, removal of the entire cortical postcentral gyrus in a person reduces but does not abolish the ability to distinguish gradations of temperature.

The Eye: I. Optics of Vision

PHYSICAL PRINCIPLES OF OPTICS

Understanding the optical system of the eye requires familiarity with the basic principles of optics, including such factors as the physics of light refraction, focusing, and depth of focus. A brief review of these physical principles is presented in this chapter, followed by discussion of the optics of the eye.

Refraction of Light

Refractive Index of a Transparent Substance. Light rays travel through air at a velocity of about 300,000 km/sec, but they travel much slower through transparent solids and liquids. The refractive index of a transparent substance is the *ratio* of the velocity of light in air to the velocity in the substance. The refractive index of air is 1.00. Thus, if light travels through a particular type of glass at a velocity of 200,000 km/sec, the refractive index of this glass is 300,000 divided by 200,000, or 1.50.

Refraction of Light Rays at an Interface Between Two Media With Different Refractive Indices. When light rays traveling forward in a beam (as shown in **Fig. 50.1A**) strike an interface that is *perpendicular* to the beam, the rays enter the second medium without deviating from their course. The only effect that occurs is decreased velocity of transmission and shorter wavelength, as shown in the figure by the shorter distances between wave fronts.

If the light rays pass through an angulated interface, as shown in **Fig. 50.1B**, the rays bend if the refractive indices of the two media are different from each other. In this figure, the light rays are leaving air, which has a refractive index of 1.00, and are entering a block of glass having a refractive index of 1.50. When the beam first strikes the angulated interface, the lower edge of the beam enters the glass ahead of the upper edge. The wave front in the upper portion of the beam continues to travel at a velocity of 300,000 km/sec, whereas that which entered the glass travels at a velocity of 200,000 km/sec. This difference in velocity causes the upper portion of the wave front to move ahead of the lower portion so that the wave front is no longer vertical but is angulated to the right. Because *the direction in which light travels is always perpendicular to the plane of the wave front*, the direction of travel of the light beam bends downward.

This bending of light rays at an angulated interface is known as *refraction*. Note particularly that the degree of refraction increases as a function of the following: (1) the ratio of the two refractive indices of the two transparent media; and (2) the degree of angulation between the interface and the entering wave front.

Application of Refractive Principles to Lenses.

Convex Lens Focuses Light Rays. **Fig. 50.2** shows parallel light rays entering a convex lens. The light rays passing through the center of the lens strike the lens exactly perpendicular to the lens surface and, therefore, pass through the lens without being refracted. Toward either edge of the

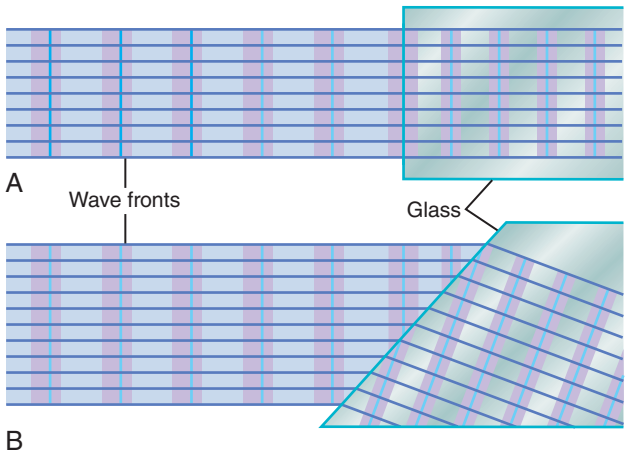

Figure 50.1 Light rays entering a glass surface perpendicular to the light rays (A) and a glass surface angulated to the light rays (B). This figure demonstrates that the distance between waves after they enter the glass is shortened to about two-thirds that in air. It also shows that light rays striking an angulated glass surface are bent.

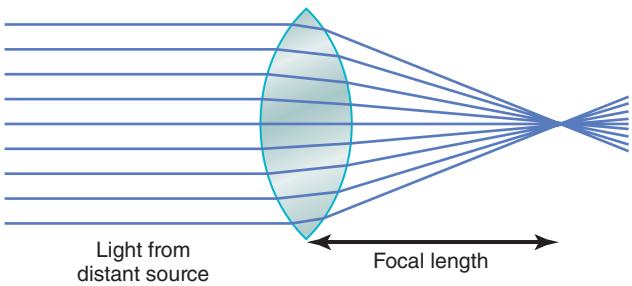

Figure 50.2 Bending of light rays at each surface of a convex spherical lens showing that parallel light rays are focused to a *focal point*.

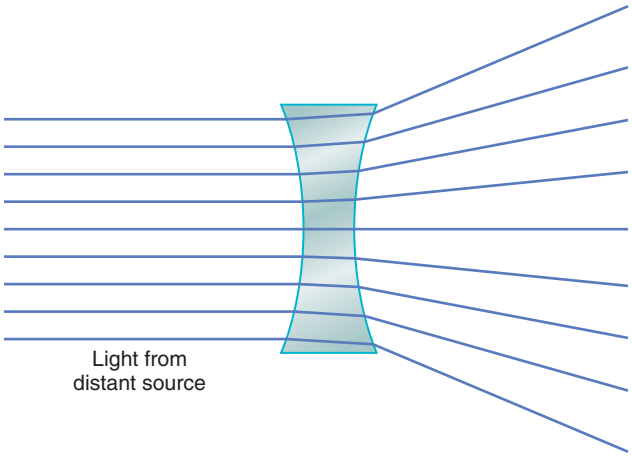

Figure 50.3 Bending of light rays at each surface of a concave spherical lens showing that parallel light rays are *diverged*.

lens, however, the light rays strike a progressively more angulated interface. The outer rays bend more and more toward the center, which is called *convergence* of the rays. Half the bending occurs when the rays enter the lens, and half occurs as the rays exit from the opposite side. If the lens has exactly the proper curvature, parallel light rays passing through each part of the lens will be bent exactly enough so that all the rays will pass through a single point, called the *focal point.*

Concave Lens Diverges Light Rays. **Fig. 50.3** shows the effect of a concave lens on parallel light rays. The rays that enter the center of the lens strike an interface that is perpendicular to the beam and, therefore, do not refract. The rays at the edge of the lens enter the lens ahead of the rays in the center. This effect is opposite to the effect in the convex lens, and it causes the peripheral light rays to *diverge* from the light rays that pass through the center of the lens. Thus, the concave lens *diverges* light rays, but the convex lens *converges* light rays.

Cylindrical Lens Bends Light Rays in Only One Plane—Comparison With Spherical Lenses. **Fig. 50.4** shows both a convex *spherical* lens and a convex *cylindrical* lens. Note that the cylindrical lens bends light rays from the two sides of the lens but not from the top or the bottom—that is, bending occurs in one plane but not the other. Thus, parallel light rays are bent to a *focal line*. Conversely, light rays that pass through the spherical lens are refracted at all edges of the lens (in both planes) toward the central ray, and all the rays come to a *focal point*.

The effect of a cylindrical lens can be demonstrated by using a test tube full of water. If the test tube is placed in a beam of sunlight and a piece of paper is brought progressively closer to the opposite side of the tube, a certain distance will be found at which the light rays come to a *focal line.* The spherical lens is demonstrated by an ordinary magnifying glass. If such a lens is placed in a beam of sunlight and a piece of paper is brought progressively closer to the lens, the light rays will impinge on a common focal point at an appropriate distance.

Concave cylindrical lenses *diverge* light rays in only one plane in the same manner that *convex* cylindrical lenses

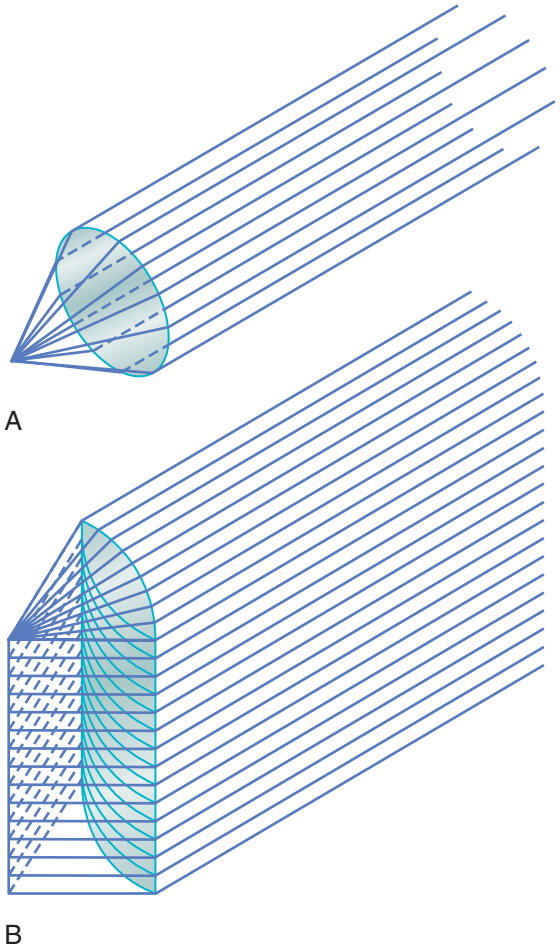

Figure 50.4 (A) *Point focus* of parallel light rays by a spherical convex lens. (B) *Line focus* of parallel light rays by a cylindrical convex lens.

converge light rays in one plane. **Fig. 50.5A** shows how light is focused from a point source to a line focus by a cylindrical lens.

Combination of Two Cylindrical Lenses at Right Angles Equals a Spherical Lens. **Fig. 50.5B** shows two convex cylindrical lenses at right angles to each other. The vertical cylindrical lens converges the light rays that pass through the two sides of the lens, and the horizontal lens converges the top and bottom rays. Thus, all the light rays come to a single point focus. In other words, *two cylindrical lenses crossed at right angles to each other perform the same function as one spherical lens of the same refractive power.*

Focal Length of a Lens

The distance beyond a convex lens at which *parallel* rays converge to a common focal point is called the *focal length* of the lens. The diagram at the top of **Fig. 50.6** demonstrates this focusing of parallel light rays.

In the middle diagram, the light rays that enter the convex lens are not parallel but are *diverging* because the origin of the light is a point source not far away from the lens. Because these rays are diverging outward from the point source, they do not focus at the same distance away from the lens as do parallel rays. In other words,

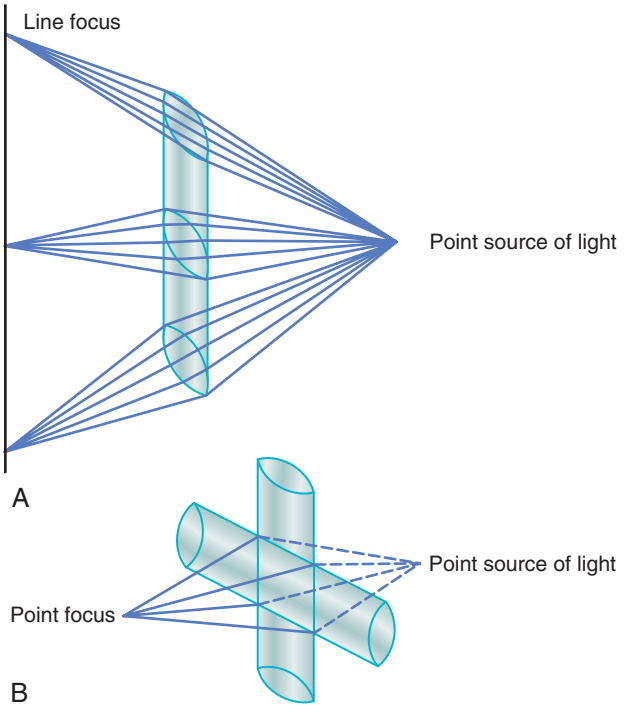

Figure 50.5 (A) Focusing of light from a point source to a line focus by a cylindrical lens. (B) Two cylindrical convex lenses at right angles to each other, demonstrating that one lens converges light rays in one plane, and the other lens converges light rays in the plane at a right angle. The two lenses combined give the same point focus as that obtained with a single spherical convex lens.

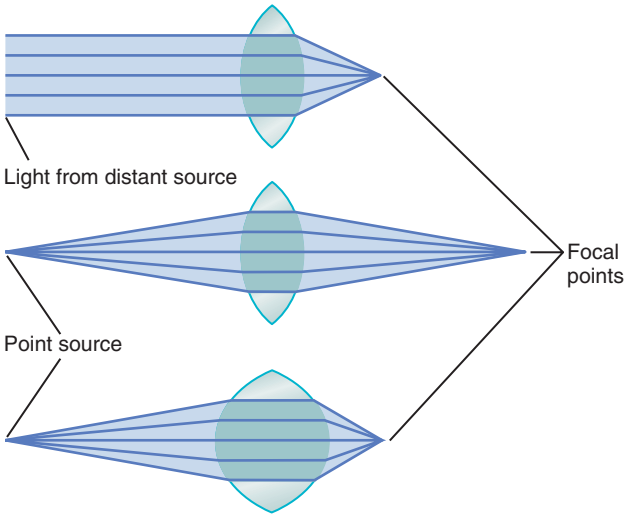

Figure 50.6 The two upper lenses of this figure have the same focal length, but the light rays entering the top lens are parallel, whereas those entering the middle lens are diverging. The effect of parallel versus diverging rays on the focal distance is shown. The bottom lens has far more refractive power than either of the other two lenses (i.e., it has a much shorter focal length), demonstrating that the stronger the lens, the nearer to the lens is the focal point.

when rays of light that are already diverging enter a convex lens, the distance of focus on the other side of the lens is farther from the lens than the focal length of the lens for parallel rays.

The bottom diagram of **Fig. 50.6** shows light rays diverging toward a convex lens that has far greater curvature than that of the other two lenses in the figure. In this diagram, the distance from the lens at which the light rays come to focus is exactly the same as that from the lens in the first diagram, in which the lens is less convex but the rays entering it are parallel. This demonstrates that both parallel rays and diverging rays can be focused at the same distance beyond a lens, provided that the lens changes its convexity.

Formation of an Image By a Convex Lens

Fig. 50.7A shows a convex lens with two point sources of light to the left. Because light rays pass through the center of a convex lens without being refracted in either direction, the light rays from each point source of light are shown to come to a point focus on the opposite side of the lens *directly in line with the point source and the center of the lens*.

Any object in front of the lens is, in reality, a mosaic of point sources of light. Some of these points are very bright and some are very weak, and they vary in color. Each point source of light on the object comes to a separate point focus on the opposite side of the lens in line with the lens center. If a white sheet of paper is placed at the focus distance from the lens, one can see an image of the object, as demonstrated in **Fig. 50.7B**. However, this image is upside down with respect to the original object, and the two lateral sides of the image are reversed. The lens of a camera focuses images via this method.

Measurement of the Refractive Power of a Lens—Diopter

The more a lens bends light rays, the greater is its "refractive power." This refractive power is measured in terms of *diopters*. The refractive power in diopters of a convex lens is equal to 1 meter divided by its focal length. Thus, a spherical lens that converges parallel light rays to a focal point 1 meter beyond the lens has a refractive power of +1 diopter, as shown in **Fig. 50.8**. If the lens is capable of bending parallel light rays twice as much as a lens with a power of +1 diopter, it is said to have a strength of +2 diopters, and the light rays come to a focal point 0.5 meter beyond the lens. A lens capable of converging parallel light rays to a focal point only 10 centimeters (0.10 meter) beyond the lens has a refractive power of +10 diopters.

The refractive power of concave lenses cannot be stated in terms of the focal distance beyond the lens because the light rays diverge rather than focus to a point. However, if a concave lens diverges light rays at the same rate that a 1-diopter convex lens converges them, the concave lens is said to have a dioptric strength of −1. Likewise, if the concave lens diverges light rays as much as a +10-diopter lens converges them, this lens is said to have a strength of −10 diopters.

Concave lenses "neutralize" the refractive power of convex lenses. Thus, placing a 1-diopter concave lens immediately in front of a 1-diopter convex lens results in a lens system with zero refractive power.

The strengths of cylindrical lenses are computed in the same manner as the strengths of spherical lenses, except

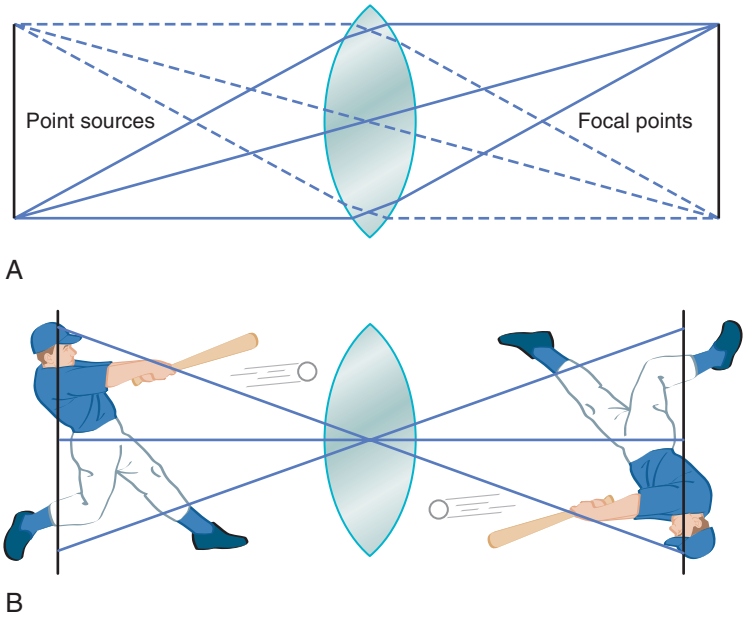

Figure 50.7 (A) Two point sources of light focused at two separate points on opposite sides of the lens. (B) Formation of an image by a convex spherical lens.

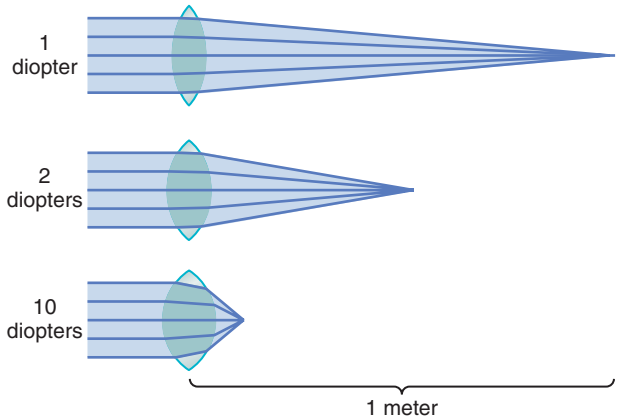

Figure 50.8 Effect of lens strength on the focal distance.

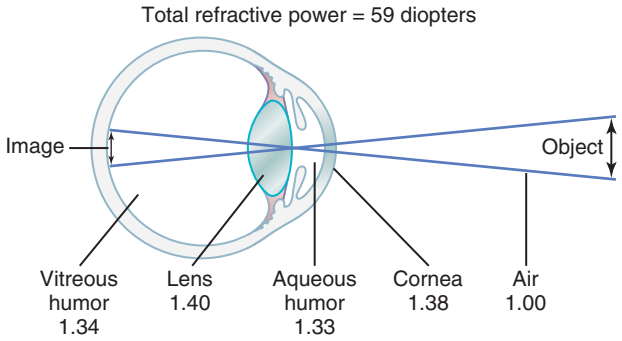

Figure 50.9 The lens system of the eye. The numbers are the refractive indices.

that the *axis* of the cylindrical lens must be stated in addition to its strength. If a cylindrical lens focuses parallel light rays to a line focus 1 meter beyond the lens, it has a strength of +1 diopter. Conversely, if a cylindrical lens of a concave type *diverges* light rays as much as a +1-diopter cylindrical lens *converges* them, it has a strength of −1 diopter. If the focused line is horizontal, its axis is said to be 0 degrees. If it is vertical, its axis is 90 degrees.

OPTICS OF THE EYE

The lens system of the eye (**Fig. 50.9**) is composed of four refractive interfaces: (1) the interface between air and the anterior surface of the cornea; (2) the interface between the posterior surface of the cornea and the aqueous humor; (3) the interface between the aqueous humor and the anterior surface of the lens of the eye; and (4) the interface between the posterior surface of the lens and the vitreous humor. The internal index of air is 1; the cornea, 1.38; the aqueous humor, 1.33; the crystalline lens (on average), 1.40; and the vitreous humor, 1.34.

Consideration of All Refractive Surfaces of the Eye as a Single Lens—The "Reduced" Eye. If all the refractive surfaces of the eye are added together algebraically and then considered to be one single lens, the optics of the normal eye may be simplified and represented schematically as a "reduced eye." This representation is useful for simple calculations. In the reduced eye, a single refractive surface is considered to exist, with its central point 17 millimeters in front of the retina and a total refractive power of 59 diopters when the lens is accommodated for distant vision.

About two-thirds of the 59 diopters of refractive power of the eye is provided by the anterior surface of the cornea (*not* by the eye lens). The principal reason is that the refractive index of the cornea is markedly different from that of air, whereas the refractive index of the eye lens

is not greatly different from the indices of the aqueous humor and vitreous humor.

The total refractive power of the internal lens of the eye, as it normally lies in the eye surrounded by fluid on each side, is only 20 diopters, about one-third the total refractive power of the eye. However, the importance of the internal lens is that in response to nervous signals from the brain, *its curvature can be increased markedly to provide "accommodation,"* which is discussed later in the chapter.

Formation of an Image on the Retina. In the same manner that a glass lens can focus an image on a sheet of paper, the lens system of the eye can focus an image on the retina. The image is inverted and reversed with respect to the object. However, the mind perceives objects in the upright position despite the upside-down orientation on the retina because the brain is trained to consider an inverted image as normal.

MECHANISM OF "ACCOMMODATION"

In children, the refractive power of the lens of the eye can be increased voluntarily from 20 diopters to about 34 diopters, which is an "accommodation" of 14 diopters. To make this accommodation, the shape of the lens is changed from that of a moderately convex lens to that of a very convex lens.

In a young person, the lens is composed of a strong elastic capsule filled with viscous, proteinaceous, but transparent fluid. When the lens is in a relaxed state, with no tension on its capsule, it assumes an almost spherical shape, owing mainly to the elastic retraction of the lens capsule. However, as shown in **Fig. 50.10**, about 70 *suspensory ligaments* attach radially around the lens, pulling the lens edges toward the outer circle of the eyeball. These ligaments are constantly tensed by their attachments at the anterior border of the choroid and retina. The tension on the ligaments causes the lens to remain relatively flat under normal eye conditions.

Also located at the lateral attachments of the lens ligaments to the eyeball is the *ciliary muscle*, which has two separate sets of smooth muscle fibers—*meridional fibers* and *circular fibers*. The meridional fibers extend from the peripheral ends of the suspensory ligaments to the corneoscleral junction. When these muscle fibers contract, the *peripheral insertions* of the lens ligaments are pulled medially toward the edges of the cornea, thereby releasing the ligaments' tension on the lens. The circular fibers are arranged circularly all the way around the ligament attachments so that when they contract, a sphincter-like action occurs, decreasing the diameter of the circle of ligament attachments; this action also allows the ligaments to pull less on the lens capsule.

Thus, contraction of either set of smooth muscle fibers in the ciliary muscle relaxes the ligaments to the lens capsule, and the lens assumes a more spherical shape, like that of a balloon, because of the natural elasticity of the lens capsule.

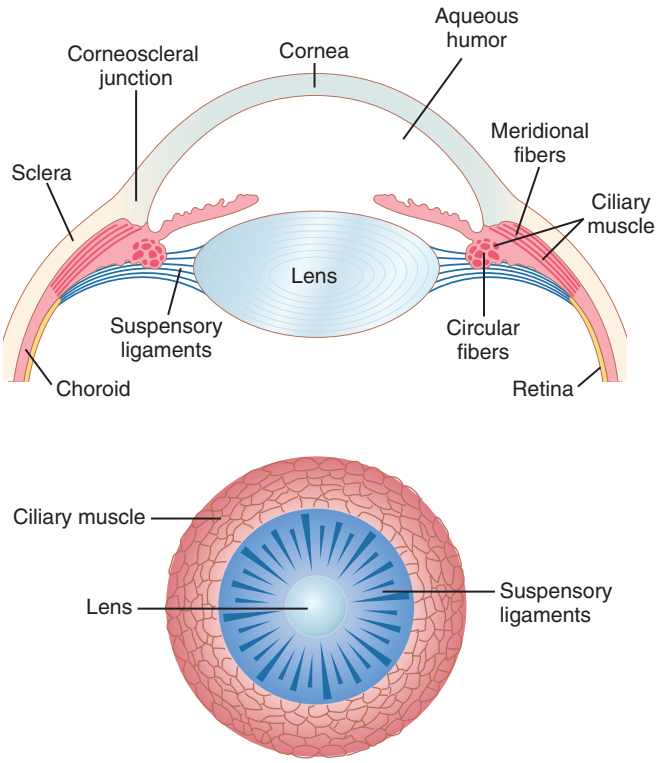

Figure 50.10 Mechanism of accommodation (focusing).

Accommodation Is Controlled By Parasympathetic Nerves. Ciliary muscle is controlled almost entirely by parasympathetic nerve signals transmitted to the eye through the third cranial nerve from the third nerve nucleus in the brain stem, as explained in Chapter 52. Stimulation of parasympathetic nerves contracts both sets of ciliary muscle fibers, which relaxes the lens ligaments, thus allowing the lens to become thicker and increase its refractive power. With this increased refractive power, the eye focuses on objects nearer than when the eye has less refractive power. Consequently, as a distant object moves toward the eye, the number of parasympathetic impulses impinging on the ciliary muscle must be progressively increased for the eye to keep the object constantly in focus. Sympathetic stimulation has an additional effect in relaxing the ciliary muscle, but this effect is so weak that it plays almost no role in the normal accommodation mechanism; the neurophysiology of this mechanism is discussed in Chapter 52.

Presbyopia—Loss of Accommodation By the Lens. As a person grows older, the lens grows larger and thicker and becomes far less elastic, partly because of progressive denaturation of the lens proteins. The ability of the lens to change shape decreases with age. The power of accommodation decreases from about 14 diopters in a child to less than 2 diopters by the time a person reaches 45 to 50 years and to essentially 0 diopters at age 70 years. Thereafter, the lens remains almost totally nonaccommodating, a condition known as *presbyopia*.

Once a person has reached the state of presbyopia, each eye remains focused permanently at an almost constant

distance; this distance depends on the physical characteristics of each person's eyes. The eyes can no longer accommodate for both near and far vision. To see clearly both in the distance and nearby, an older person must wear bifocal glasses, with the upper segment focused for far-seeing and the lower segment focused for near-seeing (e.g., for reading).

PUPILLARY DIAMETER

The major function of the iris is to increase the amount of light that enters the eye during darkness and to decrease the amount of light that enters the eye in daylight. The reflexes for controlling this mechanism are considered in Chapter 52.

The amount of light that enters the eye through the pupil is proportional to the *area* of the pupil or to the *square of the diameter* of the pupil. The pupil of the human eye can become as small as about 1.5 millimeters and as large as 8 millimeters in diameter. The quantity of light entering the eye can change about 30-fold as a result of changes in pupillary aperture.

"Depth of Focus" of the Lens System Increases With Decreasing Pupillary Diameter. **Fig. 50.11** shows two eyes that are exactly alike except for the diameters of the pupillary apertures. In the upper eye the pupillary aperture is small, and in the lower eye the aperture is large. In front of each of these two eyes are two small point sources of light; light from each passes through the pupillary aperture and focuses on the retina. Consequently, in both eyes, the retina sees two spots of light in perfect focus. If the retina is moved forward or backward to an out-of-focus position (dashed lines), the size of each spot will not change much in the upper eye, but in the lower eye the size of each spot will increase greatly, becoming a "blur circle." In other words, the upper lens system has far greater *depth of focus* than the bottom lens system. When a lens system has great depth of focus, the retina can be displaced considerably from the focal plane, or the lens strength can change considerably from normal, and the image will still remain nearly in sharp focus, whereas when a lens system has a "shallow" depth of focus, moving the retina only slightly away from the focal plane causes extreme blurring.

The greatest possible depth of focus occurs when the pupil is extremely small. The reason for this is that with a very small aperture, almost all the rays pass through the center of the lens, and the centralmost rays are always in focus, as explained earlier.

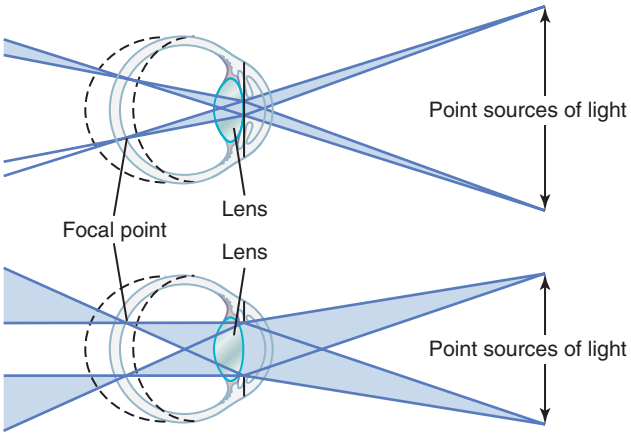

Figure 50.11 Effect of small *(top)* and large *(bottom)* pupillary apertures on depth of focus.

Errors of Refraction

See **Video 50.1**.

Emmetropia (Normal Vision). As shown in **Fig. 50.12**, the eye is considered to be normal, or *emmetropic*, if parallel light rays *from distant objects* are in sharp focus on the retina *when the ciliary muscle is completely relaxed*. This means that the emmetropic eye can see all distant objects clearly with its ciliary muscle relaxed. However, to focus objects at close range, the eye must contract its ciliary muscle and thereby provide an appropriate degree of accommodation.

Hyperopia (Farsightedness). Hyperopia, also known as "farsightedness," is usually due to either an eyeball that is too short or, occasionally, to a lens system that is too weak. In this condition, as seen in the middle panel of **Fig. 50.12**, parallel light rays are not bent sufficiently by the relaxed lens system to come to focus by the time they reach the retina. To overcome this abnormality, the ciliary muscle must contract to increase the strength of the lens. By using the mechanism of accommodation, a farsighted person is capable of focusing distant objects on the retina. If the person has used only a small amount of strength in the ciliary

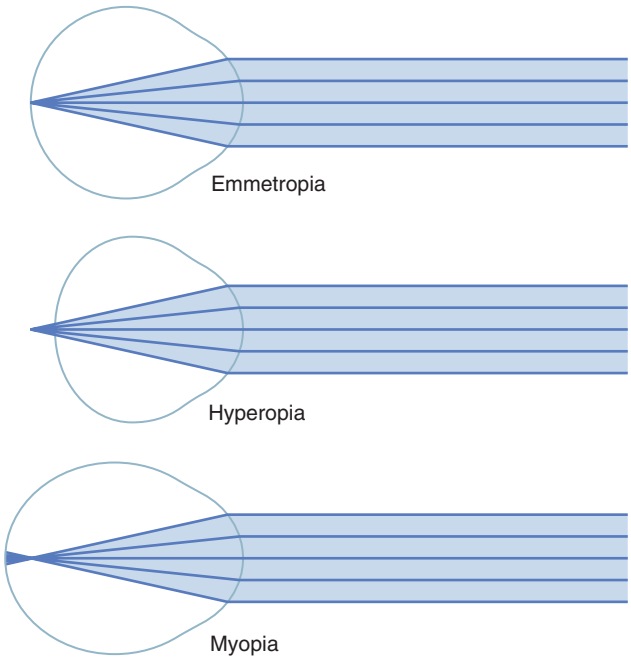

Figure 50.12 Parallel light rays focus on the retina in emmetropia, behind the retina in hyperopia, and in front of the retina in myopia.

muscle to accommodate for the distant objects, they still have much accommodative power left, and objects closer and closer to the eye can also be focused sharply until the ciliary muscle has contracted to its limit. In old age, when the lens becomes "presbyopic," a farsighted person is often unable to accommodate the lens sufficiently to focus even on distant objects, much less on near objects.

Myopia (Nearsightedness). In myopia, or "nearsightedness," when the ciliary muscle is completely relaxed, the light rays coming from distant objects are focused in front of the retina, as shown in the bottom panel of **Fig. 50.12**. This condition is usually due to too long an eyeball but also can result from too much refractive power in the lens system of the eye.

No mechanism exists whereby the eye can decrease the strength of its lens to less than that which exists when the ciliary muscle is completely relaxed. A myopic person has no mechanism to focus distant objects sharply on the retina. However, as an object moves nearer to the person's eye, it finally gets close enough that its image can be focused. Then, when the object comes still closer to the eye, the person can use the mechanism of accommodation to keep the image focused clearly. A myopic person has a definite limiting "far point" for clear vision.

Correction of Myopia and Hyperopia Through Use of Lenses. If the refractive surfaces of the eye have too much refractive power, as in *myopia*, this excessive refractive power can be neutralized by placing a concave spherical lens in front of the eye, which will diverge rays. Such correction is shown in the upper diagram of **Fig. 50.13**.

Conversely, in a person who has *hyperopia*—that is, someone who has too weak a lens system—the abnormal vision can be corrected by adding refractive power using a convex lens in front of the eye. This correction is demonstrated in the lower diagram of **Fig. 50.13**.

One usually determines the strength of the concave or convex lens needed for clear vision by "trial and error"—that is, by first trying a strong lens and then a stronger or weaker lens until the one that gives the best visual acuity is found.

Astigmatism. Astigmatism is a refractive error of the eye that causes the visual image in one plane to focus at a different distance from that of the plane at right angles. Astigmatism usually results from too great a curvature of the cornea in one plane of the eye. An example of an astigmatic lens would be a lens surface like that of an egg lying sidewise to the incoming light. The degree of curvature in the plane through the long axis of the egg is not nearly as great as the degree of curvature in the plane through the short axis.

Because the curvature of the astigmatic lens along one plane is less than the curvature along the other plane, light rays striking the peripheral portions of the lens in one plane are not bent nearly as much as the rays striking the peripheral portions of the other plane. This effect is illustrated in **Fig. 50.14**, which shows rays of light originating from a point source and passing through an oblong, astigmatic lens. The light rays in the vertical plane, indicated by plane BD, are refracted greatly by the astigmatic lens because of the greater curvature in the vertical direction than in the horizontal direction. By contrast, the light rays in the horizontal plane, indicated by plane AC, are not bent nearly as much as the light rays in vertical plane BD. Therefore, light rays passing through an astigmatic lens do not all come to a common focal point because the light rays passing through one plane focus far in front of those passing through the other plane.

The accommodative power of the eye can never compensate for astigmatism because, during accommodation, the curvature of the eye lens changes approximately equally in both planes; therefore, in astigmatism, each of the two planes requires a different degree of accommodation. Thus, without the aid of glasses, a person with astigmatism never sees in sharp focus.

Correction of Astigmatism With a Cylindrical Lens. One may consider an astigmatic eye as having a lens system made up of two cylindrical lenses of different strengths and placed at right angles to each other. To correct for astigmatism, the usual procedure is to find a spherical lens by trial and error that corrects the focus in one of the two planes of the astigmatic lens. Then, an additional cylindrical lens is

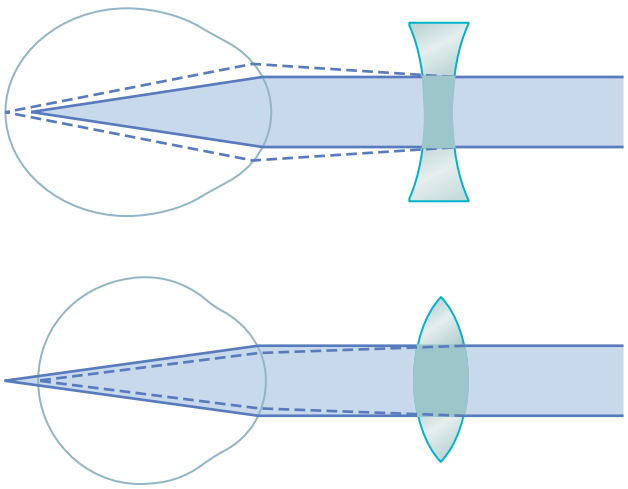

Figure 50.13 Correction of myopia with a concave lens *(top)* and correction of hyperopia with a convex lens *(bottom)*.

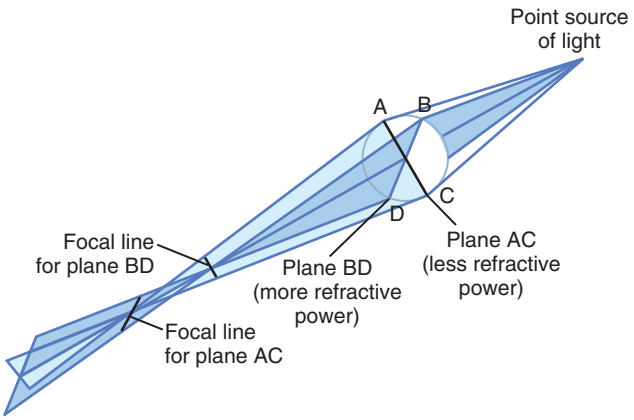

Figure 50.14 Astigmatism, demonstrating that light rays focus at one focal distance in one focal plane *(plane AC)* and at another focal distance in the plane at a right angle *(plane BD)*.

used to correct the remaining error in the remaining plane. To do this, both the *axis* and the *strength* of the required cylindrical lens must be determined.

Several methods exist for determining the axis of the abnormal cylindrical component of the lens system of an eye. One of these methods is based on the use of parallel black bars of the type shown in **Fig. 50.15**. Some of these parallel bars are vertical, some are horizontal, and some are at various angles to the vertical and horizontal axes. After placing various spherical lenses in front of the astigmatic eye, a strength of lens that causes sharp focus of one set of parallel bars but does not correct the fuzziness of the set of bars at right angles to the sharp bars is usually found. It can be shown from the physical principles of optics discussed earlier in this chapter that the *axis* of the *out of focus* cylindrical component of the optical system is parallel to the bars that are fuzzy. Once this axis is found, the examiner tries progressively stronger and weaker positive or negative *cylindrical* lenses, the axes of which are placed in line with the bars that are out of focus, until the person sees all the crossed bars with equal clarity. When this goal has been accomplished, the examiner directs the optician to grind a special lens combining both the spherical correction and the cylindrical correction at the appropriate axis.

Correction of Optical Abnormalities With Contact Lenses. Glass or plastic contact lenses that fit snugly against the anterior surface of the cornea can be inserted. These lenses are held in place by a thin layer of tear fluid that fills the space between the contact lens and the anterior eye surface.

A special feature of the contact lens is that it nullifies the refraction that normally occurs at the anterior surface of the cornea almost entirely. The reason for this nullification is that the tears between the contact lens and the cornea have a refractive index almost equal to that of the cornea, so the anterior surface of the cornea no longer plays a significant role in the eye's optical system. Instead, the outer surface of the contact lens plays the major role. Thus, the refraction of this surface of the contact lens substitutes for the cornea's usual refraction. This factor is especially important in people whose eye refractive errors are caused by an abnormally shaped cornea, such as those who have an odd-shaped, bulging cornea, a condition called *keratoconus*. Without the contact lens, the bulging cornea causes such severe abnormality of vision that almost no glasses can correct the vision satisfactorily; when a contact lens is used, however, the corneal refraction is neutralized, and normal refraction by the outer surface of the contact lens is substituted.

The contact lens has several other advantages as well, including the following: (1) the lens turns with the eye and gives a broader field of clear vision than glasses; and (2) the contact lens has little effect on the size of the object the person sees through the lens, whereas lenses placed about 1 centimeter in front of the eye do affect the size of the image in addition to correcting the focus.

Cataracts—Opaque Areas in the Lens. "Cataracts" are an especially common eye abnormality that occurs mainly in older people. A cataract is a cloudy or opaque area (or areas) in the lens. In the early stage of cataract formation, the proteins in some of the lens fibers become denatured. Later, these same proteins coagulate to form opaque areas in place of the normal transparent protein fibers.

When a cataract has obscured light transmission so greatly that it seriously impairs vision, the condition can be corrected by surgical removal of the lens. When the lens is removed, the eye loses a large portion of its refractive power, which must be replaced by placing a powerful convex lens in front of the eye; usually, however, an artificial plastic lens is implanted in the eye in place of the removed lens.

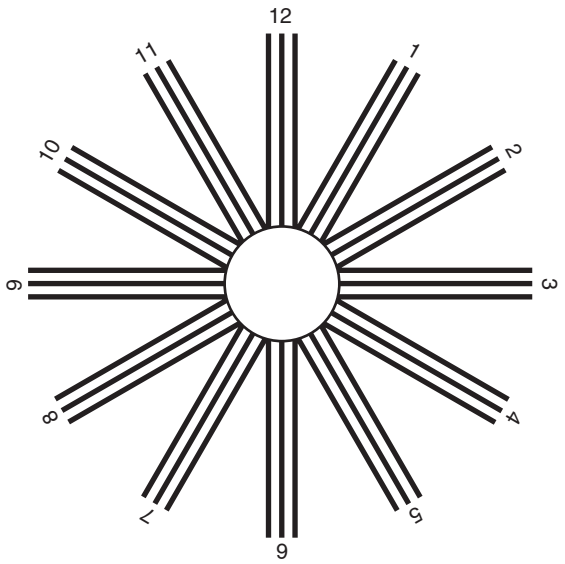

Figure 50.15 Chart composed of parallel black bars at different angular orientations for determining the axis of astigmatism.

VISUAL ACUITY

Theoretically, light from a distant point source, when focused on the retina, should be infinitely small. However, because the lens system of the eye is never perfect, such a retinal spot ordinarily has a total diameter of about 11 micrometers, even with maximal resolution of the normal eye optical system. The spot is brightest in its center and shades off gradually toward the edges, as shown by the two-point images in **Fig. 50.16**.

The average diameter of the cones in the *fovea* of the retina—the central part of the retina, where vision is most highly developed—is about 1.5 micrometers, which is one-seventh the diameter of the spot of light. Nevertheless, because the spot of light has a bright center point and shaded edges, a person can normally distinguish two separate points if their centers lie up to 2 micrometers apart on the retina, which is slightly greater than the width of a foveal cone. This discrimination between points is also shown in **Fig. 50.16**.

The normal visual acuity of the human eye for discriminating between point sources of light is about 25 seconds of arc. That is, when light rays from two separate points strike the eye with an angle of at least 25 seconds between

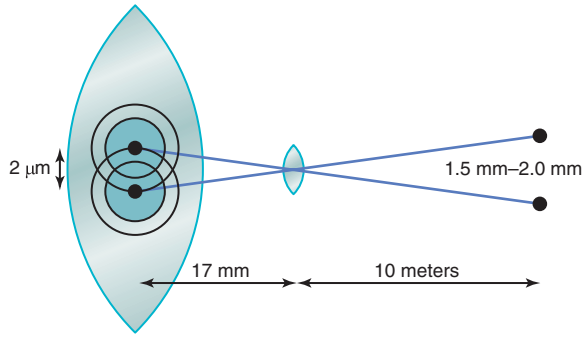

Figure 50.16 Maximum visual acuity for two point sources of light.

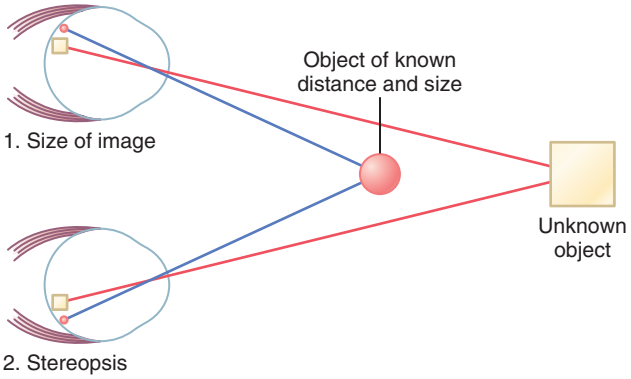

Figure 50.17 Perception of distance by the size of the image on the retina (1) and as a result of stereopsis (2).

them, they can usually be recognized as two points instead of one. This means that a person with normal visual acuity looking at two bright pinpoint spots of light 10 meters away can barely distinguish the spots as separate entities when they are 1.5 to 2 millimeters apart.

The fovea is less than 0.5 millimeter (<500 micrometers) in diameter, which means that maximum visual acuity occurs in less than 2 degrees of the visual field. Outside this foveal area, the visual acuity becomes progressively poorer, decreasing more than 10-fold as the periphery is approached. This is caused by the connection of more and more rods and cones to each optic nerve fiber in the nonfoveal, more peripheral parts of the retina, as discussed in Chapter 52.

Clinical Method for Stating Visual Acuity. The chart for testing eyes usually consists of letters of different sizes placed 20 feet away from the person being tested. If the person can see well the letters of a size that they should be able to see at 20 feet, the person is said to have 20/20 vision—that is, normal vision. If the person can see only letters that they should be able to see at 200 feet, the person is said to have 20/200 vision. In other words, the clinical method for expressing visual acuity is to use a mathematical fraction that expresses the ratio of two distances, which is also the ratio of a person's visual acuity to that of a person with normal visual acuity.

DETERMINATION OF DISTANCE OF AN OBJECT FROM THE EYE—"DEPTH PERCEPTION"

A person normally perceives distance by three main means: (1) the sizes of the images of known objects on the retina; (2) the phenomenon of moving parallax; and (3) the phenomenon of stereopsis. This ability to determine distance is called *depth perception*.

Determination of Distance By Sizes of Retinal Images of Known Objects. By knowing that a person being viewed is 6 feet tall, one can determine how far away the person is simply by the size of the person's image on the retina. One does not consciously think about the size, but the brain has learned to calculate automatically from image sizes the distances of objects when the dimensions are known.

Determination of Distance By Moving Parallax. Another important means whereby the eyes determine distance is that of *moving parallax*, a displacement in the apparent position of an object viewed along two different lines of sight. If a person looks off into the distance with the eyes completely still, the person perceives no moving parallax. However, when the person moves the head to one side or the other, the images of nearby objects move rapidly across the retinas, whereas the images of distant objects remain almost completely stationary. For example, by moving the head 1 inch to the side when the object is only 1 inch in front of the eye, the image moves almost all the way across the retinas, whereas the image of an object 200 feet away from the eyes does not move perceptibly. Thus, by using this mechanism of moving parallax, one can tell the *relative distances* of different objects even though only one eye is used.

Determination of Distance By Stereopsis—Binocular Vision. Another method whereby one perceives parallax is that of *binocular vision*. Because one eye is a little more than 2 inches to one side of the other eye, the images on the two retinas are different from each other. For example, an object 1 inch in front of the nose forms an image on the left side of the retina of the left eye but on the right side of the retina of the right eye, whereas a small object 20 feet in front of the nose has its image at closely corresponding points in the centers of the two retinas. This type of parallax is demonstrated in **Fig. 50.17**, which shows the images of a red spot and a yellow square actually reversed on the two retinas because they are at different distances in front of the eyes. This gives a type of parallax that is always present when both eyes are being used. It is almost entirely this binocular parallax (or *stereopsis*) that gives a person with two eyes far greater ability to judge relative distances *when objects are nearby* than a person who has only one eye. However, stereopsis is virtually useless for depth perception at distances beyond 50 to 200 feet.

FLUID SYSTEM OF THE EYE—INTRAOCULAR FLUID

The eye is filled with *intraocular fluid*, which maintains sufficient pressure in the eyeball to keep it distended. **Fig. 50.18** demonstrates that this fluid can be divided into two portions—*aqueous humor*, which lies in front of the lens, and *vitreous humor*, which is between the posterior surface of the lens and the retina. The aqueous humor is a freely flowing fluid, whereas the vitreous humor, sometimes called the *vitreous body*, is a gelatinous mass held together by a fine fibrillar network composed primarily of proteoglycan molecules. Although water and dissolved substances can *diffuse* slowly in the vitreous humor, there is little *flow* of fluid.

Aqueous humor is continually being formed and reabsorbed. The balance between formation and reabsorption of aqueous humor regulates the total volume and pressure of the intraocular fluid.

Formation of Aqueous Humor By the Ciliary Body

Aqueous humor is formed in the eye *at an average rate of 2 to 3 μL/min*. Essentially all of it is secreted by the *ciliary processes*, which are linear folds projecting from the *ciliary body* into the space behind the iris where the lens ligaments and ciliary muscle attach to the eyeball. A cross section of these ciliary processes is shown in **Fig. 50.19**, and their relation to the fluid chambers of the eye can be seen in **Fig. 50.18**. Because of their folded architecture, the total surface area of the ciliary processes is about 6 square centimeters in each eye—a large area, considering the small size of the ciliary body. The surfaces of these processes are covered by highly secretory epithelial cells, and immediately beneath them is a highly vascular area.

Aqueous humor is formed almost entirely as an active secretion by the epithelium of the ciliary processes. Secretion begins with active transport of sodium ions into the spaces between the epithelial cells. The sodium ions pull chloride and bicarbonate ions along with them to maintain electrical neutrality. Then, all these ions together cause osmosis of water from the blood capillaries lying below into the same epithelial intercellular spaces; the resulting solution washes from the spaces of the ciliary processes into the anterior chamber of the eye. In addition, several nutrients are transported across the epithelium by active transport or facilitated diffusion, including amino acids, ascorbic acid, and glucose.

Outflow of Aqueous Humor From the Eye

After aqueous humor is formed by the ciliary processes, it first flows, as shown in **Fig. 50.18**, *through the pupil into the anterior chamber of the eye*. From here, the fluid flows *anterior to the lens and into the angle between the cornea and the iris*, then through a meshwork of *trabeculae*, and finally entering the *canal of Schlemm*, which empties into extraocular veins. **Fig. 50.20** illustrates the anatomical structures at this iridocorneal angle, showing that the spaces between the trabeculae extend all the way from the anterior chamber to the canal of Schlemm. The canal of Schlemm is a thin-walled vein that extends circumferentially all the way around the eye. Its endothelial membrane is so porous that even large protein molecules, as well as small particulate matter up to the size of red blood cells, can pass from the anterior chamber into the canal of Schlemm. Even though the canal of Schlemm is actually a venous blood vessel, so much aqueous humor normally flows into it that it is filled only with aqueous humor rather than with blood. The small veins that lead from the canal of Schlemm to the larger veins of the eye usually contain only aqueous humor; they are called *aqueous veins*.

Intraocular Pressure

The average normal intraocular pressure is about 15 mm Hg, with a range from 12 to 20 mm Hg.

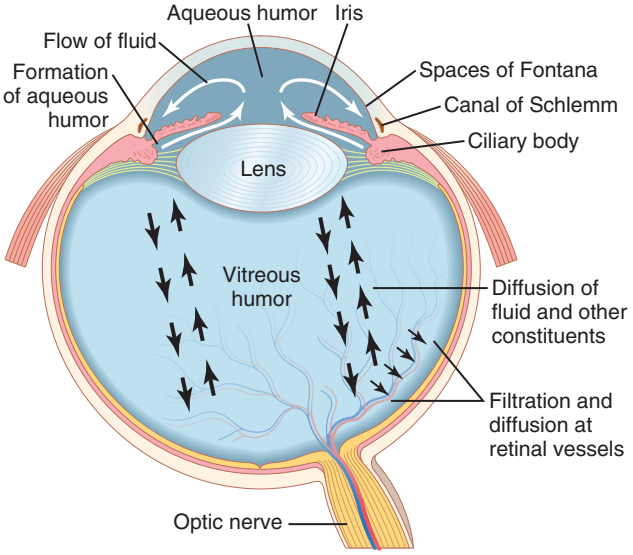

Figure 50.18 Formation and flow of fluid in the eye.

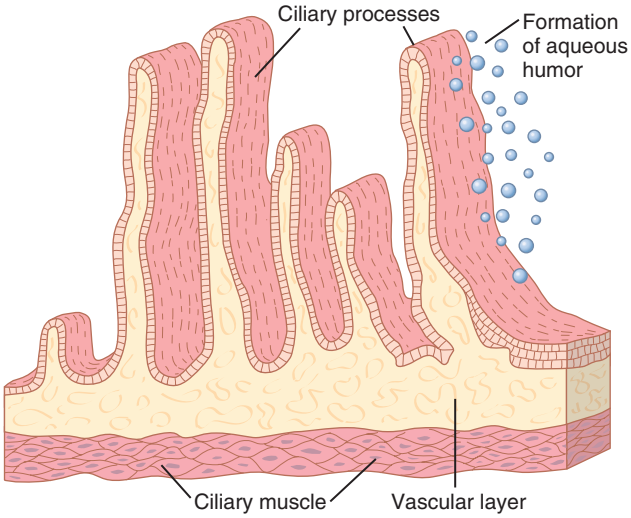

Figure 50.19 Anatomy of the ciliary processes. Aqueous humor is formed on surfaces.

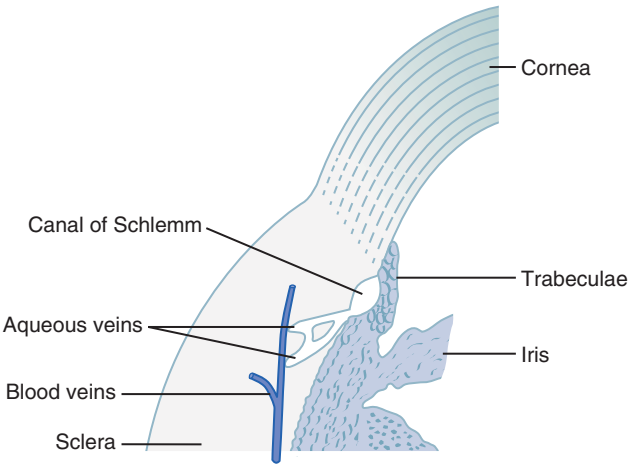

Figure 50.20 Anatomy of the iridocorneal angle, showing the system for outflow of aqueous humor from the eyeball into the conjunctival veins.

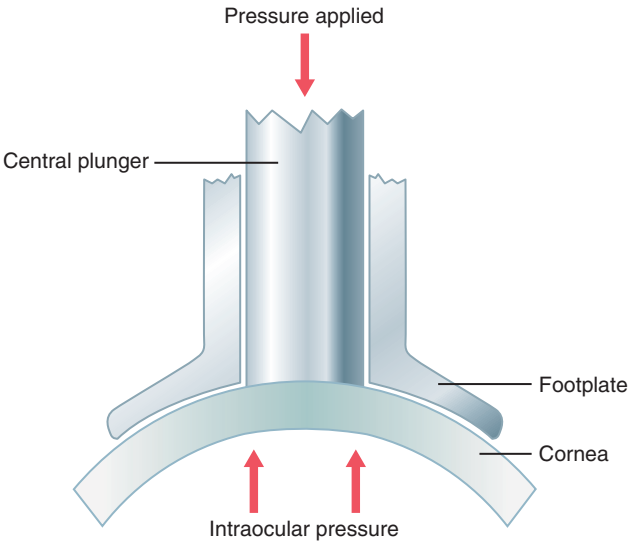

Figure 50.21 Principles of the tonometer.

Measuring Intraocular Pressure By Tonometry. Because it is impractical to pass a needle into a patient's eye to measure intraocular pressure, this pressure is measured clinically by using a "tonometer," the principle of which is shown in **Fig. 50.21**. The cornea of the eye is anesthetized with a local anesthetic, and the footplate of the tonometer is placed on the cornea. A small force is then applied to a central plunger, causing the part of the cornea beneath the plunger to be displaced inward. The amount of displacement is recorded on the scale of the tonometer, and this is calibrated in terms of intraocular pressure.

Regulation of Intraocular Pressure. Intraocular pressure remains constant in the normal eye, usually within ±2 mm Hg of its normal level, which averages about 15 mm Hg. The level of this pressure is determined mainly by the resistance to outflow of aqueous humor from the anterior chamber into the canal of Schlemm. This outflow resistance results from the meshwork of trabeculae through which the fluid must percolate on its way from the lateral angles of the anterior chamber to the wall of the canal of Schlemm. These trabeculae have minute openings of only 2 to 3 micrometers. The rate of fluid flow into the canal increases markedly as the pressure rises. At about 15 mm Hg in the normal eye, the amount of fluid leaving the eye via the canal of Schlemm usually averages 2.5 µL/min and equals the inflow of fluid from the ciliary body.

Mechanism for Cleansing the Trabecular Spaces and Intraocular Fluid. When large amounts of debris are present in the aqueous humor, as occurs after hemorrhage into the eye or during intraocular infection, the debris is likely to accumulate in the trabecular spaces leading from the anterior chamber to the canal of Schlemm; this debris can prevent adequate reabsorption of fluid from the anterior chamber, sometimes causing "glaucoma," as explained subsequently. However, on the surfaces of the trabecular plates are large numbers of phagocytic cells. Immediately outside the canal of Schlemm is a layer of interstitial gel that contains large numbers of reticuloendothelial cells that have a high capacity for engulfing debris and digesting it into small molecular substances that can then be absorbed. Thus, this phagocytic system keeps the trabecular spaces cleaned. The surface of the iris and other surfaces of the eye behind the iris are covered with an epithelium that can phagocytize proteins and small particles from the aqueous humor, thereby helping maintain a clear fluid.

"Glaucoma" Causes High Intraocular Pressure and Is a Principal Cause of Blindness. Glaucoma, one of the most common causes of blindness, is a disorder of the eye in which the intraocular pressure becomes pathologically high, sometimes rising acutely to 60 to 70 mm Hg. Pressures above 25 to 30 mm Hg can cause loss of vision when maintained for long periods. Extremely high pressures can cause blindness within days or even hours. As the pressure rises, the axons of the optic nerve are compressed where they leave the eyeball at the optic disc. This compression is believed to block axonal flow of cytoplasm from the retinal neuronal cell bodies into the optic nerve fibers leading to the brain. The result is lack of appropriate nutrition of the fibers and eventually death of the involved fibers. It is possible that compression of the retinal artery, which enters the eyeball at the optic disc, also adds to the neuronal damage by reducing nutrition to the retina.

In most cases of glaucoma, the abnormally high pressure results from increased resistance to fluid outflow through the trabecular spaces into the canal of Schlemm at the iridocorneal junction. For example, in acute eye inflammation, white blood cells and tissue debris can block these trabecular spaces and cause an acute increase in intraocular pressure. In chronic conditions, especially in older persons, fibrous occlusion of the trabecular spaces appears to be the likely culprit.

Glaucoma can sometimes be treated by placing drops in the eye that contain a drug that diffuses into the eyeball and reduces the secretion or increases the absorption of aqueous humor. When drug therapy fails, operative techniques to open the spaces of the trabeculae or to make channels to allow fluid to flow directly from the fluid space of the eyeball into the subconjunctival space outside the eyeball can often reduce the pressure effectively.

The Eye: II. Receptor and Neural Function of the Retina

The retina is the light-sensitive portion of the eye that contains the following: (1) *cones*, which are responsible for color vision; and (2) *rods*, which can detect dim light and are mainly responsible for black and white vision and vision in the dark. When either rods or cones are excited, signals are transmitted first through successive layers of neurons in the retina and, finally, into optic nerve fibers and the cerebral cortex. In this chapter, we explain the mechanisms whereby the rods and cones detect light and color and convert the visual image into optic nerve signals.

ANATOMY AND FUNCTION OF STRUCTURAL ELEMENTS OF THE RETINA

The Retina Is Composed of Ten Layers or Boundaries. **Fig. 51.1** shows the functional components of the retina, which are arranged in layers or boundaries from the outside to the inside, as follows: (1) pigmented layer; (2) photoreceptor layer containing rods and cones projecting to the pigment; (3) outer limiting membrane; (4) outer nuclear layer containing the cell bodies of the rods and cones; (5) outer plexiform layer; (6) inner nuclear layer; (7) inner plexiform layer; (8) ganglionic layer; (9) layer of optic nerve fibers (stratum opticum); and (10) inner limiting membrane.

After light passes through the lens system of the eye and then through the vitreous humor, it *enters the retina from the inside of the eye* (**Fig. 51.1**); that is, it passes first through the ganglion cells and then through the plexiform and nuclear layers before it finally reaches the layer of rods and cones located all the way on the outer edge of the retina. This distance is a thickness of several hundred micrometers; visual acuity is decreased by this passage through such nonhomogeneous tissue. However, in the *central foveal region of the retina*, as discussed

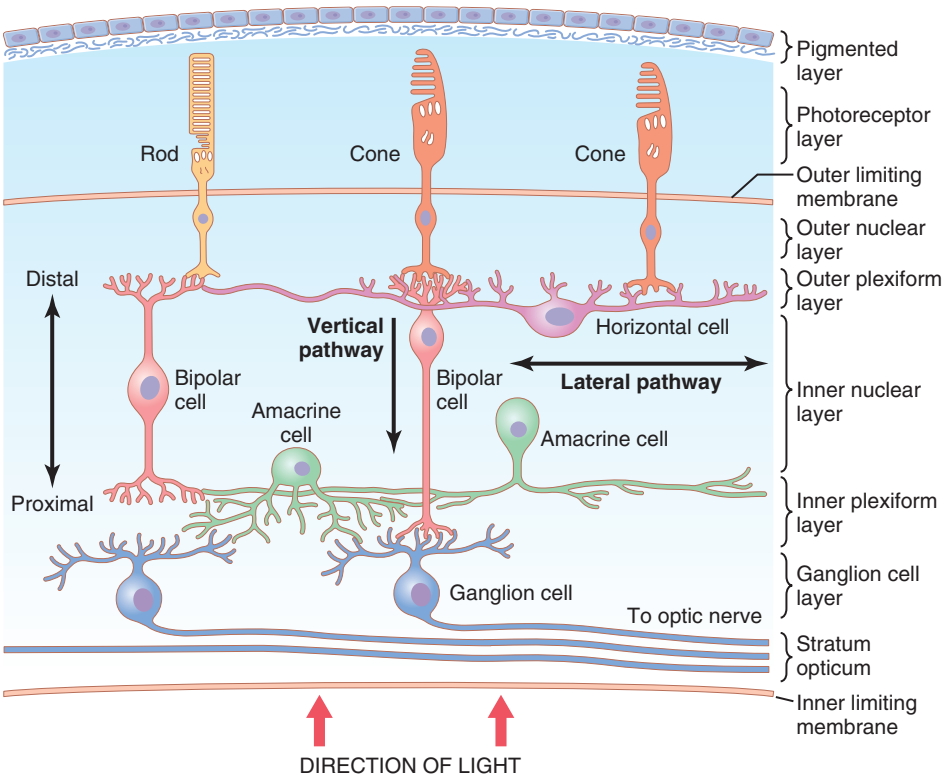

Figure 51.1 Layers of the retina.

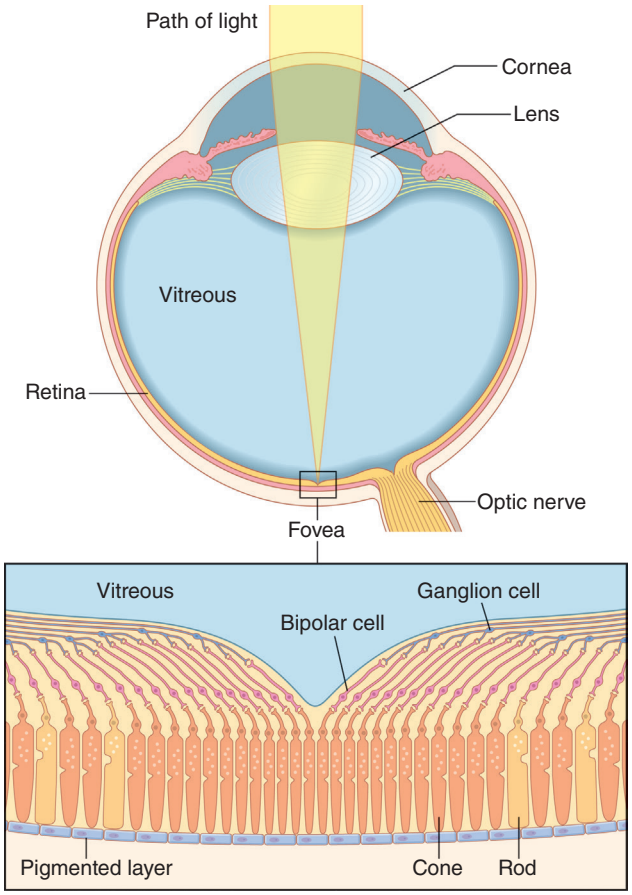

Figure 51.2 Projection of light to the photoreceptors (cones) in the retina. Note that in the foveal region the photoreceptors are entirely cones and that neuronal cells are all displaced to one side, allowing light to pass unimpeded to the cones.

subsequently, the inside layers are pulled aside to decrease this loss of acuity.

Foveal Region of the Retina and Its Importance in Acute Vision. The *fovea* is a minute area in the center of the retina, shown in **Fig. 51.2**, occupying a total area a little more than 1 square millimeter. It is especially capable of acute and detailed vision. The *central fovea*, only 0.3 millimeter in diameter, is composed almost entirely of cones. These cones have a special structure that aids their detection of detail in the visual image—that is, the foveal cones have especially long and slender bodies, in contradistinction to the much thicker cones located more peripherally in the retina. Also, in the foveal region, the blood vessels, ganglion cells, inner nuclear layer of cells, and plexiform layers are all displaced to one side rather than resting directly on top of the cones, which allows light to pass unimpeded to the cones.

Rods and Cones Are Essential Components of Photoreceptors. **Fig. 51.3** illustrates the essential components of a photoreceptor (either a rod or a cone). As shown in **Fig. 51.4**, the outer segment of the cone is conical in shape. In general, the rods are narrower and longer than the cones, but this is not always the case. In the peripheral

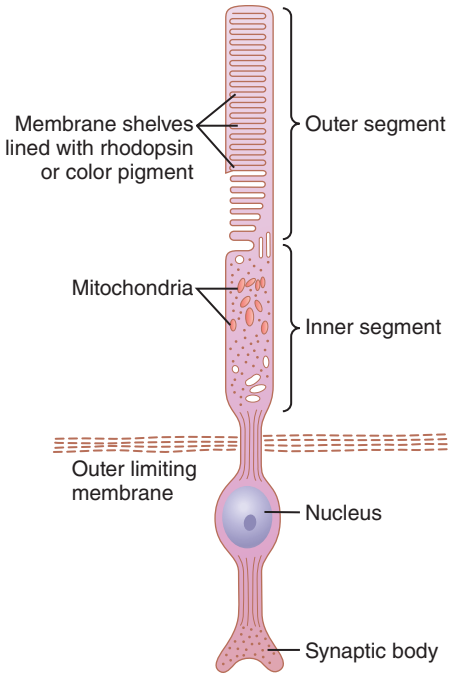

Figure 51.3 Schematic drawing of the functional parts of the rods and cones.

portions of the retina, the rods are 2 to 5 micrometers in diameter, whereas the cones are 5 to 8 micrometers in diameter; in the central part of the retina, in the fovea, there are no rods, and the cones are slender and have a diameter of only 1.5 micrometers.

The major functional segments of either a rod or cone are shown in **Fig. 51.3**: (1) the *outer segment;* (2) the *inner segment;* (3) the *nucleus;* and (4) the *synaptic body*. The light-sensitive photochemical is found in the outer segment. In the case of the rods, this photochemical is *rhodopsin*; in the cones, it is one of three "color" photochemicals, usually called simply *color pigments*, that function almost exactly the same as rhodopsin except for differences in spectral sensitivity.

In the *outer segments* of the rods and cones in **Figs. 51.3 and 51.4**, note the large numbers of *discs*. Each disc is actually an infolded shelf of cell membrane. There are as many as 1000 discs in each rod or cone.

Both rhodopsin and the color pigments are conjugated proteins. They are incorporated into the membranes of the discs in the form of transmembrane proteins. The concentrations of these photosensitive pigments in the discs are so great that the pigments themselves constitute about 40% of the entire mass of the outer segment.

The *inner segment* of the rod or cone contains the usual cytoplasm, with cytoplasmic organelles. Especially important are the mitochondria, which, as explained later, play the important role of providing energy for function of the photoreceptors.

The *synaptic body* is the portion of the rod or cone that connects with subsequent neuronal cells, the *horizontal* and *bipolar cells*, which represent the next stages in the vision chain.

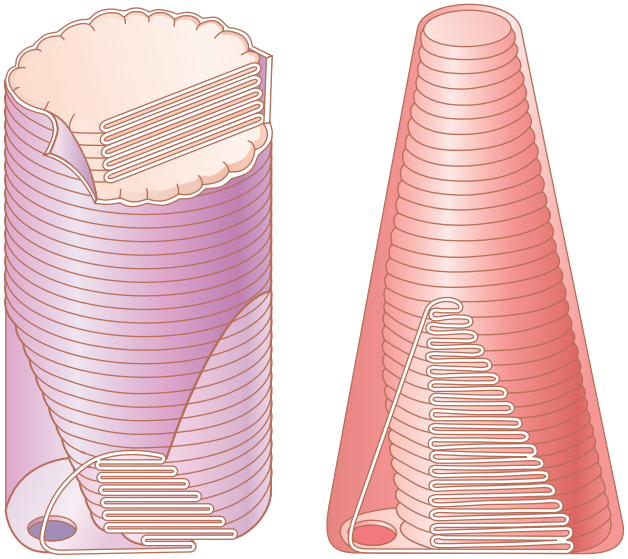

Figure 51.4 Membranous structures of the outer segments of a rod *(left)* and a cone *(right)*. (*Courtesy Dr. Richard Young.*)

Pigment Layer of the Retina. The black pigment *melanin* in the pigment layer prevents light reflection throughout the globe of the eyeball, which is extremely important for clear vision. This pigment performs the same function in the eye as the black coloring inside the bellows of a camera. Without it, light rays would be reflected in all directions in the eyeball and would cause diffuse lighting of the retina rather than the normal contrast between dark and light spots required to form precise images.

The importance of melanin in the pigment layer is well illustrated by its absence in people with *albinism* (congenital absence of melanin pigment in all parts of their bodies). When a person with albinism enters a bright room, light that impinges on the retina is reflected in all directions inside the eyeball by the unpigmented surfaces of the retina and by the underlying sclera, so a single discrete spot of light that would normally excite only a few rods or cones is reflected everywhere and excites many receptors. Therefore, the visual acuity of people with albinism, even with the best optical correction, is seldom better than 20/100 to 20/200 rather than the normal 20/20 values.

The pigment layer also stores large quantities of *vitamin A*. This vitamin A is exchanged back and forth through the cell membranes of the outer segments of the rods and cones, which are embedded in the pigment. We discuss later that vitamin A is an important precursor of the photosensitive chemicals of the rods and cones.

Blood Supply of the Retina—The Central Retinal Artery and the Choroid. The nutrient blood supply for the internal layers of the retina is derived from the central retinal artery, which enters the eyeball through the center of the optic nerve and then divides *to supply the entire inside retinal surface*. Thus, the inner layers of the retina have their own blood supply, independent of the other structures of the eye.

However, the outermost layer of the retina is adherent to the *choroid*, which is also highly vascular and lies between the retina and the sclera. The outer layers of the retina, especially the outer segments of the rods and cones, depend mainly on diffusion from the choroid blood vessels for their nutrition, especially for their oxygen.

Retinal Detachment. The neural retina occasionally *detaches from the pigment epithelium*. In some cases, the cause of such detachment is injury to the eyeball that allows fluid or blood to collect between the neural retina and the pigment epithelium. Detachment is occasionally caused by contracture of fine collagenous fibrils in the vitreous humor, which pull areas of the retina toward the interior of the globe.

Partly because of diffusion across the detachment gap and partly because of the independent blood supply to the neural retina through the retinal artery, the detached retina can resist degeneration for days and can become functional again if it is surgically replaced in its normal relation with the pigment epithelium. If it is not replaced soon, however, the retina will be destroyed and will be unable to function, even after surgical repair.

PHOTOCHEMISTRY OF VISION

Both rods and cones contain chemicals that decompose on exposure to light and, in the process, excite the nerve fibers leading from the eye. The light-sensitive chemical in the *rods* is called *rhodopsin*; the light-sensitive chemicals in the *cones*, called *cone pigments* or *color pigments*, have compositions only slightly different from that of rhodopsin.

In this section, we discuss principally the photochemistry of rhodopsin, but the same principles can be applied to the cone pigments.

RHODOPSIN-RETINAL VISUAL CYCLE AND EXCITATION OF THE RODS

Rhodopsin and Its Decomposition By Light Energy. The outer segment of the rod that projects into the pigment layer of the retina has a concentration of about 40% of the light-sensitive pigment called *rhodopsin*, or *visual purple*. This substance is a combination of the protein *scotopsin* and the carotenoid pigment *retinal* (also called "retinene"). Furthermore, the retinal is a particular type called 11-*cis* retinal. This *cis* form of retinal is important because only this form can bind with scotopsin to synthesize rhodopsin.

When light energy is absorbed by rhodopsin, the rhodopsin begins to decompose within a very small fraction of a second, as shown at the top of **Fig. 51.5**. This rapid decomposition is caused by photoactivation of electrons in the retinal portion of the rhodopsin, which leads to instantaneous change of the *cis* form of retinal into an all-*trans* form that has the same chemical structure as the *cis* form but a different physical structure—it is a straight

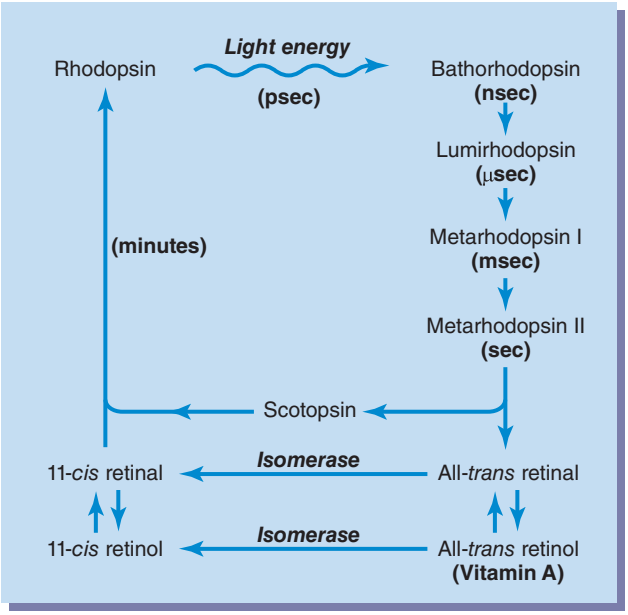

Figure 51.5 The rhodopsin-retinal visual cycle in the rod, showing decomposition of rhodopsin during exposure to light and subsequent slow re-formation of rhodopsin by the chemical processes.

molecule rather than an angulated molecule. Because the three-dimensional orientation of the reactive sites of the all-*trans* retinal no longer fits with the orientation of the reactive sites on the protein *scotopsin*, the all-*trans* retinal begins to pull away from the scotopsin. The immediate product is *bathorhodopsin*, which is a partially split combination of the all-*trans* retinal and scotopsin. Bathorhodopsin is extremely unstable and decays in nanoseconds to *lumirhodopsin*. This product then decays in microseconds to *metarhodopsin I*, then in about a millisecond to *metarhodopsin II*, and finally, much more slowly (in seconds), into the completely split products *scotopsin* and all-*trans* retinal.

It is the metarhodopsin II, also called *activated rhodopsin*, that excites electrical changes in the rods, and the rods then transmit the visual image into the central nervous system in the form of optic nerve action potentials, as we discuss later.

Re-Formation of Rhodopsin. The first stage in rhodopsin re-formation, as shown in **Fig. 51.5**, is to reconvert the all-*trans* retinal into 11-*cis* retinal. This process requires metabolic energy and is catalyzed by the enzyme *retinal isomerase*. Once the 11-*cis* retinal is formed, it automatically recombines with the scotopsin to re-form rhodopsin, which then remains stable until its decomposition is again triggered by absorption of light energy.

Role of Vitamin A for Formation of Rhodopsin. Note in **Fig. 51.5** that there is a second chemical route whereby all-*trans* retinal can be converted into 11-*cis* retinal. This second route is by conversion of the all-*trans* retinal first into all-*trans* retinol, which is one form of vitamin A. Then, the all-*trans* retinol is converted into 11-*cis* retinol under the influence of the enzyme isomerase. Finally, the 11-*cis* retinol is converted into 11-*cis* retinal, which combines with scotopsin to form new rhodopsin.

Vitamin A is present both in the cytoplasm of the rods and in the pigment layer of the retina. Therefore, vitamin A is normally always available to form new retinal when needed. Conversely, when there is excess retinal in the retina, it is converted back into vitamin A, thus reducing the amount of light-sensitive pigment in the retina. We shall see later that this interconversion between retinal and vitamin A is especially important in long-term adaptation of the retina to different light intensities.

Night Blindness Due to Vitamin A Deficiency. Night blindness occurs in persons with severe vitamin A deficiency because, without vitamin A, the amounts of retinal and rhodopsin that can be formed are severely depressed. This condition is called *night blindness* because the amount of light available at night is too little to permit adequate vision in vitamin A–deficient persons.

For night blindness to occur, a person usually must remain on a vitamin A–deficient diet for months, because large quantities of vitamin A are normally stored in the liver and can be made available to the eyes. Once night blindness develops, it can sometimes be reversed in less than 1 hour by intravenous injection of vitamin A.

Excitation of Rods When Rhodopsin Is Activated By Light

Rod Receptors Hyperpolarize in Response to Light. Exposure of the rod to light causes *increased negativity* of the intrarod membrane potential, which is a state of *hyperpolarization*. This is exactly opposite to the decreased negativity (the process of "depolarization") that occurs when most other sensory receptors are activated.

How does activation of rhodopsin cause hyperpolarization? The answer is that when rhodopsin decomposes, it decreases the rod membrane conductance for sodium ions in the outer segment of the rod causing hyperpolarization.

Fig. 51.6 shows movement of sodium and potassium ions in a complete electrical circuit through the inner and outer segments of the rod. The inner segment continually pumps sodium from inside the rod to the outside, and potassium ions are pumped to the inside of the cell. Potassium ions leak out of the cell through nongated potassium channels that are confined to the inner segment of the rod. As in other cells, this sodium-potassium pump creates a negative potential on the inside of the entire cell. However, the outer segment of the rod, where the photoreceptor discs are located, is entirely different. Here, the rod membrane, in the dark state, is leaky to sodium ions that flow through cyclic guanosine monophosphate (cGMP)–gated channels. In the dark state, cGMP levels are high, permitting positively charged sodium ions to continually leak back to the inside of the rod and thereby neutralize much of the negativity on the inside of the

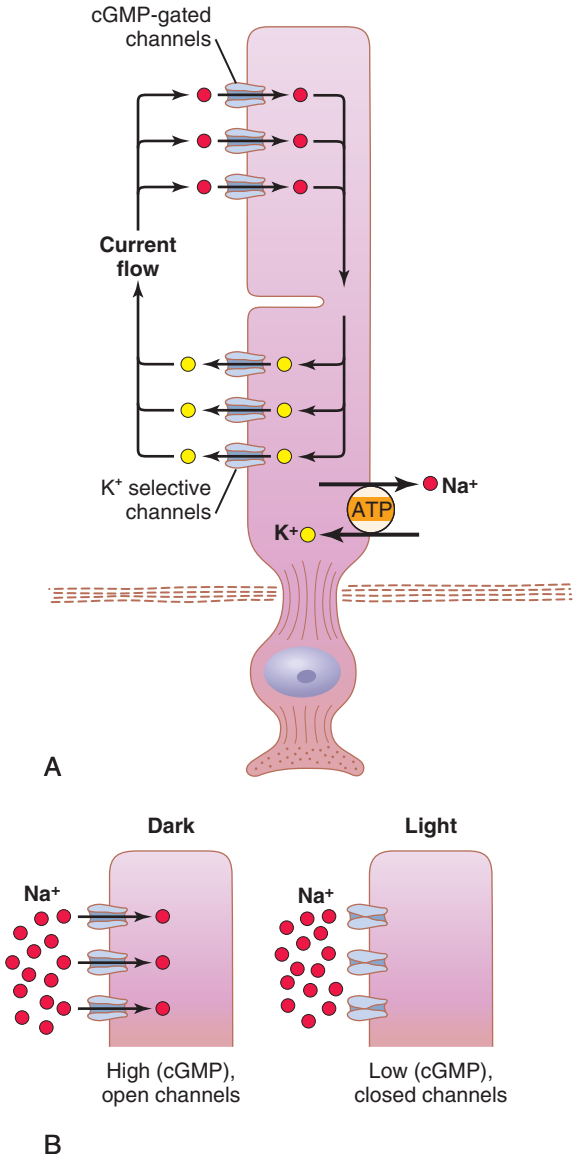

Figure 51.6 (A) Sodium flows into a photoreceptor (e.g., a rod) through cyclic guanosine monophosphate (cGMP)–gated channels. Potassium flows out of the cell through nongated potassium channels. A sodium-potassium pump maintains steady levels of sodium and potassium inside the cell. (B) In the dark, cGMP levels are high, and the sodium channels are open. In the light, cGMP levels are reduced and the sodium channels close, causing the cell to hyperpolarize. *ATP*, Adenosine triphosphate.

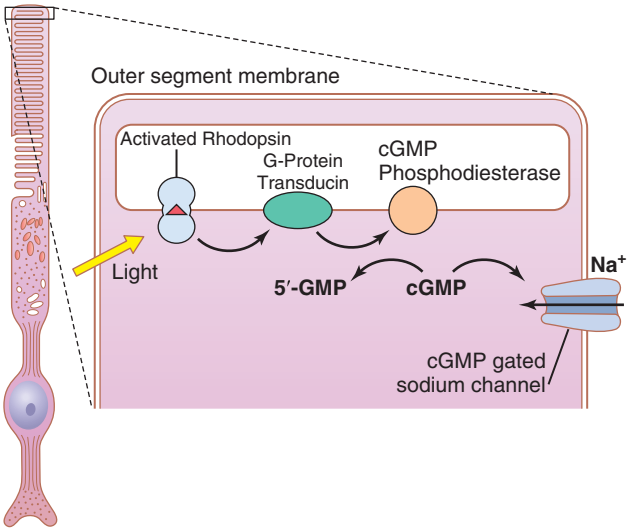

Figure 51.7 Phototransduction in the outer segment of the photoreceptor (rod or cone) membrane. When light hits the photoreceptor (e.g., a rod cell), the light-absorbing retinal portion of rhodopsin is activated to metarhodopsin (activated rhodopsin). This activation stimulates transducin, a G protein, which then activates cyclic guanosine monophosphate (cGMP) phosphodiesterase. This enzyme catalyzes the degradation of cGMP into 5′-GMP. The reduction in cGMP then causes closure of the sodium channels, which, in turn, causes hyperpolarization of the photoreceptor.

entire cell. Thus, under normal dark conditions, when the rod is not excited, there is reduced electronegativity inside the membrane of the rod, measuring about −40 millivolts rather than the usual −70 to −80 millivolts found in most sensory receptors.

When the rhodopsin in the outer segment of the rod is exposed to light, it is activated and begins to decompose. The cGMP-gated sodium channels are then closed, and the outer segment membrane conductance of sodium to the interior of the rod is reduced by a three-step process (**Fig. 51.7**): (1) light is absorbed by the rhodopsin, causing photoactivation of the electrons in the retinal portion, as previously described; (2) the activated rhodopsin stimulates a G protein called *transducin*, which then activates cGMP phosphodiesterase, an enzyme that catalyzes the breakdown of cGMP to 5′-GMP; and (3) the reduction in cGMP closes the cGMP-gated sodium channels and reduces the inward sodium current. Sodium ions continue to be pumped outward through the membrane of the inner segment. Thus, more sodium ions now leave the rod than leak back in. Because they are positive ions, their loss from inside the rod creates increased negativity inside the membrane, and the greater the amount of light energy striking the rod, the greater the electronegativity becomes—that is, the greater is the degree of *hyperpolarization*. At maximum light intensity, the membrane potential approaches −70 to −80 millivolts, which is near the equilibrium potential for potassium ions across the membrane.

Duration of the Receptor Potential, and Logarithmic Relation of the Receptor Potential to Light Intensity. When a sudden pulse of light strikes the retina, the transient hyperpolarization (*receptor potential*) that occurs in the rods reaches a peak in about 0.3 second and lasts for more than 1 second. In cones, the change occurs four times as fast as in the rods. A visual image impinged on the rods of the retina for only one-millionth of a second can sometimes cause the sensation of seeing the image for longer than 1 second.

Another characteristic of the receptor potential is that it is approximately proportional to the logarithm of the light intensity. This characteristic is exceedingly important because it allows the eye to discriminate light intensities through a range many thousand times as great as would be possible otherwise.

Mechanism Whereby Rhodopsin Decomposition Decreases Membrane Sodium Conductance—The Excitation "Cascade." Under optimal conditions, a single photon of light, the smallest possible quantal unit of light energy, can cause a receptor potential of about 1 millivolt in a rod. Only 30 photons of light will cause half-saturation of the rod. How can such a small amount of light cause such great excitation? The answer is that the photoreceptors have an extremely sensitive chemical cascade that amplifies the stimulatory effects about a millionfold, as follows:

1. The *photon activates an electron* in the 11-*cis* retinal portion of the rhodopsin; this activation leads to the formation of *metarhodopsin II*, which is the active form of rhodopsin, as shown in **Fig. 51.5**.
2. The *activated rhodopsin* functions as an enzyme to activate many molecules of *transducin*, a protein present in an inactive form in the membranes of the discs and cell membrane of the rod.
3. The *activated transducin* activates many more molecules of *phosphodiesterase*.
4. *Activated phosphodiesterase* immediately hydrolyzes many molecules of cGMP, thus destroying it. Before being destroyed, the cGMP had been bound with the sodium channel protein of the rod's outer membrane in a way that holds it in the open state. However, in light, hydrolyzation of the cGMP by phosphodiesterase allows the sodium channels to close. Several hundred channels close for each originally activated molecule of rhodopsin. Because the sodium flux through each of these channels has been extremely rapid, flow of more than 1 million sodium ions is blocked by the channel closure before the channel opens again. This diminution of sodium ion flow is what excites the rod, as already discussed.
5. Within about 1 second, another enzyme, *rhodopsin kinase*, which is always present in the rod, inactivates the activated rhodopsin (metarhodopsin II), and the entire cascade reverses back to the normal state with open sodium channels.

Thus, the rods have developed an important chemical cascade that amplifies the effect of a single photon of light to cause movement of millions of sodium ions. This mechanism explains the extreme sensitivity of the rods under dark conditions.

The cones are about 30 to 300 times less sensitive than the rods, but even this degree of sensitivity allows color vision at any intensity of light greater than extremely dim twilight.

Photochemistry of Color Vision By the Cones

We previously pointed out that the photochemicals in the cones have almost exactly the same chemical composition as that of rhodopsin in the rods. The only difference is that the protein portions, or the opsins (called *photopsins* in the cones), are slightly different from the scotopsin of the rods. The *retinal* portion of all the visual pigments is exactly the same in the cones and rods. The color-sensitive pigments of the cones, therefore, are combinations of retinal and photopsins.

Only one of three types of color pigments is present in each of the different cones, thus making the cones selectively sensitive to different colors—blue, green, or red. These color pigments are called, respectively, *blue-sensitive pigment, green-sensitive pigment*, and *red-sensitive pigment*. The pigments in the three types of cones show peak absorbencies at light wavelengths of 445, 535, and 570 nanometers, respectively. These wavelengths are also the wavelengths for peak light sensitivity for each type of cone, which begins to explain how the retina differentiates the colors. The approximate absorption curves for these three pigments are shown in **Fig. 51.8**. Also shown is the absorption curve for the rhodopsin of the rods, with a peak at 505 nanometers.

AUTOMATIC REGULATION OF RETINAL SENSITIVITY—LIGHT AND DARK ADAPTATION

If a person has been in bright light for hours, large portions of the photochemicals in both the rods and the cones will have been reduced to retinal and opsins. Furthermore, much of the retinal of both the rods and the cones will have been converted into vitamin A. Because of these two effects, the concentrations of the photosensitive chemicals remaining in the rods and cones are considerably reduced, and the sensitivity of the eye to light is correspondingly reduced. This process is called *light adaptation*.

Conversely, if a person remains in darkness for a long time, the retinal and opsins in the rods and cones are converted back into the light-sensitive pigments. Furthermore, vitamin A is converted back into retinal to increase

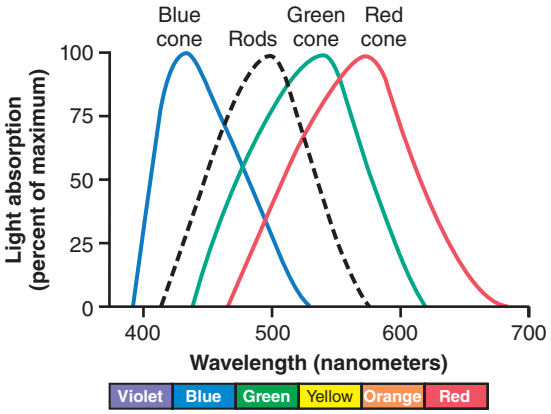

Figure 51.8 Light absorption by the pigment of the rods and by the pigments of the three color-receptive cones of the human retina. *(Data from Marks WB, Dobelle WH, MacNichol EF Jr. Visual pigments of single primate cones.* Science. *1964;143:1181; and Brown PK, Wald G. Visual pigments in single rods and cones of the human retina: direct measurements reveal mechanisms of human night and color vision.* Science. *1964;144:45.)*

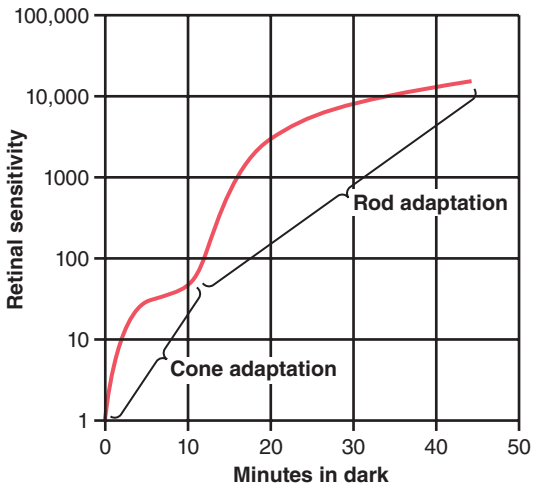

Figure 51.9 Dark adaptation demonstrating the relation of cone adaptation to rod adaptation.

light-sensitive pigments, the final limit being determined by the amount of opsins in the rods and cones to combine with the retinal. This process is called *dark adaptation*.

Fig. 51.9 shows the course of dark adaptation when a person is exposed to total darkness after having been exposed to bright light for several hours. Note that the sensitivity of the retina is very low on first entering the darkness, but within 1 minute, the sensitivity has already increased 10-fold—that is, the retina can respond to light of one-tenth that of the previously required intensity. At the end of 20 minutes, the sensitivity has increased about 6000-fold, and at the end of 40 minutes, it has increased about 25,000-fold.

The resulting curve of **Fig. 51.9** is called the *dark adaptation curve*. Note the inflection in the curve. The early portion of the curve is caused by adaptation of the cones because all the chemical events of vision, including adaptation, occur about four times as rapidly in cones as in rods. However, the cones do not achieve anywhere near the same degree of sensitivity change in darkness as the rods. Therefore, despite rapid adaptation, the cones cease adapting after only a few minutes, whereas the slowly adapting rods continue to adapt for many minutes and even hours, with their sensitivity increasing tremendously. Additional sensitivity of the rods is caused by neuronal signal convergence of 100 or more rods onto a single ganglion cell in the retina; these rods summate to increase their sensitivity, as discussed later in the chapter.

Other Mechanisms of Light and Dark Adaptation. In addition to adaptation caused by changes in concentrations of rhodopsin or color photochemicals, the eye has two other mechanisms for light and dark adaptation. The first is a *change in pupillary size*, as discussed in Chapter 50. This change can cause adaptation of approximately 30-fold within a fraction of a second because of changes in the amount of light allowed through the pupillary opening.

The other mechanism is *neural adaptation*, involving the neurons in the successive stages of the visual chain in the retina and in the brain. That is, when light intensity first increases, the signals transmitted by the bipolar cells, horizontal cells, amacrine cells, and ganglion cells are all intense. However, most of these signals decrease rapidly at different stages of transmission in the neural circuit. Although the degree of adaptation is only a fewfold rather than the many thousandfold that occurs during adaptation of the photochemical system, neural adaptation occurs in a fraction of a second, in contrast to the many minutes to hours required for full adaptation by the photochemicals.

Importance of Light and Dark Adaptation in Vision. Between the limits of maximal dark adaptation and maximal light adaptation, the eye can change its sensitivity to light as much as 500,000 to 1 million times, with the sensitivity automatically adjusting to changes in illumination.

Because registration of images by the retina requires detection of both dark and light spots in the image, it is essential that the sensitivity of the retina always be adjusted so that the receptors respond to the lighter areas but not to the darker areas. An example of maladjustment of retinal adaptation occurs when a person leaves a movie theater and enters the bright sunlight. Then, even the dark spots in the images seem exceedingly bright, and as a consequence, the entire visual image is bleached, with little contrast among its different parts. This poor vision remains until the retina has adapted sufficiently so that the darker areas of the image no longer stimulate the receptors excessively.

Conversely, when a person first enters darkness, the sensitivity of the retina is usually so slight that even the light spots in the image cannot excite the retina. After dark adaptation, the light spots begin to register. As an example of the extremes of light and dark adaptation, the intensity of sunlight is about 10 billion times that of starlight, yet the eye can function in bright sunlight after light adaptation and in starlight after dark adaptation.

COLOR VISION

From the preceding sections, we learned that different cones are sensitive to different colors of light. This section is a discussion of the mechanisms whereby the retina detects the different gradations of color in the visual spectrum.

TRICOLOR MECHANISM OF COLOR DETECTION

All theories of color vision are based on the well-known observation that the human eye can detect almost all gradations of colors when only red, green, and blue monochromatic lights are appropriately mixed in different combinations.

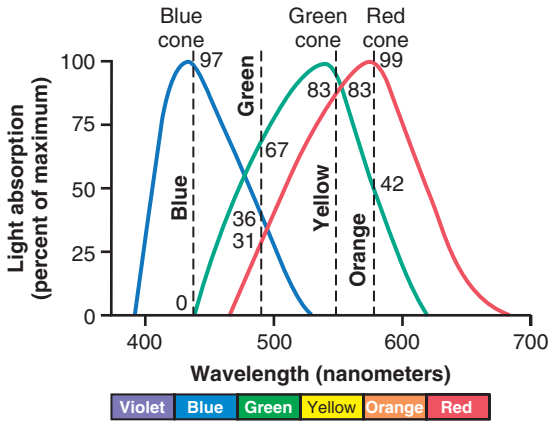

Figure 51.10 Demonstration of the degree of stimulation of the different color-sensitive cones by monochromatic lights of four colors—blue, green, yellow, and orange.

Spectral Sensitivities of the Three Types of Cones. On the basis of color vision tests, the spectral sensitivities of the three types of cones in humans have proved to be essentially the same as the light absorption curves for the three types of pigment found in the cones. These curves are shown in **Fig. 51.8** and slightly differently in **Fig. 51.10**. They can explain most of the phenomena of color vision.

Interpretation of Color in the Nervous System. In **Fig. 51.10**, one can see that an orange monochromatic light with a wavelength of 580 nanometers stimulates the red cones to a value of about 99 (99% of the peak stimulation at optimum wavelength); it stimulates the green cones to a value of about 42, but the blue cones are not stimulated at all. Thus, the ratios of stimulation of the three types of cones in this case are 99:42:0. The nervous system interprets this set of ratios as the sensation of orange. Conversely, a monochromatic blue light with a wavelength of 450 nanometers stimulates the red cones to a stimulus value of 0, the green cones to a value of 0, and the blue cones to a value of 97. This set of ratios—0:0:97—is interpreted by the nervous system as blue. Likewise, ratios of 83:83:0 are interpreted as yellow, and ratios of 31:67:36 are interpreted as green.

Perception of White Light. About equal stimulation of all the red, green, and blue cones gives one the sensation of seeing white. Yet, there is no single wavelength of light corresponding to white; instead, white is a combination of all the wavelengths of the spectrum. Furthermore, the perception of white can be achieved by stimulating the retina with a proper combination of only three chosen colors that stimulate the respective types of cones about equally.

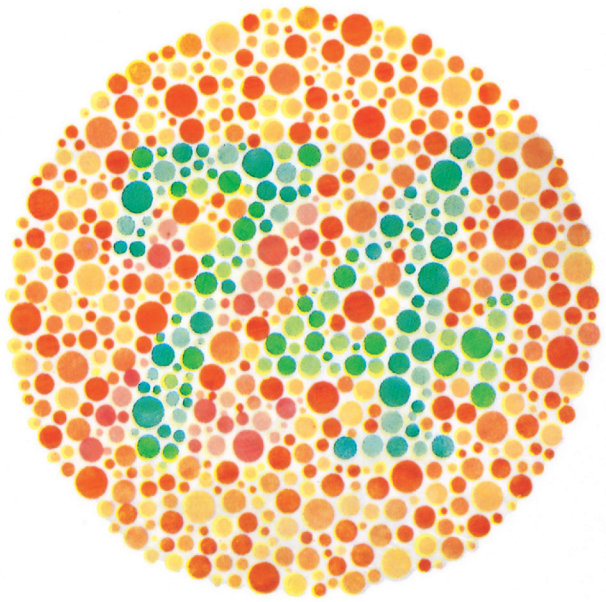
Color Blindness

Red-Green Color Blindness. When a single group of color-receptive cones is missing from the eye, the person is unable to distinguish some colors from others. For example, one can see in **Fig. 51.10** that green, yellow, orange, and red colors, which are the colors between the wavelengths of 525 and 675 nanometers, are normally distinguished from one another by the red and green cones. If either of these two cones is missing, the person cannot use this mechanism for distinguishing these four colors; the person is especially unable to distinguish red from green and is therefore said to have *red-green color blindness*.

Loss of red cones leads to red blindness, which is called *protanopia;* the overall visual spectrum is noticeably shortened at the long wavelength end because of a lack of the red cones. Lack of green cones leads to green blindness and is called a *deuteranopia*, which is not associated with an abnormal visual spectral width because red cones are available to detect the long wavelength red color. However, a person with deuteranopia can distinguish only two or three different hues, whereas somebody with normal vision sees seven unique hues.

Red-green color blindness is a genetic disorder that occurs almost exclusively in males. Genes in the female X chromosome code for the respective cones, and color blindness almost never occurs in females because at least one of the two X chromosomes almost always has a normal gene for each type of cone. Because the male has only one X chromosome, a missing gene can lead to color blindness.

Because the X chromosome in the male is always inherited from the mother, color blindness is passed from mother to son, and the mother is said to be a *color blindness carrier*. About 8% of all women are color blindness carriers.



Blue Weakness. Only rarely are blue cones missing, although sometimes they are underrepresented in a genetically inherited condition called *blue weakness*.

Color Test Charts. A rapid method for determining color blindness is based on the use of spot charts such as those shown in **Fig. 51.11**. These charts are arranged with a mixture of spots of several different colors. In the top chart, a person with normal color vision reads "74," whereas a person with red-green color-blindness reads "21." In the bottom chart, a person with normal color vision reads "42," whereas a person with red-blindness reads "2," and a person with green-blindness reads "4."

NEURAL FUNCTION OF THE RETINA

Fig. 51.12 presents the essentials of the retina's neural connections, showing the circuit in the peripheral retina at the left and the circuit in the foveal retina at the right. The different neuronal cell types are as follows:

1. The photoreceptors—the *rods and cones*—which transmit signals to the outer plexiform layer, where they synapse with bipolar cells and horizontal cells
2. The *horizontal cells*, which transmit signals horizontally in the outer plexiform layer from the rods and cones to bipolar cells
3. The *bipolar cells*, which transmit signals vertically from the rods, cones, and horizontal cells to the inner plexiform layer, where they synapse with ganglion cells and amacrine cells

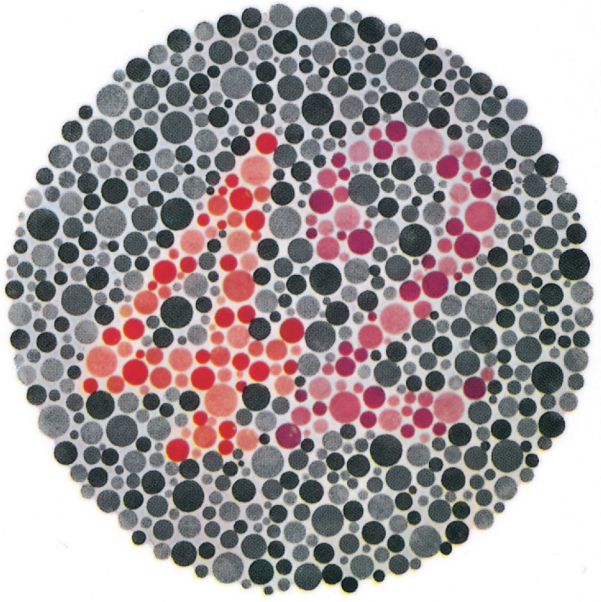


Figure 51.11 Two Ishihara charts. In this chart *(upper panel)*, a person with normal vision reads "74," but a red-green color-blind person reads "21." In this chart *(lower panel)*, a red-blind person (protanope) reads "2," but a green-blind person (deuteranope) reads "4." A person with normal vision reads "42." (From Ishihara S. *Tests for Color-blindness*. Tokyo: Handaya Hongo Harukicho; 1917. Note that tests for color blindness cannot be conducted with this material. For accurate testing, the original plates should be used.)

4. The *amacrine cells*, which transmit signals in two directions, either directly from bipolar cells to ganglion cells or horizontally within the inner plexiform layer from axons of the bipolar cells to dendrites of the ganglion cells or to other amacrine cells
5. The *ganglion cells*, which transmit output signals from the retina through the optic nerve into the brain

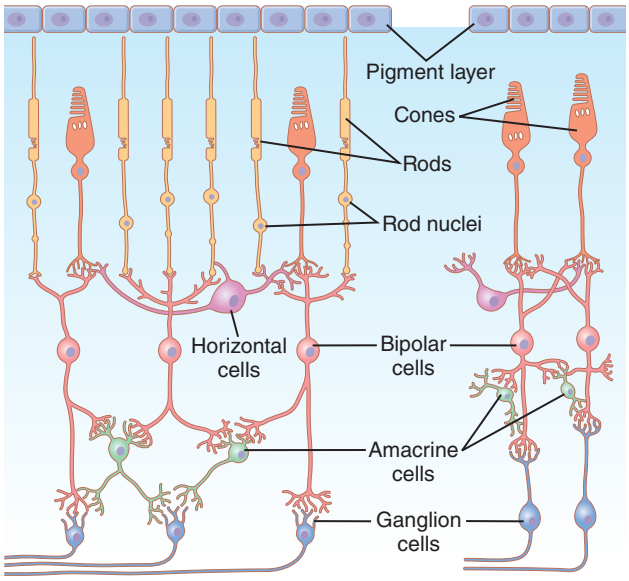

Figure 51.12 Neural organization of the retina, with the peripheral area to the left and the foveal area to the right.

A sixth type of neuronal cell in the retina, which is not very prominent and is not shown in the figure, is the *interplexiform* cell. This type of cell transmits signals in the retrograde direction from the inner plexiform layer to the outer plexiform layer. These signals are inhibitory and are believed to control lateral spread of visual signals by the horizontal cells in the outer plexiform layer. Their role may be to help control the degree of contrast in the visual image.

The Visual Pathway From the Cones to the Ganglion Cells Functions Differently From the Rod Pathway. As is true for many of our other sensory systems, the retina has an old type of vision based on rod vision and a newer type of vision based on cone vision. The neurons and nerve fibers that conduct the visual signals for cone vision are considerably larger than those that conduct the visual signals for rod vision, and the signals are conducted to the brain two to five times as rapidly. Also, the circuitry for the two systems is slightly different.

To the right in **Fig. 51.12** is the visual pathway from the *foveal portion of the retina*, representing the newer, faster cone system. This illustration shows three neurons in the direct pathway: (1) cones; (2) bipolar cells; and (3) ganglion cells. In addition, horizontal cells transmit inhibitory signals laterally in the outer plexiform layer, and amacrine cells transmit signals laterally in the inner plexiform layer.

To the left in **Fig. 51.12** are the neural connections for the peripheral retina, where both rods and cones are present. Three bipolar cells are shown; the middle of these connects only to rods, representing the type of visual system present in many lower animals. The output from the bipolar cell passes only to amacrine cells, which relay the signals to the ganglion cells. Thus, for pure rod vision, there are four neurons in the direct visual pathway: (1) rods; (2) bipolar cells; (3) amacrine cells; and (4) ganglion

cells. In addition, horizontal and amacrine cells provide lateral connectivity.

The other two bipolar cells shown in the peripheral retinal circuitry of **Fig. 51.12** connect with rods and cones; the outputs of these bipolar cells pass both directly to ganglion cells and by way of amacrine cells.

Neurotransmitters Released By Retinal Neurons. Not all the neurotransmitter chemical substances used for synaptic transmission in the retina have been entirely delineated. However, both the rods and the cones release *glutamate* at their synapses with the bipolar cells.

Histological and pharmacological studies have proven the existence of many types of amacrine cells that secrete at least eight types of transmitter substances, including *gamma-aminobutyric acid* (GABA), *glycine, dopamine, acetylcholine*, and *indolamine*, all of which normally function as inhibitory transmitters. The transmitters of the bipolar, horizontal, and interplexiform cells are unclear, but at least some of the horizontal cells release inhibitory transmitters.

Transmission of Most Signals Occurs in the Retinal Neurons By Electrotonic Conduction, Not By Action Potentials. The only retinal neurons that always transmit visual signals via action potentials are the ganglion cells, and they send their signals all the way to the brain through the optic nerve. Occasionally, action potentials have also been recorded in amacrine cells, although the importance of these action potentials is questionable. Otherwise, all the retinal neurons conduct their visual signals by *electrotonic conduction*, not by action potentials.

Electrotonic conduction means direct flow of electric current, not action potentials, in the neuronal cytoplasm and nerve axons from the point of excitation all the way to the output synapses. Even in the rods and cones, conduction from their outer segments to the synaptic bodies is by electrotonic conduction. That is, when hyperpolarization occurs in response to light in the outer segment of a rod or a cone, almost the same degree of hyperpolarization is conducted by direct electric current flow in the cytoplasm all the way to the synaptic body, and no action potential is required. Then, when the transmitter from a rod or cone stimulates a bipolar cell or horizontal cell, once again the signal is transmitted from the input to the output by direct electric current flow, not by action potentials.

The importance of electrotonic conduction is that it allows *graded conduction* of signal strength. Thus, for the rods and cones, the strength of the hyperpolarizing output signal is directly related to the intensity of illumination; the signal is not all or none, as would be the case for action potentials.

Lateral Inhibition to Enhance Visual Contrast—Function of the Horizontal Cells

The horizontal cells, shown in **Fig. 51.12**, connect laterally between the synaptic bodies of the rods and cones and with the dendrites of the bipolar cells. The outputs of the horizontal cells *are always inhibitory*. Therefore, this connection provides the same lateral inhibition that is important in other sensory systems; in this case, lateral inhibition helps to ensure transmission of visual patterns with proper visual contrast. This phenomenon is demonstrated in **Fig. 51.13**, which shows a minute spot of light focused on the retina. The visual pathway from the centralmost area where the light strikes is excited, whereas an area to the side is inhibited. In other words, instead of the excitatory signal spreading widely in the retina because of spreading dendritic and axonal trees in the plexiform layers, transmission through the horizontal cells puts a stop to this spread by providing lateral inhibition in the surrounding areas. This process is essential to allow high visual accuracy in transmitting contrast borders in the visual image.

Some of the amacrine cells probably provide additional lateral inhibition and further enhancement of visual contrast in the inner plexiform layer of the retina as well.

Depolarizing and Hyperpolarizing Bipolar Cells

Two types of bipolar cells provide opposing excitatory and inhibitory signals in the visual pathway: (1) the *depolarizing bipolar cell;* and (2) the *hyperpolarizing bipolar cell*. That is, some bipolar cells depolarize when the rods and cones are excited, and others hyperpolarize.

There are two possible explanations for this difference. One explanation is that the two bipolar cells are of entirely different types, with one responding by depolarizing in response to the glutamate neurotransmitter released by the rods and cones and the other responding by hyperpolarizing. The other possibility is that one of the bipolar cells receives direct excitation from the rods and cones, whereas the other receives its signal indirectly through a horizontal cell. Because the horizontal cell is

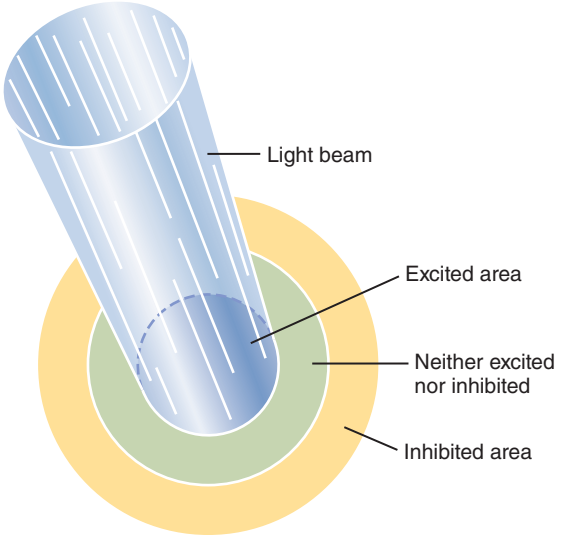

Figure 51.13 Excitation and inhibition of a retinal area caused by a small beam of light, demonstrating the principle of lateral inhibition.

an inhibitory cell, this would reverse the polarity of the electrical response.

Regardless of the mechanism for the two types of bipolar responses, the importance of this phenomenon is that it allows half the bipolar cells to transmit positive signals and the other half to transmit negative signals. We shall see later that both positive and negative signals are used in transmitting visual information to the brain.

Another important aspect of this reciprocal relation between depolarizing and hyperpolarizing bipolar cells is that it provides a second mechanism for lateral inhibition, in addition to the horizontal cell mechanism. Because depolarizing and hyperpolarizing bipolar cells lie immediately against each other, this provides a mechanism for separating contrast borders in the visual image, even when the border lies exactly between two adjacent photoreceptors. In contrast, the horizontal cell mechanism for lateral inhibition operates over a much greater distance.

Amacrine Cells and Their Functions

Amacrine cells are the most structurally and functionally diverse type of neuron in the retina. More than 60 types of amacrine cells have been identified by morphological, histochemical, and molecular methods. The functions of several types of amacrine cells have been characterized, and all of them are different:

- One type of amacrine cell is part of the direct pathway for rod vision—that is, from rod to bipolar cells to amacrine cells to ganglion cells.
- Another type of amacrine cell responds strongly at the onset of a continuing visual signal, but the response dies rapidly.
- Other amacrine cells respond strongly at the offset of visual signals but, again, the response fades quickly.
- Still other amacrine cells respond when a light is turned either on or off, signaling simply a change in illumination, irrespective of direction.
- Another type of amacrine cell responds to movement of a spot across the retina in a specific direction; therefore, these amacrine cells are said to be *directionally sensitive*.

In a sense, many or most amacrine cells are interneurons that help analyze visual signals before they ever leave the retina.

GANGLION CELLS AND OPTIC NERVE FIBERS

Each retina contains about 100 million rods and 3 million cones, yet the number of ganglion cells is only about 1.6 million. Thus, an average of 60 rods and 2 cones converge on each ganglion cell and the optic nerve fiber leading from the ganglion cell to the brain.

However, major differences exist between the peripheral retina and the central retina. As one approaches the fovea, fewer rods and cones converge on each optic fiber, and the rods and cones also become slenderer. These effects progressively increase the acuity of vision in the central retina. In the *central fovea*, there are only slender cones—about 35,000 of them—and no rods. Also, the number of optic nerve fibers leading from this part of the retina is almost exactly equal to the number of cones, as shown at the right in **Fig. 51.12**. This phenomenon explains the high degree of visual acuity in the central retina in comparison with the much poorer acuity peripherally.

Another difference between the peripheral and central portions of the retina is the much greater sensitivity of the peripheral retina to weak light, which occurs partly because rods are 30 to 300 times more sensitive to light than cones. However, this greater sensitivity is further magnified by the fact that as many as 200 rods converge on a single optic nerve fiber in the more peripheral portions of the retina, so signals from the rods summate to give even more intense stimulation of the peripheral ganglion cells and their optic nerve fibers.

Retinal Ganglion Cells and Their Respective Fields

W, X, and Y Cells. Studies in cats described three distinct types of retinal ganglion cells, designated W, X, and Y cells, based on their differences in structure and function.

The W cells transmit signals in their optic nerve fibers at a slow velocity and receive most of their excitation from rods, transmitted via small bipolar cells and amacrine cells. They have broad fields in the peripheral retina, are sensitive for detecting directional movement in the field of vision, and are probably important for crude rod vision under dark conditions.

The X cells have small fields because their dendrites do not spread widely in the retina, and thus the signals of X cells represent discrete retinal locations and transmit fine details of visual images. In addition, because every X cell receives input from at least one cone, X cell transmission is probably responsible for color vision.

The Y cells are the largest of all and transmit signals to the brain at 50 m/sec or faster. Because they have broad dendritic fields, signals are picked up by these cells from widespread retinal areas. The Y cells respond to rapid changes in visual images and apprise the central nervous system almost instantaneously when a new visual event occurs anywhere in the visual field, but they do not specify the location of the event with great accuracy, other than to give clues that make the eyes move toward the exciting vision.

P and M Cells. In primates, a different classification of retinal ganglion cells is used, and as many as 20 types of retinal ganglion cells have been described, each responding to a different feature of the visual scene. Some cells respond best to specific directions of motion or orientations, whereas others respond to fine details, increases or decreases in light, or particular colors. The two general

classes of retinal ganglion cells that have been studied most extensively in primates, including humans, are designated as *magnocellular* (M) and *parvocellular* (P) cells.

The P cells (also known as *beta cells* or, in the central retina, as *midget ganglion cells*) project to the parvocellular (small cells) layer of the *lateral geniculate nucleus* of the thalamus. The M cells (also called *alpha* or *parasol cells*) project to the magnocellular (large cells) layer of the lateral geniculate nucleus, which, in turn, relays information from the optic tract to the visual cortex, as discussed in Chapter 52. The main differences between P and M cells are as follows:

1. The receptive fields for P cells are much smaller than for M cells.
2. P-cell axons conduct impulses much more slowly than do M cells.
3. The responses of P cells to stimuli, especially color stimuli, can be sustained, whereas the responses of M cells are much more transient.
4. The P cells are generally sensitive to the color of a stimulus, whereas M cells are not sensitive to color stimuli.
5. The M cells are much more sensitive than are P cells to low-contrast, black and white stimuli.

The main functions of M and P cells are obvious from their differences: The P cells are highly sensitive to visual signals that relate to fine details and to different colors but are relatively insensitive to low-contrast signals. The M cells are highly sensitive to low-contrast stimuli and to rapid movement visual signals.

A third type of photosensitive retinal ganglion cell has been described that contains its own photopigment, *melanopsin*. Much less is known about this cell type, but these cells appear to send signals mainly to nonvisual areas of the brain, particularly the suprachiasmatic nucleus of the hypothalamus, the master circadian pacemaker. Presumably, these signals help control circadian rhythms that synchronize physiological changes with night and day.

EXCITATION OF THE GANGLION CELLS

Spontaneous, Continuous Action Potentials in the Ganglion Cells. It is from the ganglion cells that the long fibers of the optic nerve lead into the brain. Because of the distance involved, the electrotonic method of conduction employed in the rods, cones, and bipolar cells in the retina is no longer appropriate; therefore, ganglion cells transmit their signals by means of repetitive action potentials instead. Furthermore, even when unstimulated, they still transmit continuous impulses at rates varying between 5 and 40 per second. The visual signals, in turn, are superimposed onto this background ganglion cell firing.

Transmission of Changes in Light Intensity—The On-Off Response. As noted previously, many ganglion cells are specifically excited by *changes* in light intensity, demonstrated by the records of nerve impulses in **Fig. 51.14**.

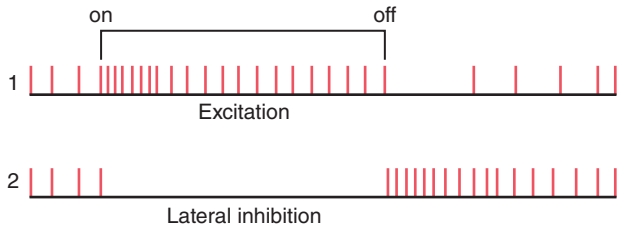

Figure 51.14 Responses of a ganglion cell to light in (1) an area excited by a spot of light and (2) an area adjacent to the excited spot. The ganglion cell in this area is inhibited by the mechanism of *lateral inhibition*. *(Modified from Granit R.* Receptors and Sensory Perception: A Discussion of Aims, Means, and Results of Electrophysiological Research Into the Process of Reception. *New Haven, CT: Yale University Press; 1955.)*

The upper panel shows rapid impulses for a fraction of a second when a light is first turned on, but these impulses decrease rapidly in the next fraction of a second. The lower tracing is from a ganglion cell located laterally to the spot of light; this cell is markedly inhibited when the light is turned on because of lateral inhibition. Then, when the light is turned off, opposite effects occur. The opposite directions of these responses to light are caused, respectively, by the depolarizing and hyperpolarizing bipolar cells, and the transient nature of the responses is probably at least partly generated by the amacrine cells, many of which have similar transient responses themselves.

This capability of the eyes to detect *changes* in light intensity is strongly developed in the peripheral retina and the central retina. For example, a minute gnat flying across the field of vision is instantaneously detected. Conversely, the same gnat sitting quietly may remain below the threshold of visual detection.

Transmission of Signals Depicting Contrasts in the Visual Scene—The Role of Lateral Inhibition

Many ganglion cells respond mainly to contrast borders in the scene, which seems to be the major means whereby the pattern of a scene is transmitted to the brain. When flat light is applied to the entire retina and all the photoreceptors are stimulated equally by the incident light, the contrast type of ganglion cell is neither stimulated nor inhibited. The reason for this is that signals transmitted *directly* from the photoreceptors through depolarizing bipolar cells are excitatory, whereas the signals transmitted *laterally* through hyperpolarizing bipolar cells, as well as through horizontal cells, are mainly inhibitory. Thus, the direct excitatory signal through one pathway is likely to be neutralized by inhibitory signals through lateral pathways. One circuit for this process is demonstrated in **Fig. 51.15**, which shows three photoreceptors at the top of the illustration. The central receptor excites a depolarizing bipolar cell. The two receptors on each side are connected to the same bipolar cell through inhibitory horizontal cells that neutralize the direct excitatory signal if all three receptors are stimulated simultaneously by light.

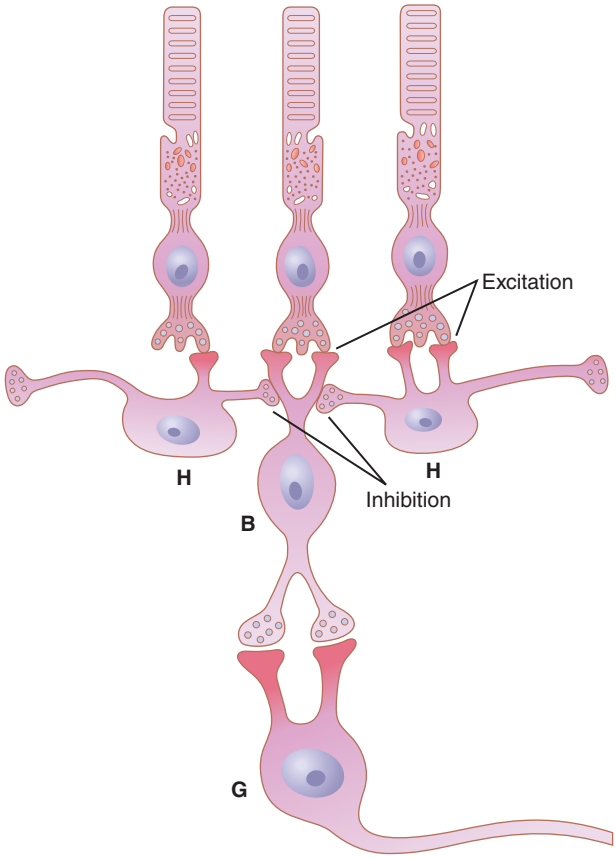

Figure 51.15 Typical arrangement of rods, horizontal cells (H), a bipolar cell (B), and a ganglion cell (G) in the retina, showing excitation at the synapses between the rods and the bipolar cell and horizontal cells but inhibition from the horizontal cells to the bipolar cell.

Now, let us examine what happens when a contrast border occurs in the visual scene. Referring again to **Fig. 51.15**, assume that the central photoreceptor is stimulated by a bright spot of light while one of the two lateral receptors is in the dark. The bright spot of light excites the direct pathway through the bipolar cell. The fact that one of the lateral photoreceptors is in the dark causes one of the horizontal cells to remain unstimulated. Therefore, this cell does not inhibit the bipolar cell, which allows extra excitation of the bipolar cell. Thus, where visual contrasts occur, the signals through the direct and lateral pathways accentuate one another.

In summary, the mechanism of lateral inhibition functions in the eye in the same way that it functions in most other sensory systems—to provide contrast detection and enhancement.

Transmission of Color Signals By the Ganglion Cells

A single ganglion cell may be stimulated by several or only a few cones. When all three types of cones—the red, blue, and green types—stimulate the same ganglion cell, the signal transmitted through the ganglion cell is the same for any color of the spectrum. Therefore, the signal from the ganglion cell plays no role in the detection of different colors. Instead, it is a "white" signal.

Conversely, some of the ganglion cells are excited by only one color type of cone but are inhibited by a second type. For example, this mechanism frequently occurs for the red and green cones, with red causing excitation and green causing inhibition, or vice versa.

The same type of reciprocal effect occurs between blue cones on the one hand and a combination of red and green cones (both of which are excited by yellow) on the other hand, giving a reciprocal excitation-inhibition relation between the blue and yellow colors.

The mechanism of this opposing effect of colors is as follows. One color type of cone excites the ganglion cell by the direct excitatory route through a depolarizing bipolar cell, whereas the other color type inhibits the ganglion cell by the indirect inhibitory route through a hyperpolarizing bipolar cell.

The importance of these color contrast mechanisms is that they represent a means whereby the retina begins to differentiate colors. Thus, each color contrast type of ganglion cell is excited by one color but inhibited by the "opponent" color. Therefore, color analysis begins in the retina and is not entirely a function of the brain.

The Eye: III. Central Neurophysiology of Vision

VISUAL PATHWAYS

Fig. 52.1 shows the principal visual pathways from the two retinas to the *visual cortex*. The visual nerve signals leave the retinas through the *optic nerves*. At the *optic chiasm*, the optic nerve fibers from the nasal halves of the retinas cross to the opposite sides, where they join the fibers from the opposite temporal retinas to form the *optic tracts*. The fibers of each optic tract then synapse in the *dorsal lateral geniculate nucleus* of the thalamus and, from there, *geniculocalcarine fibers* pass via the *optic radiation* (also called the *geniculocalcarine tract*) to the *primary visual cortex* in the *calcarine fissure* area of the medial occipital lobe.

Visual fibers also pass to several older areas of the brain: (1) from the optic tracts to the *suprachiasmatic nucleus of the hypothalamus*, presumably to control circadian rhythms that synchronize various physiological changes of the body with night and day; (2) into the *pretectal nuclei* in the midbrain to elicit reflex movements of the eyes to focus on objects of importance and activate the pupillary light reflex; (3) into the *superior colliculus* to control rapid directional movements of the two eyes; and (4) into the *ventral lateral geniculate nucleus* of the thalamus and surrounding basal regions of the brain, presumably to help control some of the body's behavioral functions.

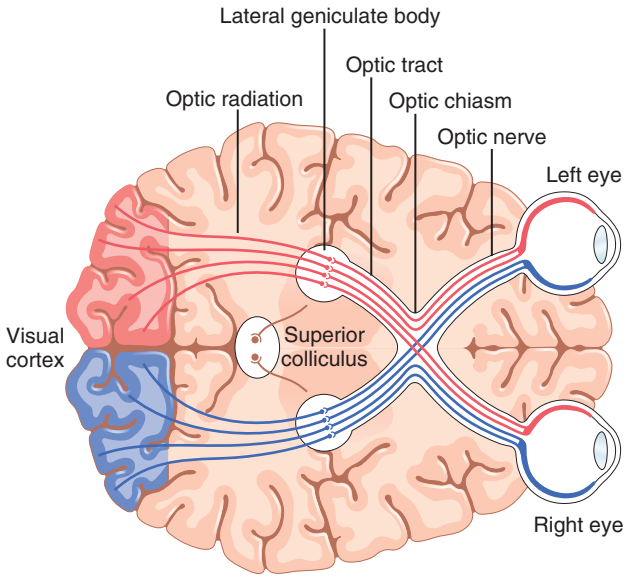

Figure 52.1 Principal visual pathways from the eyes to the visual cortex.

Thus, the visual pathways can be divided roughly into an *old system* to the midbrain and base of the forebrain and a *new system* for direct transmission of visual signals into the visual cortex located in the occipital lobes. In humans, the new system is responsible for perception of virtually all aspects of visual form, colors, and other conscious vision. In many primitive animals, however, even visual form is detected by the older system, using the superior colliculus in the same manner that the visual cortex is used in mammals.

FUNCTION OF THE DORSAL LATERAL GENICULATE NUCLEUS OF THE THALAMUS

The optic nerve fibers of the new visual system terminate in the *dorsal lateral geniculate nucleus*, located at the dorsal end of the thalamus and also called the *lateral geniculate body*, as shown in **Fig. 52.1**. The dorsal lateral geniculate nucleus serves two principal functions. First, it relays visual information from the optic tract to the *visual cortex* by way of the *optic radiation*. This relay function is so accurate that there is exact point to point transmission with a high degree of spatial fidelity all the way from the retina to the visual cortex.

After passing the optic chiasm, half the fibers in each optic tract are derived from one eye and half are derived from the other eye, representing corresponding points on the two retinas. However, the signals from the two eyes are kept apart in the dorsal lateral geniculate nucleus. This nucleus is composed of six nuclear layers. Layers II, III, and V (from ventral to dorsal) receive signals from the lateral half of the ipsilateral retina, whereas layers I, IV, and VI receive signals from the medial half of the retina of the opposite eye. The respective retinal areas of the two eyes connect with neurons that are superimposed over one another in the paired layers, and similar parallel transmission is preserved all the way to the visual cortex.

The second major function of the dorsal lateral geniculate nucleus is to "gate" the transmission of signals to the visual cortex—that is, to control how much of the signal is

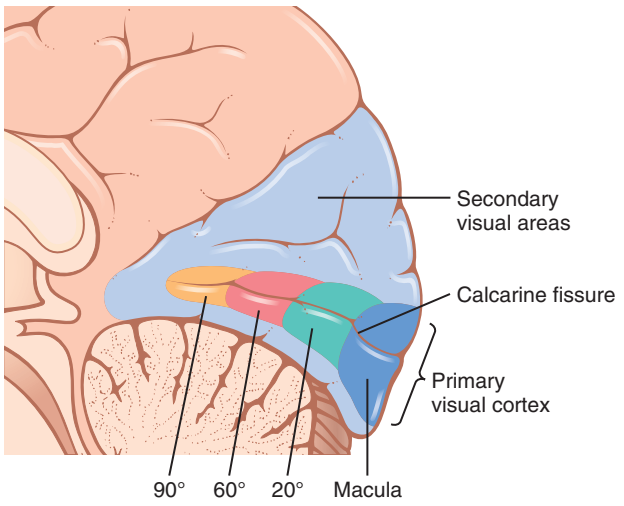

Figure 52.2 The visual cortex in the *calcarine fissure area* of the *medial* occipital cortex.

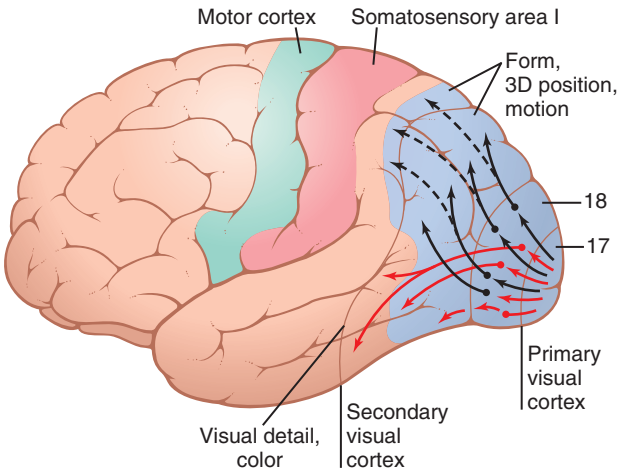

Figure 52.3 Transmission of visual signals from the primary visual cortex into secondary visual areas on the lateral surfaces of the occipital and parietal cortices. Note that the signals representing form, third-dimensional (3D) position, and motion are transmitted mainly into the superior portions of the occipital lobe and posterior portions of the parietal lobe. By contrast, the signals for visual detail and color are transmitted mainly into the anteroventral portion of the occipital lobe and the ventral portion of the posterior temporal lobe.

allowed to pass to the cortex. The nucleus receives gating control signals from two major sources: (1) *corticofugal fibers* returning in a backward direction from the primary visual cortex to the lateral geniculate nucleus; and (2) *reticular areas of the mesencephalon*. Both of these sources are inhibitory and, when stimulated, can turn off transmission through selected portions of the dorsal lateral geniculate nucleus. Both of these gating circuits help highlight the visual information that is allowed to pass.

Finally, the dorsal lateral geniculate nucleus is divided in another way:

1. Layers I and II are called *magnocellular layers* because they contain large neurons. These neurons receive their input almost entirely from the large *type M retinal ganglion cells*. This magnocellular system provides a *rapidly conducting* pathway to the visual cortex. However, this system is color blind, transmitting only black-and-white information. Also, its point to point transmission is poor because there are not many M ganglion cells, and their dendrites spread widely in the retina.
2. Layers III through VI are called *parvocellular layers* because they contain large numbers of small to medium-sized neurons. These neurons receive their input almost entirely from the *type P retinal ganglion cells* that transmit color and convey accurate point to point spatial information, but at only a moderate velocity of conduction rather than at high velocity.

ORGANIZATION AND FUNCTION OF THE VISUAL CORTEX

Figs. 52.2 and 52.3 show the *visual cortex*, which is located primarily on the medial aspect of the occipital lobes. Like the cortical representations of the other sensory systems, the visual cortex is divided into a *primary visual cortex* and *secondary visual areas*.

Primary Visual Cortex. The primary visual cortex (see **Fig. 52.2**) lies in the *calcarine fissure area*, extending forward from the *occipital pole* on the *medial* aspect of each occipital cortex. This area is the terminus of direct visual signals from the eyes. Signals from the macular area of the retina terminate near the occipital pole, as shown in **Fig. 52.2**, whereas signals from the more peripheral retina terminate in concentric half-circles anterior to the pole but still along the calcarine fissure on the medial occipital lobe. The upper portion of the retina is represented superiorly, and the lower portion is represented inferiorly.

Note in the figure the large area that represents the macula. It is to this region that the retinal fovea transmits its signals. The fovea is responsible for the highest degree of visual acuity. Based on retinal area, the fovea has several hundred times as much representation in the primary visual cortex as do the most peripheral portions of the retina.

The primary visual cortex is also called *visual area I* or the *striate cortex* because this area has a grossly striated appearance.

Secondary Visual Areas of the Cortex. The secondary visual areas, also called *visual association areas*, lie lateral, anterior, superior, and inferior to the primary visual cortex. Most of these areas also fold outward over the lateral surfaces of the occipital and parietal cortex, as shown in **Fig. 52.3**. Secondary signals are transmitted to these areas for analysis of visual meanings. For example, on all sides of the primary visual cortex is *Brodmann area 18* (see **Fig. 52.3**), which is where virtually all signals from the primary visual cortex pass next. Therefore, Brodmann area 18 is called *visual area II*, or simply V-2. The other, more distant secondary visual areas have specific

designations—V-3, V-4, and so forth—up to more than a dozen areas. The importance of all these areas is that various aspects of the visual image are progressively dissected and analyzed.

The Primary Visual Cortex Has Six Major Layers

Like almost all other portions of the cerebral cortex, the primary visual cortex has six distinct layers, as shown in **Fig. 52.4**. Also, as is true for the other sensory systems, the geniculocalcarine fibers terminate mainly in layer IV, but this layer is also organized into subdivisions. The rapidly conducted signals from the M retinal ganglion cells terminate in layer IVcα, and from there they are relayed vertically, both outward toward the cortical surface and inward toward deeper levels.

The visual signals from the medium-sized optic nerve fibers, derived from the P ganglion cells in the retina, also terminate in layer IV, but at points different from the M signals. They terminate in layers IVa and IVcβ, the shallowest and deepest portions of layer IV, shown to the right in **Fig. 52.4**. From there, these signals are transmitted vertically both toward the surface of the cortex and to deeper layers. It is these P ganglion pathways that transmit the accurate point to point type of vision, as well as color vision.

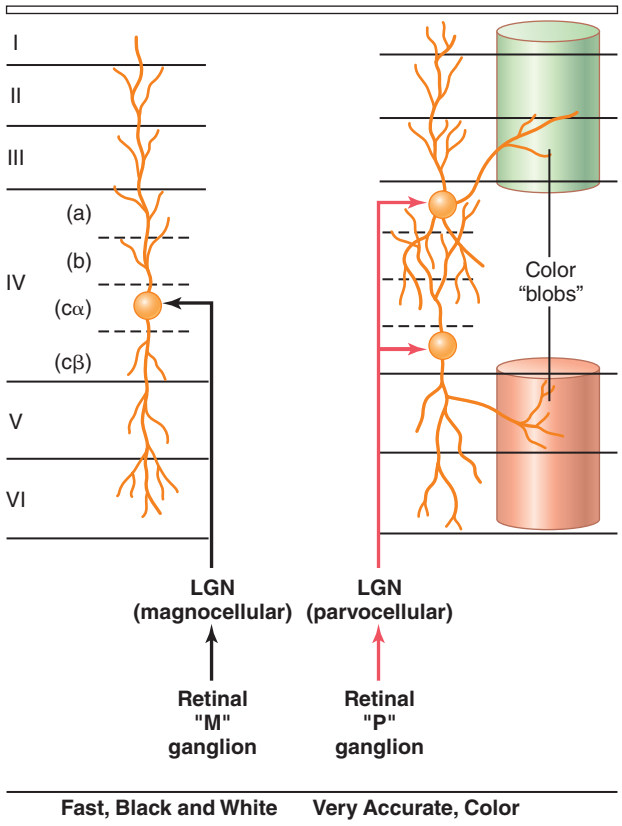

Figure 52.4 Six layers of the primary visual cortex. The connections shown on the left side of the figure originate in the magnocellular layers of the lateral geniculate nucleus (LGN) and transmit rapidly changing black-and-white visual signals. The pathways to the right originate in the parvocellular layers (layers III–VI) of the LGN; they transmit signals that depict accurate spatial detail, as well as color. Note especially the areas of the visual cortex called *color blobs*, which are necessary for detection of color.

Vertical Neuronal Columns in the Visual Cortex. The visual cortex is organized structurally into several million vertical columns of neuronal cells, with each column having a diameter of 30 to 50 micrometers. The same vertical columnar organization is found throughout the cerebral cortex for the other senses, as well as in the motor and analytical cortical regions. Each column represents a functional unit. One can roughly calculate that each of the visual vertical columns has perhaps 1000 or more neurons.

After the optic signals terminate in layer IV, they are further processed as they spread outward and inward along each vertical column unit. This processing is believed to decipher separate bits of visual information at successive stations along the pathway. The signals that pass outward to layers I, II, and III eventually transmit signals for short distances laterally in the cortex. The signals that pass inward to layers V and VI excite neurons that transmit signals over much greater distances.

"Color Blobs" in the Visual Cortex. Interspersed among the primary visual columns, as well as among the columns of some of the secondary visual areas, are special column-like areas called *color blobs*. They receive lateral signals from adjacent visual columns and are activated specifically by color signals. Therefore, these blobs are presumably the primary areas for deciphering color.

Interaction of Visual Signals From the Two Separate Eyes. Recall that visual signals from the two separate eyes are relayed through separate neuronal layers in the lateral geniculate nucleus. These signals remain separated from each other when they arrive in layer IV of the primary visual cortex. In fact, layer IV is interlaced with stripes of neuronal columns, with each stripe about 0.5 millimeter wide; the signals from one eye enter the columns of every other stripe, alternating with signals from the second eye. This cortical area deciphers whether the respective areas of the two visual images from the two separate eyes are "in register" with each other—that is, whether corresponding points from the two retinas fit with each other. In turn, the deciphered information is used to adjust the directional gaze of the separate eyes so that they will fuse with each other (i.e., be brought into "register"). The information observed about degree of register of images from the two eyes also allows a person to distinguish the distance of objects by the mechanism called *stereopsis*, as discussed later.

Two Major Pathways for Analysis of Visual Information: (1) The Fast "Position" and "Motion" Pathway and (2) the Accurate Color Pathway. **Fig. 52.3** shows that after leaving the primary visual cortex, the visual information is analyzed in two major pathways in the secondary visual areas.

1. **Analysis of Third-Dimensional Position, Gross Form, and Motion of Objects**. One of the analytical pathways, demonstrated in **Fig. 52.3** by the black arrows, analyzes the third-dimensional positions of visual objects in the space around the body. This pathway also analyzes the gross physical form of the visual scene, as well as motion in the scene. This pathway reveals where every object is during each instant and whether it is moving. After leaving the primary visual cortex, the signals flow generally into the *posterior midtemporal area* and upward into the broad *occipitoparietal cortex*. At the anterior border of the parietal cortex, the signals overlap with signals from the posterior somatic association areas that analyze three-dimensional aspects of somatosensory signals. The signals transmitted in this *position-form-motion* pathway are mainly from the large M optic nerve fibers of the retinal M ganglion cells, transmitting rapid signals but depicting only black and white with no color.
2. **Analysis of Visual Detail and Color**. The red arrows in **Fig. 52.3**, passing from the primary visual cortex into secondary visual areas of the *inferior, ventral*, and *medial regions* of the *occipital* and *temporal cortex*, show the principal pathway for analysis of visual detail. Separate portions of this pathway specifically dissect out color as well. Therefore, this pathway is concerned with such visual feats as recognizing letters, reading, determining the texture of surfaces, determining detailed colors of objects, and deciphering from all this information what the object is and what it means.

NEURONAL PATTERNS OF STIMULATION DURING ANALYSIS OF VISUAL IMAGES

Analysis of Contrasts in Visual Images. If a person looks at a blank wall, only a few neurons in the primary visual cortex will be stimulated, regardless of whether the illumination of the wall is bright or weak. Therefore, what does the primary visual cortex detect? To answer this question, let us now place on the wall a large solid cross, as shown to the left in **Fig. 52.5**. To the right is shown the spatial pattern of the most excited neurons in the visual cortex. *Note that the areas of maximum excitation occur along the sharp borders of the visual pattern*. Thus, the visual signal in the primary visual cortex is concerned mainly with *contrasts* in the visual scene, rather than with noncontrasting areas. We noted in Chapter 51 that this is also true of most of the retinal ganglion cells because equally stimulated adjacent retinal receptors mutually inhibit one another. However, at any border in the visual scene where there is a change from dark to light or light to dark, mutual inhibition does not occur, and the intensity of stimulation of most neurons is proportional to the *gradient of contrast*. The greater the sharpness of contrast and the greater the intensity difference between light and dark areas, the greater the degree of stimulation.

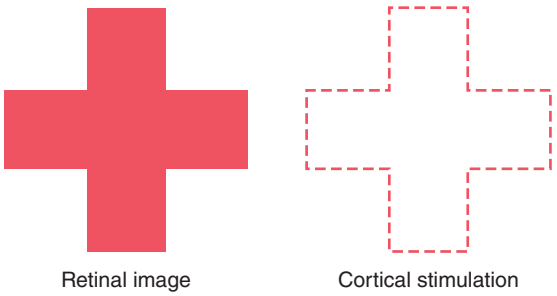

Figure 52.5 Pattern of excitation that occurs in the visual cortex in response to a retinal image of a dak cross.

Visual Cortex Also Detects Orientation of Lines and Borders—"Simple" Cells. The visual cortex detects not only the existence of lines and borders in the different areas of the retinal image but also the direction of orientation of each line or border—that is, whether it is vertical or horizontal or lies at some degree of inclination. This capability is believed to result from linear organizations of mutually inhibiting cells that excite second-order neurons when inhibition occurs all along a line of cells where there is a contrast edge. Thus, for each such orientation of a line, specific neuronal cells are stimulated. A line oriented in a different direction excites a different set of cells. These neuronal cells are called *simple cells*. They are found mainly in layer IV of the primary visual cortex.

"Complex" Cells Detect Line Orientation When a Line Is Displaced Laterally or Vertically in the Visual Field. As the visual signal progresses farther away from layer IV, some neurons respond to lines that are oriented in the same direction but are not position-specific. That is, even if a line is displaced moderate distances laterally or vertically in the field, the same few neurons will still be stimulated if the line has the same direction. These cells are called *complex cells*.

Detection of Lines of Specific Lengths, Angles, or Other Shapes. Some neurons in the outer layers of the primary visual columns, as well as neurons in some secondary visual areas, are stimulated only by lines or borders of specific lengths, by specific angulated shapes, or by images that have other characteristics. That is, these neurons detect still higher orders of information from the visual scene. Thus, as one goes farther into the analytical pathway of the visual cortex, progressively more characteristics of each visual scene are deciphered.

DETECTION OF COLOR

Color is detected in much the same way that lines are detected—by means of color contrast. For example, a red area is often contrasted against a green area, a blue area against a red area, or a green area against a yellow

area. All these colors can also be contrasted against a white area within the visual scene. In fact, this contrasting against white is believed to be mainly responsible for the phenomenon called "color constancy"—that is, when the color of an illuminating light changes, the color of the "white" changes with the light, and appropriate computation in the brain allows red to be interpreted as red, even though the illuminating light has changed the color entering the eyes.

The mechanism of color contrast analysis depends on the fact that contrasting colors, called "opponent colors," excite specific neuronal cells. It is presumed that the initial details of color contrast are detected by simple cells, whereas more complex contrasts are detected by complex and hypercomplex cells.

Effect of Removing the Primary Visual Cortex

Removal of the primary visual cortex in the human being causes loss of conscious vision—that is, blindness. However, psychological studies demonstrate that such "blind" people can still, at times, react subconsciously to changes in light intensity, to movement in the visual scene or, rarely, even to some gross patterns of vision. These reactions include turning the eyes, turning the head, and avoidance. This vision is believed to be subserved by neuronal pathways that pass from the optic tracts mainly into the superior colliculi and other portions of the older visual system.

Fields of Vision; Perimetry

The *field of vision* is the visual area seen by an eye at a given instant. The area seen to the nasal side is called the *nasal field of vision*, and the area seen to the lateral side is called the *temporal field of vision*.

To diagnose blindness in specific portions of the retina, one charts the field of vision for each eye by a process called *perimetry*. This charting is performed by having the subject look with one eye toward a central spot directly in front of the eye; the other eye is closed. A small dot of light or a small object is then moved back and forth in all areas of the field of vision, and the subject indicates when the spot of light or object can and cannot be seen. The field of vision for the left eye is plotted as shown in **Fig. 52.6**. In all perimetry charts, a *blind spot* caused by lack of rods and cones in the retina over the *optic disc* is found about 15 degrees lateral to the central point of vision, as shown in the figure.

Abnormalities in the Fields of Vision. Occasionally, blind spots are found in portions of the field of vision other than the optic disc area. Such blind spots, called *scotomata*, are frequently caused by damage to the optic nerve resulting from glaucoma (excessive fluid pressure in the eyeball), allergic reactions in the retina, or toxic conditions such as lead poisoning or excessive use of tobacco.

Another condition that can be diagnosed by perimetry is *retinitis pigmentosa*. In this disease, portions of the retina degenerate, and excessive melanin pigment is deposited in the degenerated areas. Retinitis pigmentosa usually causes blindness in the peripheral field of vision first and then gradually encroaches on the central areas.

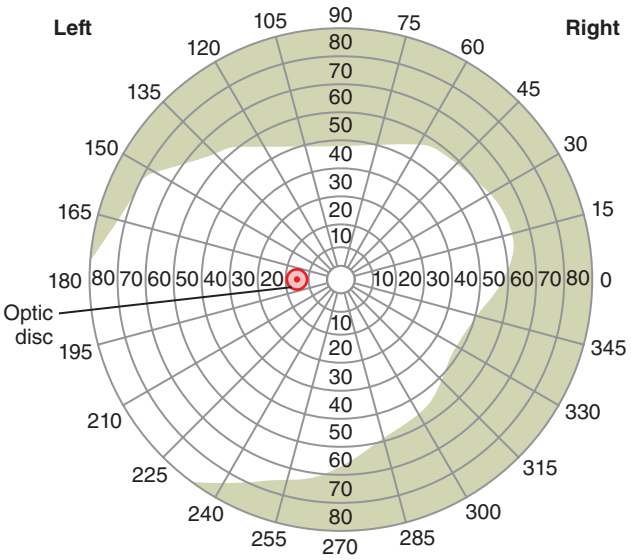

Figure 52.6 Perimetry chart showing the field of vision for the left eye. The *red circle* shows the blind spot.

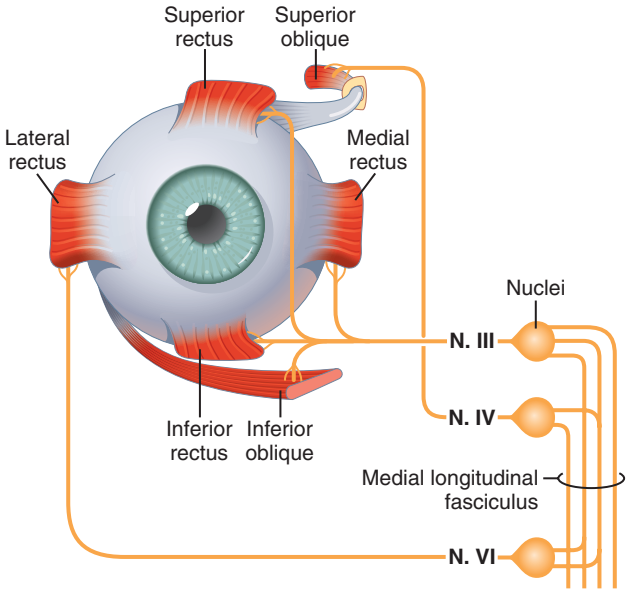

Figure 52.7 Anterior view of the right eye showing extraocular muscles of the eye and their innervation. *N.*, Nerve.

EYE MOVEMENTS AND THEIR CONTROL

Full use of the visual abilities of the eyes also requires the cerebral control system for directing the eyes toward the object to be viewed.

Muscular Control of Eye Movements. Eye movements are controlled by three pairs of muscles, shown in **Fig. 52.7**: (1) the *medial* and *lateral recti;* (2) the *superior* and *inferior recti;* and (3) the *superior* and *inferior obliques*. The medial and lateral recti contract to move the eyes from side to side. The superior and inferior recti contract to move the eyes upward or downward. The oblique muscles function mainly to rotate the eyeballs to keep the visual fields in the upright position.

Neural Pathways for Control of Eye Movements. Fig. 52.7 also shows brain stem nuclei for the third, fourth, and sixth cranial nerves and their connections with the peripheral nerves to the ocular muscles. Also shown are interconnections among the brain stem nuclei via the nerve tract called the *medial longitudinal fasciculus*. Each of the three sets of muscles to each eye is *reciprocally innervated* so that one muscle of the pair relaxes while the other contracts.

Fig. 52.8 illustrates cortical control of the oculomotor apparatus, showing spread of signals from visual areas in the occipital cortex through occipitotectal and occipitocollicular tracts to the pretectal and superior colliculus areas of the brain stem. From both the pretectal and the superior colliculus areas, the oculomotor control signals pass to the brain stem nuclei of the oculomotor nerves. Strong signals are also transmitted from the body's equilibrium control centers in the brain stem (the vestibular nuclei) into the oculomotor system via the medial longitudinal fasciculus.

FIXATION MOVEMENTS OF THE EYES

Perhaps the most important movements of the eyes are those that cause the eyes to "fix" on a discrete portion of the field of vision. Fixation movements are controlled by two neuronal mechanisms. The first of these mechanisms, called the *voluntary fixation mechanism*, allows a person to move the eyes voluntarily to find the object on which to fix the vision. The second is the *involuntary fixation mechanism* that holds the eyes firmly on the object once it has been found.

The voluntary fixation movements are controlled by a cortical field located bilaterally in the premotor cortical regions of the frontal lobes, as shown in Fig. 52.8. Bilateral dysfunction or destruction of these areas makes it difficult for a person to "unlock" the eyes from one point of fixation and move them to another point. It is usually necessary to blink the eyes or put a hand over the eyes for a short time, which then allows the eyes to be moved.

The involuntary fixation mechanism that causes the eyes to "lock" on the object of attention once it is found is controlled by *secondary visual areas in the occipital cortex*, located mainly anterior to the primary visual cortex. When this fixation area is destroyed bilaterally in an animal, the animal has difficulty keeping its eyes directed toward a given fixation point or may become unable to do so.

To summarize, posterior "involuntary" occipital cortical eye fields automatically "lock" the eyes on a given spot of the visual field and thereby prevent movement of the image across the retinas. To unlock this visual fixation,

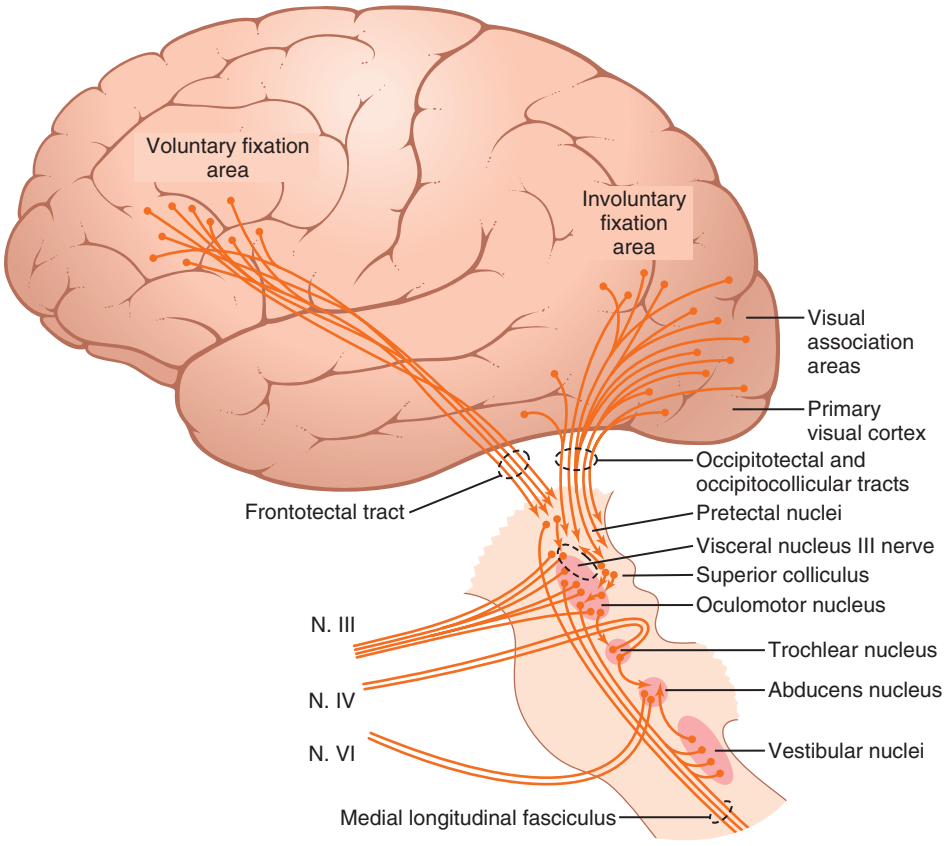

Figure 52.8 Neural pathways for control of conjugate movement of the eyes. *N.*, Nerve.

voluntary signals must be transmitted from cortical "voluntary" eye fields located in the frontal cortices.

Mechanism of Involuntary Locking Fixation—Role of the Superior Colliculi. The involuntary locking type of fixation discussed in the previous section results from a negative feedback mechanism that prevents the object of attention from leaving the foveal portion of the retina. The eyes normally have three types of continuous but almost imperceptible movements: (1) a *continuous tremor* at a rate of 30 to 80 cycles/sec caused by successive contractions of the motor units in the ocular muscles; (2) a *slow drift* of the eyeballs in one direction or another; and (3) sudden *flicking movements* that are controlled by the involuntary fixation mechanism.

When a spot of light becomes fixed on the foveal region of the retina, the tremulous movements cause the spot to move back and forth at a rapid rate across the cones, and the drifting movements cause the spot to drift slowly across the cones. Each time the spot drifts as far as the edge of the fovea, a sudden reflex reaction occurs, producing a flicking movement that moves the spot away from this edge back toward the center of the fovea. Thus, an automatic response moves the image back toward the central point of vision.

These drifting and flicking motions are demonstrated in **Fig. 52.9**. The dashed lines show the slow drifting across the fovea, and the solid lines show the flicks that keep the image from leaving the foveal region. This involuntary fixation capability is mostly lost when the superior colliculi are destroyed.

Saccadic Movement of the Eyes Provides a Mechanism of Successive Fixation Points. When a visual scene is moving continually before the eyes, such as when a person is riding in a car, the eyes fix on one highlight after another in the visual field, jumping from one to the next at a rate of two to three jumps per second. The jumps are called *saccades*, and the movements are called *optokinetic movements*. The saccades occur so rapidly that no more than 10% of the total time is spent moving the eyes, with 90% of the time being allocated to the fixation sites. Also, the brain suppresses the visual image during saccades, so the person is not conscious of the movements from point to point.

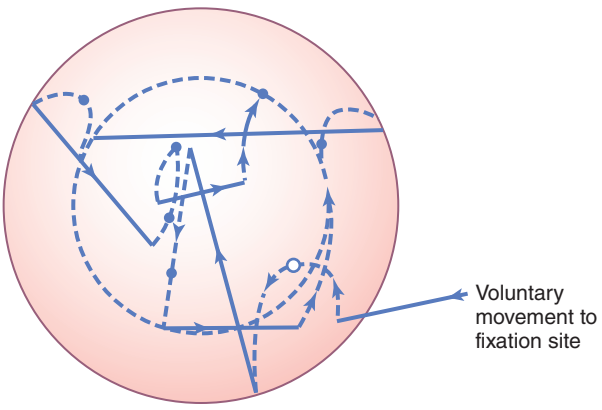

Figure 52.9 Movements of a spot of light on the fovea, showing sudden "flicking" eye movements that move the spot back toward the center of the fovea whenever it drifts to the foveal edge. The dashed lines represent slow drifting movements, and the solid lines represent sudden flicking movements. *(Modified from Whitteridge D. Central control of the eye movements. In: Field J, Magoun HW, Hall VE, eds.* Handbook of Physiology. *Vol. 2, sec. 1. Washington, DC: American Physiological Society; 1960.)*

Saccadic Movements During Reading. During the process of reading, a person usually makes several saccadic eye movements for each line. In this case, the visual scene is not moving past the eyes, but the eyes are trained to move by several successive saccades across the visual scene to extract the important information. Similar saccades occur when a person observes a painting, except that the saccades occur in upward, sideways, downward, and angulated directions one after another from one highlight of the painting to another, and so forth.

Fixation on Moving Objects—"Pursuit Movement." The eyes can also remain fixed on a moving object, which is called *pursuit movement*. A highly developed cortical mechanism automatically detects the course of movement of an object and then rapidly develops a similar course of movement for the eyes. For example, if an object is moving up and down in a wavelike form at a rate of several times per second, the eyes at first may be unable to fixate on it. However, after a second or so, the eyes begin to jump by means of saccades in approximately the same wavelike pattern of movement as that of the object. Then, after another few seconds, the eyes develop progressively smoother movements and finally follow the wave movement almost exactly. This represents a high degree of automatic subconscious computational ability by the pursuit system for controlling eye movements.

Superior Colliculi Are Mainly Responsible for Turning the Eyes and Head Toward a Visual Disturbance. Even after the visual cortex has been destroyed, a sudden visual disturbance in a lateral area of the visual field often causes immediate turning of the eyes in that direction. This turning does not occur if the superior colliculi have also been destroyed. To support this function, the various points of the retina are represented topographically in the superior colliculi in the same way as in the primary visual cortex, although with less accuracy. Even so, the principal direction of a flash of light in a peripheral retinal field is mapped by the colliculi, and secondary signals are transmitted to the oculomotor nuclei to turn the eyes. To help in this directional movement of the eyes, the superior colliculi also have topological maps of somatic sensations from the body and acoustic signals from the ears.

The optic nerve fibers from the eyes to the colliculi, which are responsible for these rapid turning movements, are branches from the *rapidly conducting M fibers*, with one branch going to the visual cortex and the other going to the superior colliculi. In addition to causing the eyes to

turn toward a visual disturbance, signals are relayed from the superior colliculi through the *medial longitudinal fasciculus* to other levels of the brain stem to cause turning of the whole head and even of the whole body toward the direction of the disturbance.

Other types of nonvisual disturbances, such as strong sounds or even stroking of the side of the body, cause similar turning of the eyes, head, and body, but only if the superior colliculi are intact. Therefore, the superior colliculi play a global role in orienting the eyes, head, and body with respect to external disturbances, whether they are visual, auditory, or somatic.

"Fusion" of the Visual Images From the Two Eyes

To make the visual perceptions more meaningful, the visual images in the two eyes normally *fuse* with each other on "corresponding points" of the two retinas. The visual cortex plays an important role in this fusion. We previously discussed that corresponding points of the two retinas transmit visual signals to different neuronal layers of the lateral geniculate body, and these signals, in turn, are relayed to parallel neurons in the visual cortex. Interactions occur between these cortical neurons to cause *interference excitation* in specific neurons when the two visual images are not "in register"—that is, are not precisely "fused." This excitation presumably provides the signal that is transmitted to the oculomotor apparatus to cause convergence or divergence or rotation of the eyes so that fusion can be reestablished. Once the corresponding points of the two retinas are in register, excitation of the specific "interference" neurons in the visual cortex disappears.

Neural Mechanism of Stereopsis for Judging Distances of Visual Objects

Because the two eyes are more than 2 inches apart, the images on the two retinas are not exactly the same. That is, the right eye sees a little more of the right-hand side of the object, and the left eye sees a little more of the left-hand side; the closer the object, the greater the disparity. Therefore, even when the two eyes are fused with each other, it is still impossible for all corresponding points in the two visual images to be exactly in register at the same time. Furthermore, the nearer the object is to the eyes, the less the degree of register. This degree of nonregister provides the neural mechanism for *stereopsis*, an important mechanism for judging the distances of visual objects up to about 200 feet (61 meters).

The neuronal cellular mechanism for stereopsis is based on the fact that some of the fiber pathways from the retinas to the visual cortex stray 1 to 2 degrees on each side of the central pathway. Therefore, some optic pathways from the two eyes are exactly in register for objects 2 meters away; still another set of pathways is in register for objects 25 meters away. Thus, the distance is determined by which set or sets of pathways are excited by nonregister or register. This phenomenon is called *depth perception*, another name for stereopsis.

Monocular Clues Contribute to Depth Perception. Although stereopsis plays a major role in depth perception, monocular clues also contribute to depth perception, including the following: (1) *differences in image size*—images farther away appear to be smaller; (2) *motion parallax*—images farther away appear to move slower; and (3) *image blocking*—if an image blocks the ability to view another image, then it is clear that the image doing the blocking is in front of the image being blocked. These monocular clues provide a person with only one functioning eye some depth perception.

Strabismus—Misalignment of the Eyes

Strabismus, also called *squint* or *cross-eye*, means lack of fusion or misalignment of the eyes in one or more of the visual coordinates: horizontal, vertical, or rotational. The basic types of strabismus are shown in **Fig. 52.10**: (1) *esotropia*, in which one or both eyes turn inward toward the nose ("crossed eyes"); (2) *exotropia*, in which one or both eyes turn outward; (3) *hypertropia*, in which one or both eyes turn upward; and (4) *hypotropia*, in which one or both eyes turn downward.

Strabismus is caused by abnormalities of one or more of the extraocular muscles involved in eye movements, the nerves that transmit information to the muscles, or the control center in the brain that directs eye movements. These neuromuscular abnormalities can be congenital or acquired due to various health problems, such as diabetes mellitus, stroke, brain tumors, and injuries.

Strabismus in early childhood may be caused by abnormal "set" of the fusion mechanism of the visual system. That is, in a young child's early efforts to fixate the two eyes on the same object, one of the eyes fixates satisfactorily while the other fails to do so, or they both fixate satisfactorily but never simultaneously. Soon the patterns of conjugate movements of the eyes become abnormally "set" in the neuronal control pathways themselves, so the eyes never fuse.

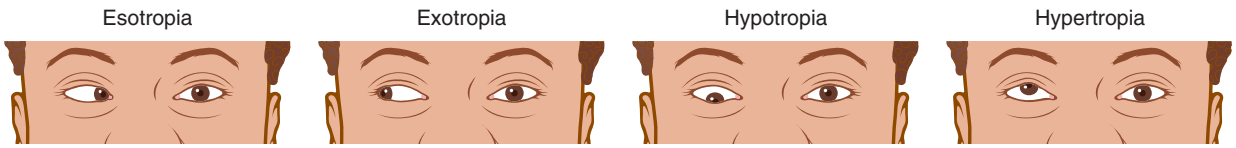

Figure 52.10 Basic types of strabismus.

Suppression of the Visual Image From a Repressed Eye. In a few patients with strabismus, the eyes alternate in fixing on the object of attention. In other patients, one eye alone is used all the time, and the other eye becomes repressed and is never used for precise vision. The visual acuity of the repressed eye develops only slightly, sometimes remaining as 20/400 or less. If the dominant eye then becomes blinded, vision in the repressed eye can develop only to a slight extent in adults but far more in young children. These observations demonstrate that visual acuity is highly dependent on proper development of central nervous system synaptic connections from the eyes. In fact, even anatomically, the numbers of neuronal connections in the visual cortex areas that would normally receive signals from the repressed eye are reduced.

AUTONOMIC CONTROL OF ACCOMMODATION AND PUPILLARY APERTURE

AUTONOMIC NERVES TO THE EYES

The eye is innervated by parasympathetic and sympathetic nerve fibers, as shown in **Fig. 52.11**. The parasympathetic preganglionic fibers arise in the *Edinger-Westphal nucleus*—the visceral nucleus portion of the third cranial nerve—and then pass in the *third nerve* to the *ciliary ganglion*, which lies immediately behind the eye. There, the preganglionic fibers synapse with postganglionic parasympathetic neurons, which in turn send fibers through *ciliary nerves* into the eyeball. These nerves excite (1) the ciliary muscle that controls focusing of the eye lens and (2) the sphincter of the iris that constricts the pupil.

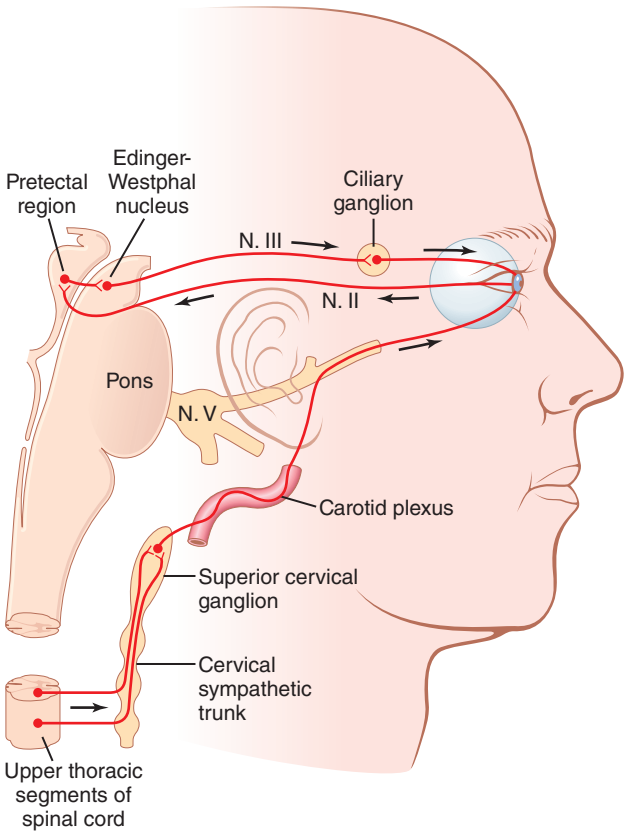

Figure 52.11 Autonomic innervation of the eye, showing also the reflex arc of the light reflex. *N.*, Nerve.

The sympathetic innervation of the eye originates in the *intermediolateral horn cells* of the first thoracic segment of the spinal cord. From there, sympathetic fibers enter the sympathetic chain and pass upward to the *superior cervical ganglion*, where they synapse with postganglionic neurons. Postganglionic sympathetic fibers from these neurons then spread along the surfaces of the carotid artery and successively smaller arteries until they reach the eye. There, the sympathetic fibers innervate the radial fibers of the iris, which open the pupil, as well as several extraocular muscles of the eye, discussed subsequently in relation to Horner syndrome.

CONTROL OF ACCOMMODATION (FOCUSING THE EYES)

Accommodation, the mechanism that focuses the lens system of the eye, is essential for a high degree of visual acuity. Accommodation results from contraction or relaxation of the eye ciliary muscle. Contraction causes increased refractive power of the lens, as explained in Chapter 50, and relaxation causes decreased refractive power. How does a person adjust accommodation to keep the eyes in focus all the time?

Accommodation of the lens is regulated by a negative feedback mechanism that automatically adjusts the refractive power of the lens to achieve the highest degree of visual acuity. When the eyes have been focused on some far object and must then suddenly focus on a near object, the lens usually accommodates for best acuity of vision within less than 1 second. Although the precise control mechanism that causes this rapid and accurate focusing of the eye is not fully understood, the following features are known.

First, when the eyes suddenly change distance of the fixation point, the lens changes its strength in the proper direction to achieve a new state of focus within a fraction of a second. Second, different types of clues help change the lens strength in the proper direction, as follows:

1. *Chromatic aberration* appears to be important. That is, red light rays focus slightly posteriorly to blue light rays because the lens bends blue rays more than red rays. The eyes appear to be able to detect which of these two types of rays is in better focus, and this clue relays information to the accommodation mechanism with regard to whether to make the lens stronger or weaker.

2. When the eyes fixate on a near object, the eyes must converge. *The neural mechanisms for convergence cause a simultaneous signal to strengthen the lens of the eye.*
3. *Because the fovea lies in a hollowed-out depression that is slightly deeper than the remainder of the retina, the clarity of focus in the depth of the fovea is different from the clarity of focus on the edges.* This difference may also give clues about which way the strength of the lens needs to be changed.
4. *The degree of accommodation of the lens oscillates slightly* all the time at a frequency up to twice per second. The visual image becomes clearer when the oscillation of the lens strength is changing in the appropriate direction and becomes poorer when the lens strength is changing in the wrong direction. This could give a rapid clue as to which way the strength of the lens needs to change to provide appropriate focus.

The brain cortical areas that control accommodation closely parallel those that control fixation movements of the eyes. Analysis of the visual signals in Brodmann cortical areas 18 and 19 and transmission of motor signals to the ciliary muscle occur through the *pretectal area in the brain* stem, then through the *Edinger-Westphal nucleus*, and finally via parasympathetic nerve fibers to the eyes.

CONTROL OF PUPILLARY DIAMETER

Stimulation of the parasympathetic nerves also excites the pupillary sphincter muscle, thereby decreasing the pupillary aperture; this process is called *miosis*. Conversely, stimulation of the sympathetic nerves excites the radial fibers of the iris and causes pupillary dilation, called *mydriasis*.

Pupillary Light Reflex. When light is shone into the eyes, the pupils constrict, a reaction called the *pupillary light reflex*. The neuronal pathway for this reflex is illustrated by the upper two black arrows in **Fig. 52.11**. When light impinges on the retina, a few of the resulting impulses pass from the optic nerves to the pretectal nuclei. From here, secondary impulses pass to the *Edinger-Westphal nucleus* and, finally, back through *parasympathetic nerves* to constrict the sphincter of the iris. Conversely, in darkness, the reflex becomes inhibited, which results in dilation of the pupil.

The function of the light reflex is to help the eye adapt rapidly to changing light conditions, as explained in Chapter 51. The limits of pupillary diameter are about 1.5 millimeters on the small side and 8 millimeters on the large side. Therefore, because light brightness on the retina increases with the square of pupillary diameter, the range of light and dark adaptation that can be brought about by the pupillary reflex is about 30 to 1—that is, up to as much as 30 times change in the amount of light entering the eye.

Pupillary Reflexes or Reactions in Central Nervous System Diseases. A few central nervous system diseases damage nerve transmission of visual signals from the retinas to the Edinger-Westphal nucleus, thus sometimes blocking the pupillary reflexes. Such blocks may occur as a result of disorders including *central nervous system syphilis, chronic alcoholism, encephalitis, multiple sclerosis, and Lyme disease.* The block usually occurs in the pretectal region of the brain stem, although it can result from destruction of some small fibers in the optic nerves.

The final nerve fibers in the pathway through the pretectal area to the Edinger-Westphal nucleus are mostly of the inhibitory type. When their inhibitory effect is lost, the nucleus becomes chronically active, causing the pupils to remain mostly constricted, in addition to their failure to respond to light.

Yet, the pupils can constrict a little more if the Edinger-Westphal nucleus is stimulated through some other pathway. For example, when the eyes fixate on a near object, the signals that cause accommodation of the lens, and those that cause convergence of the two eyes, cause a mild degree of pupillary constriction at the same time. This phenomenon is called the *pupillary reaction to accommodation*. A pupil that fails to respond to light but does respond to accommodation and is also very small (an *Argyll Robertson pupil*) is an important diagnostic sign of a central nervous system disease such as syphilis.

Horner Syndrome (Oculosympathetic Paresis). Interruption of the sympathetic nerves to the eye causes the clinical condition called *Horner syndrome*. This interruption frequently occurs in the cervical sympathetic chain, leading to the following effects:

1. Because of interruption of sympathetic nerve fibers to the pupillary dilator muscle, the pupil remains persistently constricted to a smaller diameter than the pupil of the opposite eye.
2. The superior eyelid droops because it is normally maintained in an open position during waking hours, partly by contraction of smooth muscle fibers embedded in the superior eyelid and innervated by the sympathetics. Therefore, destruction of the sympathetic nerves makes it impossible to open the superior eyelid as widely as normally.
3. The blood vessels on the corresponding side of the face and head become persistently dilated.
4. Sweating (which requires sympathetic nerve signals) cannot occur on the side of the face and head affected by Horner syndrome.

The Sense of Hearing

This chapter describes the mechanisms whereby the ear receives sound waves, discriminates their frequencies, and transmits auditory information into the central nervous system, where its meaning is deciphered.

TYMPANIC MEMBRANE AND THE OSSICULAR SYSTEM

CONDUCTION OF SOUND FROM THE TYMPANIC MEMBRANE TO THE COCHLEA

Fig. 53.1 shows the *tympanic membrane* (commonly called the *eardrum*) and the *ossicles*, which conduct sound from the tympanic membrane through the middle ear to the *cochlea* (the inner ear). Attached to the tympanic membrane is the *handle of the malleus*. The malleus is bound to the *incus* by minute ligaments, so whenever the malleus moves, the incus moves with it. The opposite end of the incus articulates with the stem of the *stapes*, and the *faceplate* of the stapes lies against the *membranous labyrinth* of the cochlea in the opening of the *oval window*.

The tip end of the handle of the malleus is attached to the center of the tympanic membrane, and this point of attachment is constantly pulled by the *tensor tympani muscle*, which keeps the tympanic membrane tensed. This tension allows sound vibrations on *any* portion of the tympanic membrane to be transmitted to the ossicles, which would not occur if the membrane were lax.

The ossicles of the middle ear are suspended by ligaments so that the combined malleus and incus act as a single lever, having its fulcrum approximately at the border of the tympanic membrane.

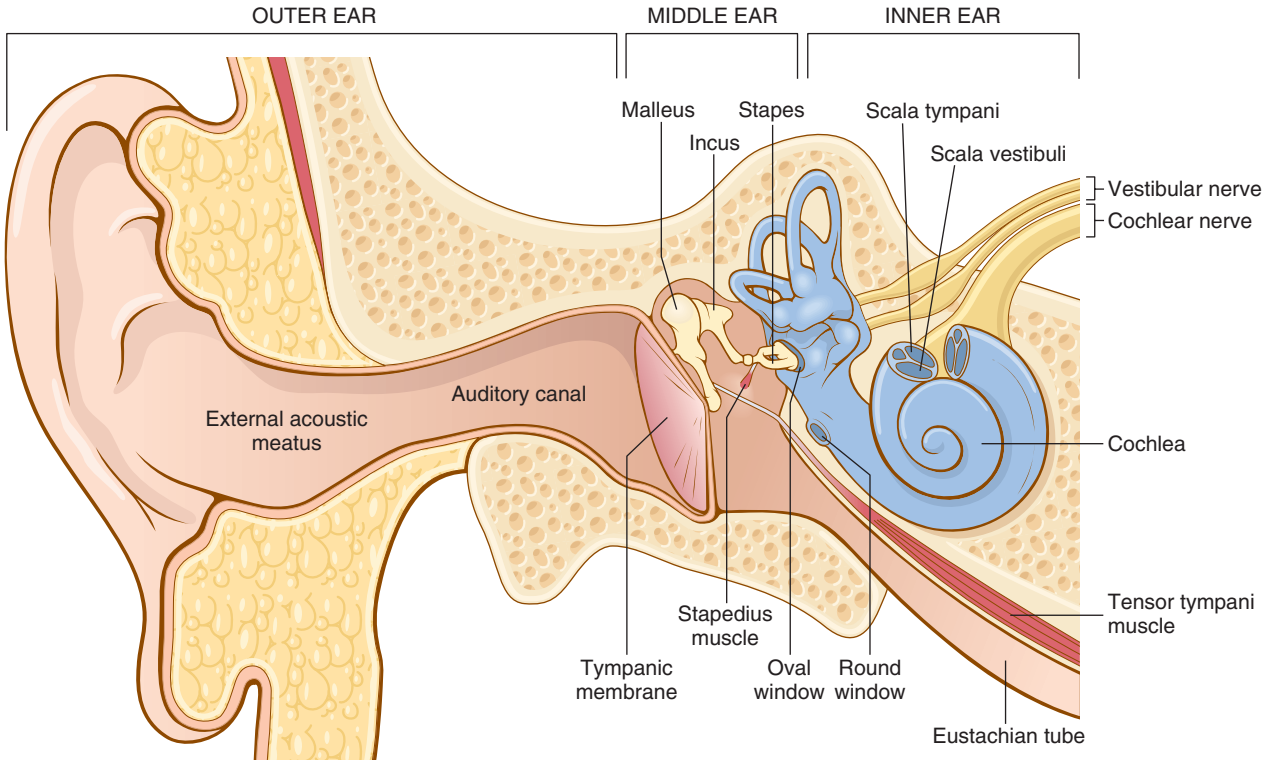

Figure 53.1 The outer ear, tympanic membrane, and ossicular system of the middle ear and inner ear.

The articulation of the incus with the stapes causes the stapes to (1) push forward on the oval window and on the cochlear fluid on the other side of window every time the tympanic membrane moves inward; and (2) pull backward on the fluid every time the malleus moves outward.

"Impedance Matching" By the Ossicular System. The amplitude of movement of the stapes faceplate with each sound vibration is only three-fourths as much as the amplitude of the handle of the malleus. Therefore, the ossicular lever system does not increase the movement distance of the stapes, as is commonly believed. Instead, the system actually reduces the distance but increases the *force* of movement about 1.3 times. In addition, the surface area of the tympanic membrane is about 55 square millimeters, whereas the surface area of the stapes averages 3.2 square millimeters. This 17-fold difference times the 1.3-fold ratio of the lever system causes about 22 times as much *total force* to be exerted on the fluid of the cochlea as is exerted by the sound waves against the tympanic membrane. Because fluid has far greater inertia than air, increased amounts of force are necessary to cause vibration in the fluid. Therefore, the tympanic membrane and ossicular system provide *impedance matching* between the sound waves in air and the sound vibrations in the fluid of the cochlea. The impedance matching is about 50% to 75% of perfect for sound frequencies between 300 and 3000 cycles/sec, which allows utilization of most of the energy in the incoming sound waves.

In the absence of the ossicular system and tympanic membrane, sound waves can still travel directly through the air of the middle ear and enter the cochlea at the oval window. However, the sensitivity for hearing is then 15 to 20 decibels less than for ossicular transmission—equivalent to a decrease from a medium to a barely perceptible voice level.

Attenuation of Sound By Contraction of the Tensor Tympani and Stapedius Muscles. When loud sounds are transmitted through the ossicular system and from there into the central nervous system, a reflex occurs after a latent period of 40 to 80 milliseconds to cause contraction of the *stapedius muscle* and, to a lesser extent, the *tensor tympani muscle*. The tensor tympani muscle pulls the handle of the malleus inward while the stapedius muscle pulls the stapes outward. These two forces oppose each other and thereby cause the entire ossicular system to develop increased rigidity, thus greatly reducing the ossicular conduction of low-frequency sound, mainly frequencies below 1000 cycles/sec.

This *attenuation reflex* can reduce the intensity of lower frequency sound transmission by 30 to 40 decibels, which is about the same difference as that between a loud voice and a whisper. The function of this mechanism is believed to be 2-fold—to *protect* the cochlea from damaging vibrations caused by excessively loud sound and to *mask* low-frequency sounds in loud environments. Masking usually removes a major share of the background noise and allows a person to concentrate on sounds above 1000 cycles/sec, where most of the pertinent information in voice communication is transmitted.

Another function of the tensor tympani and stapedius muscles is to decrease a person's hearing sensitivity to their own speech. This effect is activated by collateral nerve signals transmitted to these muscles at the same time that the brain activates the voice mechanism.

TRANSMISSION OF SOUND THROUGH BONE

Because the inner ear, the *cochlea*, is embedded in a bony cavity in the temporal bone, called the *bony labyrinth*, vibrations of the entire skull can cause fluid vibrations in the cochlea. Therefore, under appropriate conditions, a tuning fork or an electronic vibrator placed on any bony protuberance of the skull, but especially on the mastoid process near the ear, causes the person to hear the sound. However, the energy available even in loud sound in the air is not sufficient to cause hearing via bone conduction unless a special electromechanical sound-amplifying device is applied to the bone.

COCHLEA

FUNCTIONAL ANATOMY OF THE COCHLEA

The cochlea is a system of coiled tubes, shown in **Fig. 53.1** and in cross section in **Fig. 53.2**. It consists of three tubes coiled side by side: (1) the *scala vestibuli;* (2) the *scala media;* and (3) the *scala tympani*. The scala vestibuli and scala media are separated from each other by the *Reissner membrane* (also called the *vestibular membrane*), shown in **Fig. 53.2B**; the scala tympani and scala media are separated from each other by the *basilar membrane*. On the surface of the basilar membrane lies the *organ of Corti*, which contains a series of electromechanically sensitive *hair cells*. They are the receptive end organs that generate nerve impulses in response to sound vibrations.

Fig. 53.3 diagrams the functional parts of the uncoiled cochlea for conduction of sound vibrations. First, note that the Reissner membrane is missing from this figure. This membrane is so thin and so easily moved that it does not obstruct the passage of sound vibrations from the scala vestibuli into the scala media. Therefore, for fluid conduction of sound, the scala vestibuli and scala media are considered to be a single chamber. As discussed later, the Reissner membrane maintains a special kind of fluid in the scala media that is required for normal function of the sound-receptive hair cells.

Sound vibrations enter the scala vestibuli from the faceplate of the stapes at the oval window. The faceplate covers this window and is connected with the window's edges by a loose annular ligament so that it can move inward and outward with the sound vibrations. Inward movement causes the fluid to move forward in the scala vestibuli and scala media, and outward movement causes the fluid to move backward.

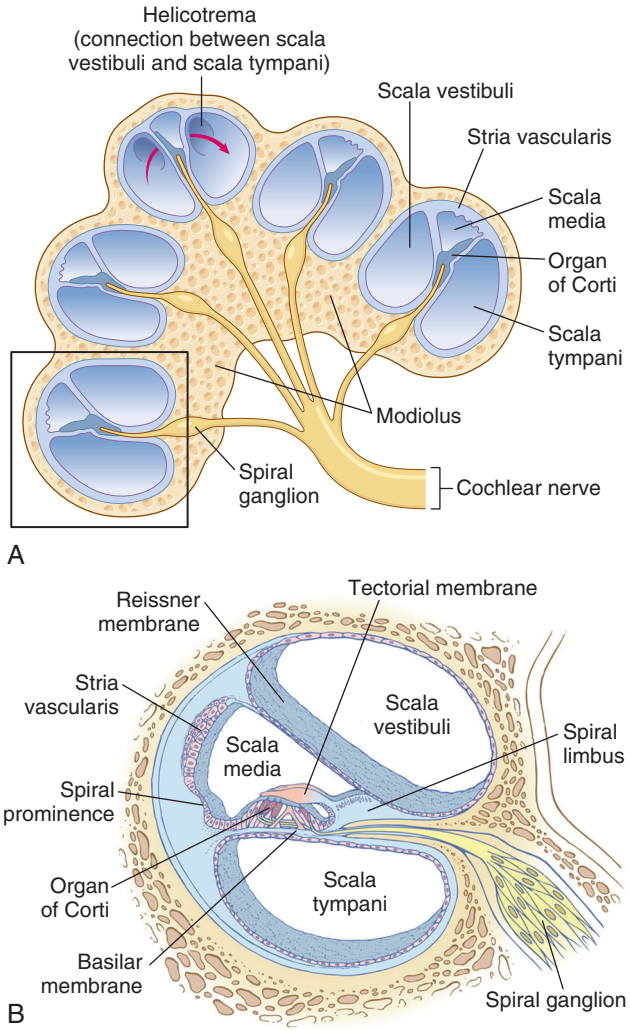

Figure 53.2 The cochlea (A) and section through one of the turns of the cochlea (B).

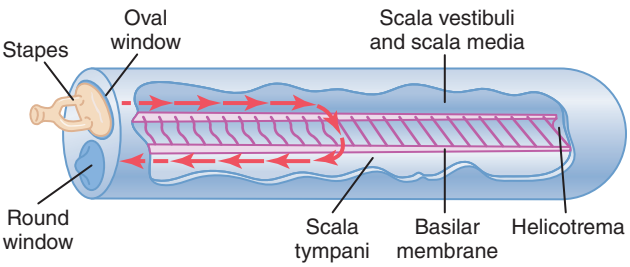

Figure 53.3 Movement of fluid in the cochlea after forward thrust of the stapes.

Basilar Membrane and Resonance in the Cochlea. The basilar membrane is a fibrous membrane that separates the scala media from the scala tympani. It contains 20,000 to 30,000 *basilar fibers* that project from the bony center of the cochlea, the *modiolus*, toward the outer wall. These fibers are stiff, elastic, reedlike structures that are fixed at their basal ends in the central bony structure of the cochlea (the modiolus) but are not fixed at their distal ends, except that the distal ends are embedded in the loose basilar membrane. Because the fibers are stiff and free at one end, they can vibrate like the reeds of a harmonica.

The *lengths* of the basilar fibers *increase* progressively, beginning at the oval window and going from the base of the cochlea to the apex, increasing from a length of about 0.04 millimeter near the oval and round windows to 0.5 millimeter at the tip of the cochlea (the "*helicotrema*"), a 12-fold increase in length.

The *diameters* of the fibers, however, *decrease* from the oval window to the helicotrema, so their overall stiffness decreases more than 100-fold. As a result, the stiff, short fibers near the oval window of the cochlea vibrate best at a very high frequency, whereas the long, limber fibers near the tip of the cochlea vibrate best at a low frequency.

Thus, *high-frequency resonance* of the basilar membrane occurs near the base, where the sound waves enter the cochlea through the oval window. However, *low-frequency resonance* occurs near the helicotrema, mainly because of the less stiff fibers but also because of increased "loading" with extra masses of fluid that must vibrate along the cochlear tubules.

TRANSMISSION OF SOUND WAVES IN THE COCHLEA—"TRAVELING WAVE"

When the foot of the stapes moves inward against the *oval* window, the *round* window must bulge outward because the cochlea is bounded on all sides by bony walls. The initial effect of a sound wave entering at the oval window is to cause the basilar membrane at the base of the cochlea to bend in the direction of the round window. However, the elastic tension that is built up in the basilar fibers as they bend toward the round window initiates a fluid wave that "travels" along the basilar membrane toward the helicotrema. **Fig. 53.4A** shows movement of a high-frequency wave down the basilar membrane, **Fig. 53.4B** shows a medium-frequency wave, and **Fig. 53.4C** shows a very low frequency wave. Movement of the wave along the basilar membrane is comparable to the movement of a pressure wave along the arterial walls, discussed in Chapter 15; it is also comparable to a wave that travels along the surface of a pond.

Vibration Patterns of the Basilar Membrane for Different Sound Frequencies. Note in **Fig. 53.4** the different patterns of transmission for sound waves of different frequencies. Each wave is relatively weak at the outset but becomes strong when it reaches the portion of the basilar membrane that has a natural resonant frequency equal to the respective sound frequency. At this point, the basilar membrane can vibrate back and forth with such ease that the energy in the wave is dissipated. Consequently, the wave dies at this point and fails to travel the remaining distance along the basilar membrane. Thus, a high-frequency sound wave travels only a short distance along the basilar membrane before it reaches its resonant point and dies, a medium-frequency sound wave travels about halfway and then dies, and a very low frequency sound wave travels the entire distance along the membrane.

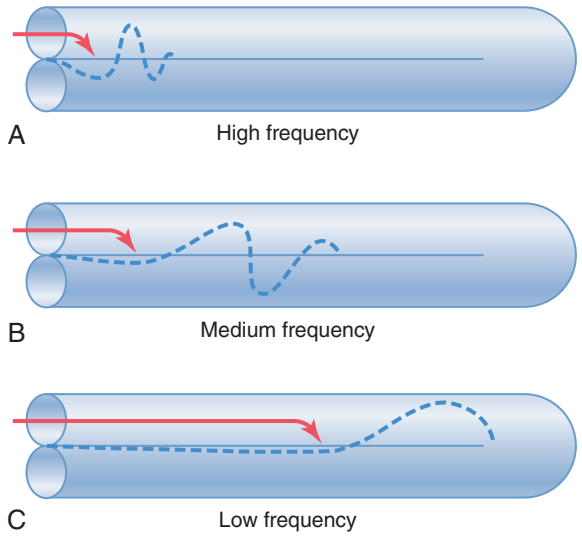

Figure 53.4 "Traveling waves" along the basilar membrane for high- (A), medium- (B), and low-frequency (C) sounds.

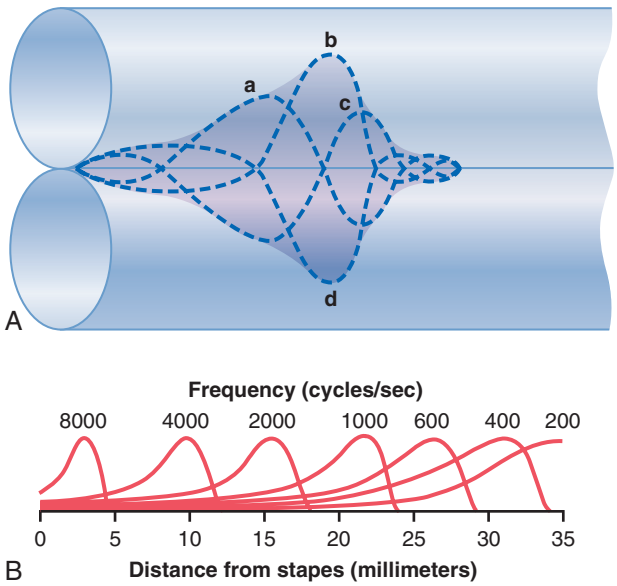

Figure 53.5 (A) Amplitude pattern of vibration of the basilar membrane for a medium-frequency sound (a–d). (B) Amplitude patterns for sounds of frequencies between 200 and 8000 cycles/sec, showing the points of maximum amplitude on the basilar membrane for the different frequencies.

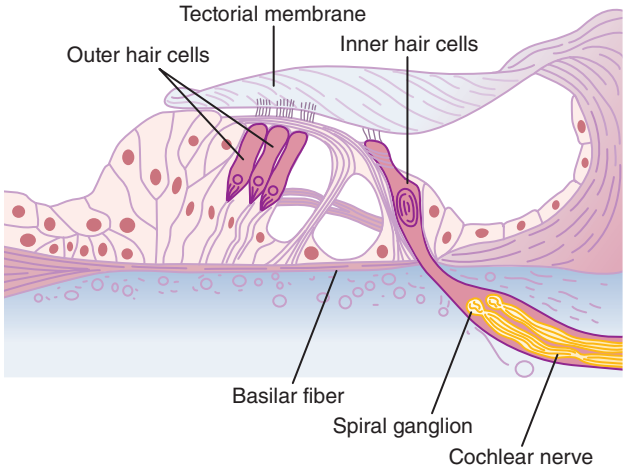

Figure 53.6 The organ of Corti, showing especially the hair cells and the tectorial membrane pressing against the projecting hairs.

Another feature of the traveling wave is that it travels fast along the initial portion of the basilar membrane but becomes progressively slower as it goes farther into the cochlea. The cause of this difference is the high coefficient of elasticity of the basilar fibers near the oval window and a progressively decreasing coefficient farther along the membrane. This rapid initial transmission of the wave allows the high-frequency sounds to travel far enough into the cochlea to spread out and separate from one another on the basilar membrane. Without this rapid initial transmission, all the high-frequency waves would be bunched together within the first millimeter or so of the basilar membrane, and their frequencies could not be discriminated.

Vibration Amplitude Pattern of the Basilar Membrane. The dashed curves of **Fig. 53.5A** show the position of a sound wave on the basilar membrane when the stapes is (a) all the way inward, (b) has moved back to the neutral point, (c) is all the way outward, and (d) has moved back again to the neutral point but is moving inward. The shaded area around these different waves shows the extent of vibration of the basilar membrane during a complete vibratory cycle. This is the *amplitude pattern of vibration* of the basilar membrane for this particular sound frequency.

Fig. 53.5B shows the amplitude patterns of vibration for different frequencies, demonstrating that the maximum amplitude for sound at 8000 cycles/sec occurs near the base of the cochlea, whereas that for frequencies less than 200 cycles/sec is all the way at the tip of the basilar membrane near the helicotrema, the minute opening whereby the scala tympani and scala vestibuli communicate (**Fig. 53.2**).

The principal method whereby sound frequencies are discriminated from one another is based on the "place" of maximum stimulation of the nerve fibers from the organ of Corti lying on the basilar membrane, as explained in the next section.

FUNCTION OF THE ORGAN OF CORTI

The organ of Corti, shown in **Fig. 53.2** and **Fig. 53.6**, is the receptor organ that generates nerve impulses in response to vibration of the basilar membrane. Note that the organ of Corti lies on the surface of the basilar fibers and basilar membrane. The actual sensory receptors in the organ of Corti are two specialized types of nerve cells called *hair cells*—a single row of *internal ("inner") hair cells*, numbering about 3500 and measuring about 12 micrometers in diameter, and three or four rows of *external ("outer") hair*

cells, numbering about 12,000 and having diameters of only about 8 micrometers. The bases and sides of the hair cells synapse with a network of cochlear nerve endings. Between 90% and 95% of these endings terminate on the inner hair cells, emphasizing their special importance for detection of sound.

The nerve fibers stimulated by the hair cells lead to the *spiral ganglion of Corti*, which lies in the modiolus (center) of the cochlea. The spiral ganglion neuronal cells send axons—a total of about 30,000—into the *cochlear nerve* and then into the central nervous system at the level of the upper medulla. The relations of the organ of Corti to the spiral ganglion and to the cochlear nerve are shown in **Fig. 53.2**.

Excitation of the Hair Cells. Note in **Fig. 53.7** that minute hairs, or *stereocilia*, project upward from the hair cells and either touch or are embedded in the surface gel coating of the *tectorial membrane*, which lies above the stereocilia in the scala media. These hair cells are similar to the hair cells found in the macula and cristae ampullaris of the vestibular apparatus, discussed in Chapter 56. Bending of the hairs in one direction depolarizes the hair cells, and bending in the opposite direction hyperpolarizes them. This in turn excites the auditory nerve fibers synapsing with their bases.

Fig. 53.7A shows the mechanism whereby vibration of the basilar membrane excites the hair endings. The outer ends of the hair cells are fixed tightly in a rigid structure composed of a flat plate, called the *reticular lamina*, supported by triangular *rods of Corti*, which are attached tightly to the basilar fibers. The basilar fibers, the rods of Corti, and the reticular lamina move as a rigid unit.

Upward movement of the basilar fiber rocks the reticular lamina upward and *inward* toward the modiolus. Then, when the basilar membrane moves downward, the reticular lamina rocks downward and *outward*. The inward and outward motion causes the hairs on the hair cells to shear back and forth against the tectorial membrane. Thus, the hair cells are excited whenever the basilar membrane vibrates.

Auditory Signals Are Transmitted Mainly By the Inner Hair Cells. Even though there are three to four times as many outer hair cells as inner hair cells, about 90% of the auditory nerve fibers are stimulated by the inner cells rather than by the outer cells. Nonetheless, if the outer cells are damaged while the inner cells remain fully functional, a large amount of hearing loss occurs. Therefore, it has been proposed that the outer hair cells in some way control the sensitivity of the inner hair cells at different sound pitches, a phenomenon called "*tuning*" of the receptor system. In support of this concept, a large number of retrograde nerve fibers pass from the brain stem to the vicinity of the outer hair cells. Stimulating these nerve fibers can actually cause shortening of the outer hair cells and possibly also change their degree of stiffness. These effects suggest a retrograde nervous mechanism for

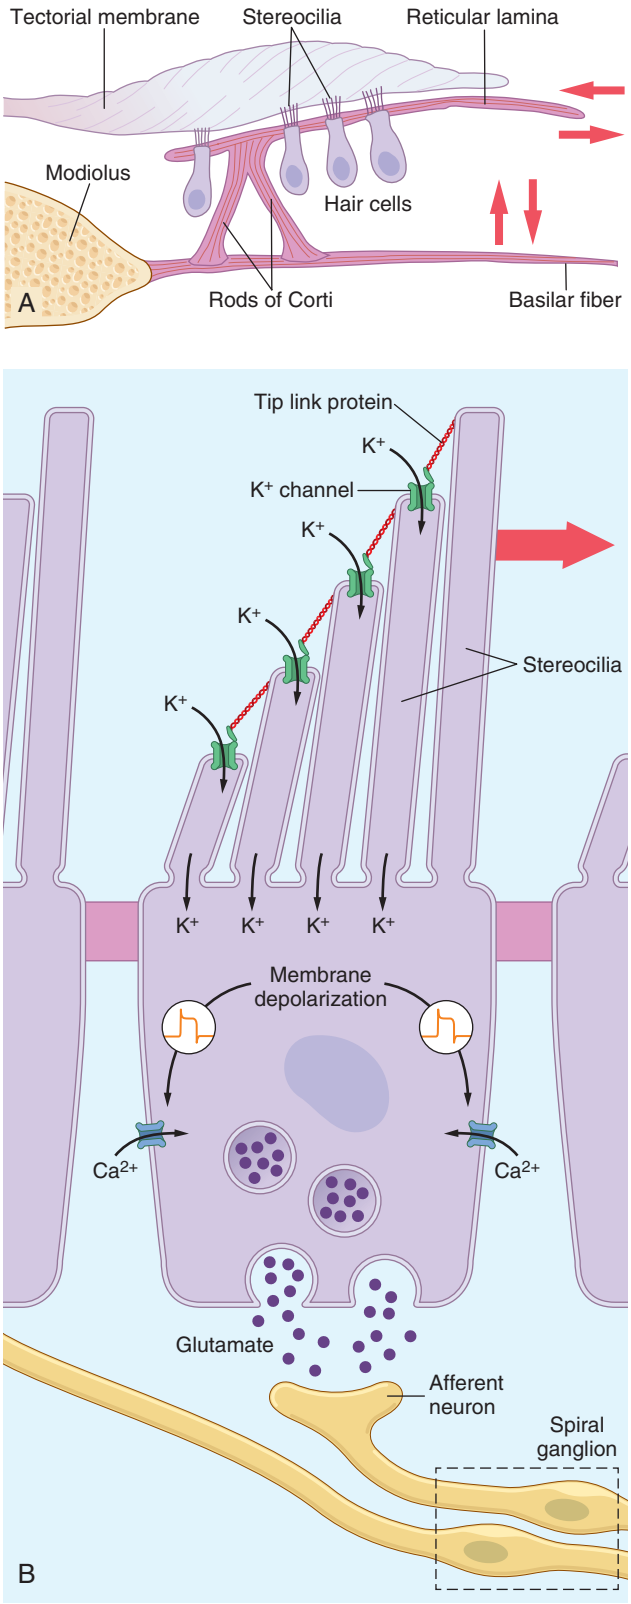

Figure 53.7 (A) Stimulation of the hair cells by to and fro movement of the hairs projecting into the gel coating of the tectorial membrane. (B) Transduction of mechanical energy into neural signals by the hair cells. When the stereocilia are bent in the direction of the longer ones, K^+ channels are opened, causing depolarization, which in turn opens voltage-gated Ca^{2+} channels. The influx of Ca^{2+} augments the depolarization and elicits release of the excitatory transmitter glutamate, which depolarizes the sensory nerve.

control of the ear's sensitivity to different sound pitches, activated through the outer hair cells.

Hair Cell Receptor Potentials and Excitation of Auditory Nerve Fibers. The stereocilia (i.e., the "hairs" protruding from the ends of the hair cells) are stiff structures because each has a rigid protein framework. Each hair cell has about 100 stereocilia on its apical border. These stereocilia become progressively longer on the side of the hair cell away from the modiolus. The tops of the shorter stereocilia are attached by thin filaments to the back sides of their adjacent longer stereocilia. Therefore, whenever the cilia are bent in the direction of the longer ones, the tips of the smaller stereocilia are tugged outward from the surface of the hair cell. This causes a mechanical transduction that opens 200 to 300 cation-conducting channels, allowing for the rapid movement of positively charged potassium ions from the surrounding scala media fluid into the stereocilia, which causes depolarization of the hair cell membrane (see **Fig. 53.7B**). The depolarization opens voltage-sensitive calcium channels and causes influx of calcium ions, which augments the depolarization. Repolarization of the hair cell occurs mainly by exit of potassium ions through calcium ion–sensitive potassium channels.

Thus, when the basilar fibers bend toward the scala vestibuli, the hair cells depolarize, and in the opposite direction they hyperpolarize, thereby generating an alternating hair cell receptor potential that, in turn, stimulates the cochlear nerve endings that synapse with the bases of the hair cells. Current evidence indicates that the rapidly acting neurotransmitter glutamate is released by the hair cells at these synapses during depolarization.

Endocochlear Potential. To further explain the electrical potentials generated by the hair cells, we need to explain another electrical phenomenon called the *endocochlear potential*. The scala media is filled with a fluid called *endolymph*, in contradistinction to the *perilymph* present in the scala vestibuli and scala tympani. The scala vestibuli and scala tympani communicate directly with the subarachnoid space around the brain, so the perilymph is almost identical to cerebrospinal fluid. Conversely, the endolymph that fills the scala media is an entirely different fluid secreted by the *stria vascularis*, a highly vascular area on the outer wall of the scala media. Endolymph contains a high concentration of potassium and a low concentration of sodium, which is exactly opposite to the contents of perilymph.

An electrical potential of about +80 millivolts exists all the time between endolymph and perilymph, with positivity inside the scala media and negativity outside. This is called the *endocochlear potential*, and it is generated by continual secretion of positive potassium ions into the scala media by the stria vascularis.

The importance of the endocochlear potential is that the tops of the hair cells project through the reticular lamina and are bathed by the endolymph of the scala media, whereas perilymph bathes the lower bodies of the hair cells. Furthermore, the hair cells have a negative intracellular potential of −70 millivolts with respect to the perilymph but −150 millivolts with respect to the endolymph at their upper surfaces, where the hairs project through the reticular lamina and into the endolymph. This high electrical potential at the tips of the stereocilia likely sensitizes the cell an extra amount, thereby increasing its ability to respond to the slightest sound.

DETERMINATION OF SOUND FREQUENCY—THE "PLACE" PRINCIPLE

From earlier discussions in this chapter, it is apparent that low-frequency sounds cause maximal activation of the basilar membrane near the apex of the cochlea, and high-frequency sounds activate the basilar membrane near the base of the cochlea. Intermediate-frequency sounds activate the membrane at intermediate distances between the two extremes. Furthermore, there is spatial organization of the nerve fibers in the cochlear pathway, all the way from the cochlea to the cerebral cortex. Recordings of signals in the auditory tracts of the brain stem and in the auditory receptive fields of the cerebral cortex show that specific brain neurons are activated by specific sound frequencies. Therefore, the *major* method used by the nervous system to detect different sound frequencies is to determine the positions along the basilar membrane that are stimulated the most, called the *place principle* for the determination of sound frequency.

Referring again to **Fig. 53.5**, one can see that the distal end of the basilar membrane at the helicotrema is stimulated by all sound frequencies below 200 cycles/sec. Therefore, it has been difficult to understand from the place principle how one can differentiate between low sound frequencies in the range of 200 down to 20 cycles/sec. These low frequencies have been postulated to be discriminated mainly by the so-called *volley* or *frequency principle*. That is, low-frequency sounds, from 20 to 1500 to 2000 cycles/sec, can cause volleys of nerve impulses synchronized at the same frequencies, and these volleys are transmitted by the cochlear nerve into the cochlear nuclei of the brain. It is further suggested that the cochlear nuclei can distinguish the different frequencies of the volleys. In fact, destruction of the entire apical half of the cochlea, which destroys the basilar membrane where all lower frequency sounds are normally detected, does not totally eliminate discrimination of the lower frequency sounds.

DETERMINATION OF LOUDNESS

Loudness is determined by the auditory system in at least three ways.

First, as the sound becomes louder, the amplitude of vibration of the basilar membrane and hair cells also

increases so that the hair cells excite the nerve endings at more rapid rates.

Second, as the amplitude of vibration increases, it causes more and more of the hair cells on the fringes of the resonating portion of the basilar membrane to become stimulated, thus causing *spatial summation* of impulses—that is, transmission through many nerve fibers rather than through only a few.

Third, the outer hair cells do not become stimulated significantly until vibration of the basilar membrane reaches high intensity, and stimulation of these cells presumably apprises the nervous system that the sound is loud.

Detection of Changes in Loudness—The Power Law. As pointed out in Chapter 47, a person interprets changes in intensity of sensory stimuli approximately in proportion to an inverse power function of the actual intensity. In the case of sound, the interpreted sensation changes approximately in proportion to the cube root of the actual sound intensity. To express this concept in another way, the ear can discriminate differences in sound intensity from the softest whisper to the loudest possible noise, representing an *approximately 1 trillion times* increase in sound energy or 1 million times increase in amplitude of movement of the basilar membrane. Yet, the ear interprets this much difference in sound level as approximately a 10,000-fold change. Thus, the scale of intensity is greatly "compressed" by the sound perception mechanisms of the auditory system, which allows a person to interpret differences in sound intensities over a far wider range than would otherwise be possible.

Decibel Unit. Because of the extreme changes in sound intensities that the ear can detect and discriminate, sound intensities are usually expressed in terms of the logarithm of their actual intensities. A 10-fold increase in sound energy is called 1 *bel*, and 0.1 bel is called 1 *decibel*. One decibel represents an actual increase in sound energy of 1.26 times.

Another reason for using the decibel system to express changes in loudness is that in the usual sound intensity range for communication, the ears can barely distinguish an approximately 1-decibel *change* in sound intensity.

Threshold for Hearing Sound at Different Frequencies. **Fig. 53.8** shows the pressure thresholds at which sounds of different frequencies can barely be heard by the ear. This figure demonstrates that a 3000 cycles/sec sound can be heard even when its intensity is as low as 70 decibels below 1 dyne/cm^2 sound pressure level, which is one 10-millionth microwatt per square centimeter. Conversely, a 100 cycles/sec sound can be detected only if its intensity is 10,000 times as great as this.

Frequency Range of Hearing. The frequencies of sound that a young person can hear are usually between 20 and 20,000 cycles/sec. However, referring again to **Fig. 53.8**, we see that the sound range depends to a great extent

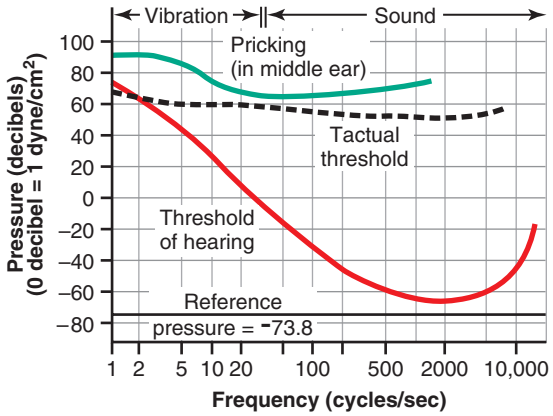

Figure 53.8 Relation of the threshold of hearing and of somesthetic perception (pricking and tactual threshold) to the sound energy level at each sound frequency.

on loudness. If the loudness is 60 decibels below 1 dyne/cm^2 sound pressure level, the sound range is 500 to 5000 cycles/sec; only with intense sounds can the complete range of 20 to 20,000 cycles be achieved. In old age, there is usually a gradual loss of hearing (*presbycusis*) and this frequency range is shortened to 50 to 8000 cycles/sec or less, as discussed later in this chapter.

CENTRAL AUDITORY MECHANISMS

AUDITORY NERVOUS PATHWAYS

Fig. 53.9 shows the major auditory pathways. Nerve fibers from the *spiral ganglion of Corti* enter the *dorsal* and *ventral cochlear nuclei* located in the upper part of the medulla. At this point, all the fibers synapse, and second-order neurons pass mainly to the opposite side of the brain stem to terminate in the *superior olivary nucleus*. A few second-order fibers also pass to the superior olivary nucleus on the same side.

From the superior olivary nucleus, the auditory pathway passes upward through the *lateral lemniscus*. Some of the fibers terminate in the *nucleus of the lateral lemniscus*, but many fibers bypass this nucleus and travel on to the inferior colliculus, where all or almost all the auditory fibers synapse. From there, the pathway passes to the *medial geniculate nucleus*, where all the fibers do synapse. Finally, the pathway proceeds via *auditory radiation* to the *auditory cortex*, located mainly in the superior gyrus of the temporal lobe.

Several important points should be noted. First, signals from both ears are transmitted through the pathways of both sides of the brain, with a preponderance of transmission in the contralateral pathway. In at least three places in the brain stem, crossing over occurs between the two pathways: (1) in the trapezoid body; (2) in the commissure between the two nuclei of the lateral lemnisci; and (3) in the commissure connecting the two inferior colliculi.

Second, many collateral fibers from the auditory tracts pass directly into the *reticular activating system of*

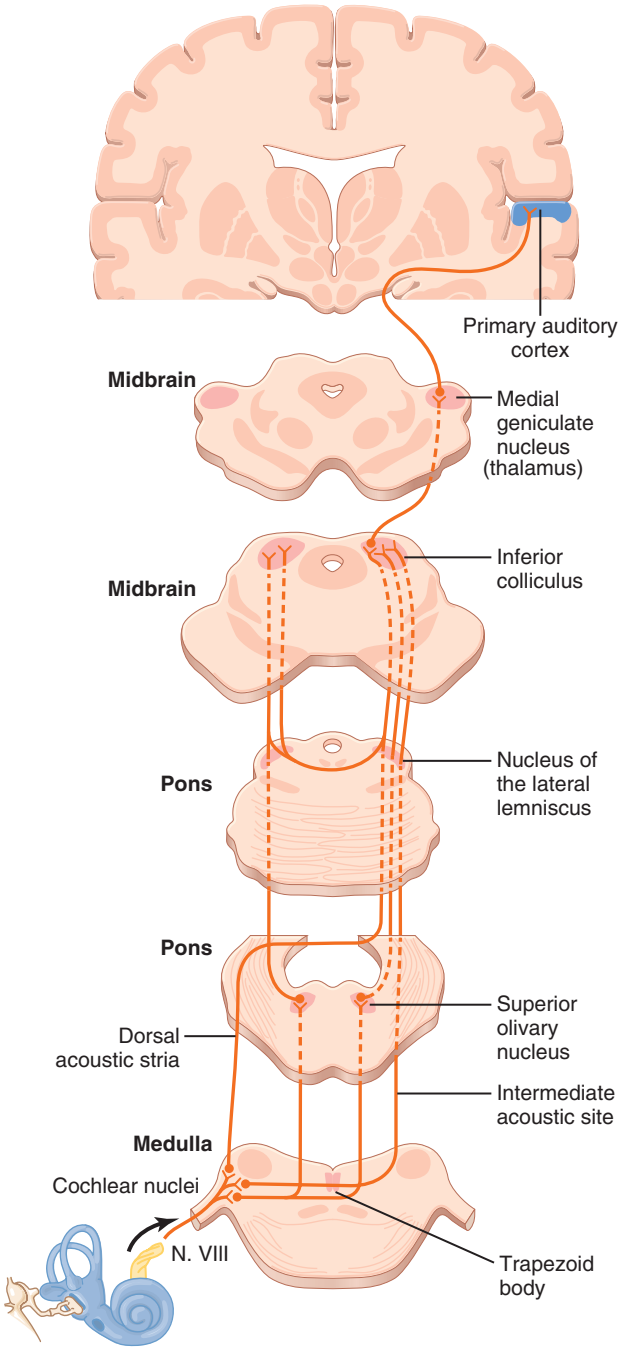

Figure 53.9 Auditory nervous pathways. *N.*, Nerve.

the brain stem. This system projects diffusely upward in the brain stem and downward into the spinal cord and activates the entire nervous system in response to loud sounds. Other collaterals go to the *vermis of the cerebellum*, which is also activated almost instantaneously in the event of a sudden noise.

Third, a high degree of spatial orientation is maintained in the fiber tracts from the cochlea all the way to the cortex. In fact, there are *three spatial patterns* for termination of the different sound frequencies in the cochlear nuclei, *two patterns* in the inferior colliculi, *one precise pattern* for discrete sound frequencies in the auditory cortex, and *at least five other less precise patterns* in the auditory cortex and auditory association areas.

Firing Rates at Different Levels of the Auditory Pathways. Single nerve fibers entering the cochlear nuclei from the auditory nerve can fire at rates up to at least 1000/sec, with the rate being determined mainly by the loudness of the sound. At sound frequencies up to 2000 to 4000 cycles/sec, the auditory nerve impulses are often synchronized with the sound waves, but they do not necessarily occur with every wave.

In the auditory tracts of the brain stem, the firing is usually no longer synchronized with the sound frequency, except at sound frequencies below 200 cycles/sec. Above the level of the inferior colliculi, even this synchronization is mainly lost. These findings demonstrate that the sound signals are not transmitted unchanged directly from the ear to the higher levels of the brain; instead, information from the sound signals begins to be dissected from the impulse traffic at levels as low as the cochlear nuclei. We will have more to say about this subject later, especially in relation to perception of direction from which sound comes.

FUNCTION OF THE CEREBRAL CORTEX IN HEARING

The projection area of auditory signals to the cerebral cortex is shown in **Fig. 53.10**, which demonstrates that the auditory cortex lies principally on the *supratemporal plane of the superior temporal gyrus* but also extends onto the *lateral side of the temporal lobe*, over much of the *insular cortex*, and even onto the lateral portion of the *parietal operculum*.

Two separate subdivisions are shown in **Fig. 53.10**—the *primary auditory cortex* and the *auditory association cortex* (also called the *secondary auditory cortex*). The primary auditory cortex is directly excited by projections from the medial geniculate body, whereas the auditory association areas are excited secondarily by impulses from the primary auditory cortex, as well as by some projections from thalamic association areas adjacent to the medial geniculate body.

Sound Frequency Perception in the Primary Auditory Cortex. At least six *tonotopic maps* have been described in the primary auditory cortex and auditory association areas. In each of these maps, high-frequency sounds excite neurons at one end of the map, whereas low-frequency sounds excite neurons at the opposite end. In most maps, the low-frequency sounds are located anteriorly, as shown in **Fig. 53.10**, and the high-frequency sounds are located posteriorly. This setup is not true for all the maps.

Why does the auditory cortex have so many different tonotopic maps? The answer, presumably, is that each of the separate areas dissects out some specific feature of the sounds. For example, one of the large maps in the primary auditory cortex almost certainly discriminates the

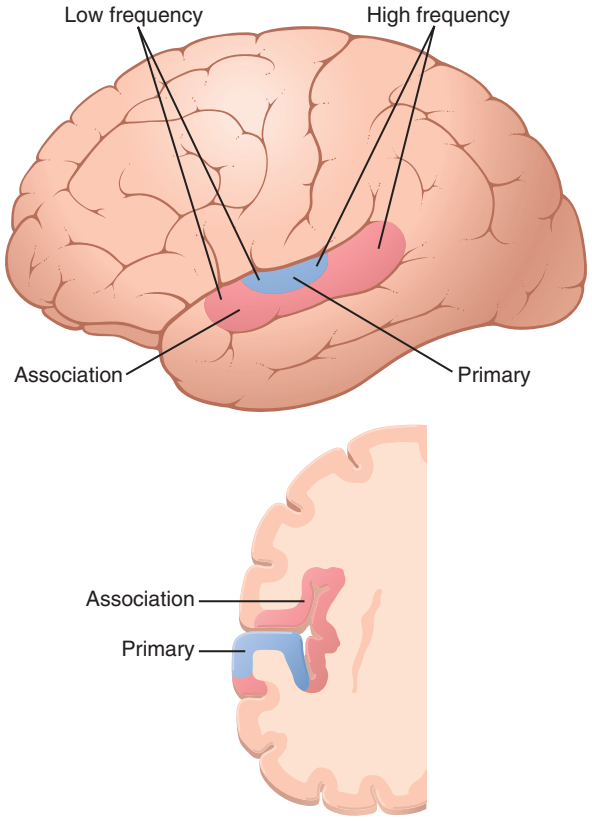

Figure 53.10 Auditory cortex.

sound frequencies and gives the person the psychic sensation of sound pitches. Another map is probably used to detect the direction from which the sound comes. Other auditory cortex areas detect special qualities, such as the sudden onset of sounds, or perhaps special modulations, such as noise versus pure frequency sounds.

The frequency range to which each individual neuron in the auditory cortex responds is much narrower than that in the cochlear and brain stem relay nuclei. Referring to **Fig. 53.5B**, note that the basilar membrane near the base of the cochlea is stimulated by sounds of all frequencies and, in the cochlear nuclei, this same breadth of sound representation is found. Yet, by the time the excitation has reached the cerebral cortex, most sound-responsive neurons respond only to a narrow range of frequencies rather than to a broad range. Therefore, somewhere along the pathway, processing mechanisms "sharpen" the frequency response. This sharpening effect is believed to be caused mainly by lateral inhibition, discussed in Chapter 47 in relation to mechanisms for transmitting information in nerves. That is, stimulation of the cochlea at one frequency inhibits sound frequencies on both sides of this primary frequency; this inhibition is caused by collateral fibers angling off the primary signal pathway and exerting inhibitory influences on adjacent pathways. This same effect is important in sharpening patterns of somesthetic images, visual images, and other types of sensations.

Many of the neurons in the auditory cortex, *especially in the auditory association cortex*, do not respond only to specific sound frequencies in the ear. These neurons may "associate" different sound frequencies with one another or associate sound information with information from other sensory areas of the cortex. Indeed, the parietal portion of the auditory association cortex partly overlaps somatosensory area II, which could provide an opportunity for the association of auditory information with somatosensory information.

Discrimination of Sound "Patterns" By the Auditory Cortex. Complete bilateral removal of the auditory cortex does not prevent a cat or monkey from detecting sounds or reacting in a crude manner to sounds. However, it does greatly reduce or sometimes even abolish the animal's ability to discriminate different sound pitches and especially *patterns of sound*. For example, an animal that has been trained to recognize a combination or sequence of tones, one following the other in a particular pattern, loses this ability when the auditory cortex is destroyed; furthermore, the animal cannot relearn this type of response. Therefore, the auditory cortex is especially important in the discrimination of *tonal* and *sequential sound patterns*.

Destruction of both primary auditory cortices in the human being greatly reduces one's sensitivity for hearing. Destruction of one side only slightly reduces hearing in the opposite ear; it does not cause deafness in the ear because of many crossover connections from side to side in the auditory neural pathway. However, it does affect one's ability to localize the source of a sound because comparative signals in both cortices are required for sound localization.

Lesions that affect the auditory association areas but not the primary auditory cortex do not decrease a person's ability to hear and differentiate sound tones or even to interpret at least simple patterns of sound. However, the person is often unable to interpret the *meaning* of the sound heard. For example, lesions in the posterior portion of the superior temporal gyrus, which is called the *Wernicke area* and is part of the auditory association cortex, often make it impossible for a person to interpret the meanings of words even though they hear them perfectly well and can even repeat them. These functions of the auditory association areas and their relation to the overall intellectual functions of the brain are discussed in Chapter 58.

DETERMINATION OF THE DIRECTION FROM WHICH SOUND COMES

A person determines the horizontal direction from which sound comes by two principal means: (1) the time lag between the entry of sound into one ear and its entry into the opposite ear; and (2) the difference between the intensities of the sounds in the two ears.

The first mechanism functions best at frequencies below 3000 cycles/sec, and the second mechanism operates best at higher frequencies because the head is a greater sound barrier at these frequencies. The time lag mechanism discriminates direction much more exactly than the intensity mechanism because it does not depend on extraneous factors but only on the exact interval of time between two acoustical signals. If a person is looking straight toward the source of the sound, the sound reaches both ears at exactly the same instant, whereas if the right ear is closer to the sound than the left ear is, the sound signals from the right ear enter the brain ahead of those from the left ear.

These two mechanisms cannot tell whether the sound is emanating from in front of or behind the person or from above or below. This discrimination is achieved mainly by the *pinnae* (the visible outer part), which act as funnels to direct the sound into the two ears. The shape of the pinna changes the *quality* of the sound entering the ear, depending on the direction from which the sound comes, by emphasizing specific sound frequencies from the different directions.

Neural Mechanisms for Detecting Sound Direction. Destruction of the auditory cortex on both sides of the brain causes loss of almost all ability to detect the direction from which sound comes. Yet, the neural analyses for this detection process begin in the *superior olivary nuclei* in the brain stem, even though the neural pathways all the way from these nuclei to the cortex are required for interpretation of the signals.

The superior olivary nucleus is divided into two sections: (1) the *medial superior olivary nucleus;* and (2) the *lateral superior olivary nucleus*. The lateral nucleus is concerned with detecting the direction from which the sound is coming, presumably by comparing the *difference in intensities of the sound* reaching the two ears and sending an appropriate signal to the auditory cortex to estimate the direction.

The *medial superior olivary nucleus*, however, has a specific mechanism for *detecting the time lag between acoustical signals entering the two ears*. This nucleus contains large numbers of neurons that have two major dendrites, one projecting to the right and the other to the left. The acoustical signal from the right ear impinges on the right dendrite, and the signal from the left ear impinges on the left dendrite. The intensity of excitation of each neuron is highly sensitive to a specific time lag between the two acoustical signals from the two ears. The neurons near one border of the nucleus respond maximally to a short time lag, whereas those near the opposite border respond to a long time lag; those in between respond to intermediate time lags.

Thus, a spatial pattern of neuronal stimulation develops in the medial superior olivary nucleus, with sound from directly in front of the head stimulating one set of olivary neurons maximally and sounds from different side angles stimulating other sets of neurons on opposite sides. This spatial orientation of signals is then transmitted to the auditory cortex, where sound direction is determined by the locus of the maximally stimulated neurons. All these signals for determining sound direction are thought to be transmitted through a different pathway and excite a different locus in the cerebral cortex from the transmission pathway and termination locus for tonal patterns of sound.

This mechanism for detection of sound direction indicates again how specific information in sensory signals is dissected out as the signals pass through different levels of neuronal activity. In this case, the "quality" of sound direction is separated from the "quality" of sound tones at the level of the superior olivary nuclei.

Centrifugal Signals From the Central Nervous System to Lower Auditory Centers

Retrograde pathways have been demonstrated at each level of the auditory nervous system from the brain cortex to the cochlea in the ear. The final pathway is mainly from the superior olivary nucleus to the sound-receptor hair cells in the organ of Corti.

These retrograde fibers are inhibitory. Indeed, direct stimulation of discrete points in the olivary nucleus has been shown to inhibit specific areas of the organ of Corti, reducing their sound sensitivities by 15 to 20 decibels. This mechanism allows a person to direct their attention to sounds of particular qualities while rejecting sounds of other qualities. This characteristic is readily demonstrated when one listens to a single instrument in a symphony orchestra.

Types of Deafness

Deafness is usually divided into two types: (1) that caused by impairment of the cochlea, the auditory nerve, or the central nervous system circuits from the ear, which is usually classified as "nerve deafness," and (2) that caused by impairment of the physical structures of the ear that conduct sound to the cochlea, which is usually called "conduction deafness."

If either the cochlea or the auditory nerve is destroyed, the person becomes permanently deaf. However, if the cochlea and nerve are still intact but the tympanum-ossicular system has been destroyed or ankylosed ("frozen" in place by fibrosis or calcification), sound waves can still be conducted into the cochlea by means of bone conduction from a sound generator applied to the skull over the ear.

Audiometer. An *audiometer* can be used to assess the nature of hearing disabilities. This instrument is an earphone connected to an electronic oscillator capable of emitting pure tones ranging from low frequencies to high frequencies, and it is calibrated so that zero-intensity-level sound at each frequency is the loudness that can barely be heard by the normal ear. A calibrated volume control can increase the loudness above the zero level. If the loudness must be increased to 30 decibels above normal before it can be heard, the person is said to have a *hearing loss* of 30 decibels at that particular frequency.

In performing a hearing test using an audiometer, one tests about 8 to 10 frequencies covering the auditory spectrum, and the hearing loss is determined for each of these frequencies. Then an *audiogram* is plotted, as shown in **Figs. 53.11 and 53.12**, depicting hearing loss at each of the frequencies in the auditory spectrum. An audiometer for testing air conduction is equipped with an earphone for each ear and a feedback button used by the test subject to acknowledge hearing the sound. The audiometer is also equipped with a mechanical vibrator for testing bone conduction from the mastoid process of the skull into the cochlea.

Audiogram in Nerve Deafness. In nerve deafness, which includes damage to the cochlea, the auditory nerve, or the central nervous system circuits from the ear, the person has loss of ability to hear sound as tested by both air conduction and bone conduction. An audiogram depicting partial nerve deafness is shown in **Fig. 53.11**. In this figure, the deafness is mainly for high-frequency sound. Such deafness could be caused by damage to the base of the cochlea. This type of deafness occurs to some extent in almost all older people.

Other patterns of nerve deafness frequently occur as follows: (1) deafness for low-frequency sounds caused by excessive and prolonged exposure to very loud sounds (e.g., a rock band or a jet airplane engine) because low-frequency sounds are usually louder and more damaging to the organ of Corti; and (2) deafness for all frequencies caused by drug sensitivity of the organ of Corti—in particular, sensitivity to some antibiotics such as streptomycin, gentamicin, kanamycin, and chloramphenicol.

Audiogram for Middle Ear Conduction Deafness. A common type of deafness is caused by fibrosis in the middle ear after repeated infection or by fibrosis that occurs in the hereditary disease called *otosclerosis*. In either case, the sound waves cannot be transmitted easily through the ossicles from the tympanic membrane to the oval window. **Fig. 53.12** shows an audiogram from a person with "middle ear air conduction deafness." In this case, bone conduction is essentially normal, but conduction through the ossicular system is greatly depressed at all frequencies, but more so at low frequencies.

In some cases of conduction deafness, the faceplate of the stapes becomes "ankylosed" by bone overgrowth to the edges of the oval window. Here, the person becomes totally deaf for ossicular conduction but can regain almost normal hearing by the surgical removal of the stapes and its replacement with a minute Teflon or metal prosthesis that transmits the sound from the incus to the oval window.

CHAPTER 54

The Chemical Senses—Taste and Smell

The senses of taste and smell allow us to separate undesirable or even lethal foods from those that are pleasant to eat and nutritious. They also elicit physiological responses involved in the digestion and utilization of foods. The sense of smell also allows animals to recognize the proximity of other animals or even individual animals. Finally, both senses are strongly tied to emotional and behavioral functions of our nervous systems. In this chapter, we discuss how taste and smell stimuli are detected and how they are encoded in neural signals transmitted to the brain.

SENSE OF TASTE

Taste is mainly a function of the *taste buds* in the mouth, but one's sense of smell also contributes strongly to taste perception. In addition, the texture of food, as detected by tactual senses of the mouth, and the presence of substances in the food that stimulate pain endings, such as pepper, greatly alter the taste experience. The importance of taste lies in the fact that it allows a person to select food in accord with desires and often in accord with the body tissues' metabolic need for specific substances.

PRIMARY TASTE SENSATIONS

The identities of the many specific chemicals that excite different taste receptors are not all known. For practical analysis, the *primary sensations of taste* have been grouped into five general categories—*sour, salty, sweet, bitter*, and "*umami*." There is emerging evidence that *fat taste* may be another major taste modality.

A person can perceive hundreds of different tastes. They are all thought to be combinations of the elementary taste sensations, just as all the colors we can see are combinations of the three primary colors, as described in Chapter 51.

Sour Taste. The sour taste is caused by acids—that is, by the hydrogen ion concentration—and the intensity of this taste sensation is approximately proportional to the *logarithm of the hydrogen ion concentration*; the more acidic the food, the stronger the sour sensation becomes.

Salty Taste. The salty taste is elicited by ionized salts, mainly by the sodium ion concentration. The quality of the taste varies somewhat from one salt to another because some salts elicit other taste sensations in addition to saltiness. The cations of the salts, especially sodium cations, are mainly responsible for the salty taste, but the anions also contribute to a lesser extent.

Sweet Taste. The sweet taste is not caused by any single class of chemicals. Some of the types of chemicals that cause this taste include sugars, glycols, alcohols, aldehydes, ketones, amides, esters, some amino acids, some small proteins, sulfonic acids, halogenated acids, and inorganic salts of lead and beryllium. Most of the substances that cause a sweet taste are organic chemicals. It is especially interesting that slight changes in the chemical structure, such as the addition of a simple radical, can often change the substance from sweet to bitter.

Bitter Taste. The bitter taste, like the sweet taste, is not caused by any single type of chemical agent. Here again, the substances that give the bitter taste are almost entirely organic substances. Two particular classes of substances are especially likely to cause bitter taste sensations: (1) long-chain organic substances that contain nitrogen; and (2) alkaloids. The alkaloids include many of the drugs used in medicines, such as quinine, caffeine, strychnine, and nicotine.

Some substances that initially taste sweet have a bitter aftertaste. This characteristic is true of saccharin, which makes this substance objectionable to some people. High concentrations of salts may also result in a bitter taste.

The bitter taste, when it occurs in high intensity, usually causes the person or animal to reject the food. This reaction is undoubtedly an important function of the bitter taste sensation because many deadly toxins found in poisonous plants are alkaloids, and virtually all these alkaloids cause an intensely bitter taste, usually followed by rejection of the food.

Umami Taste. *Umami*, a Japanese word meaning "delicious," designates a pleasant taste sensation that is qualitatively different from sour, salty, sweet, or bitter. Umami is the dominant taste of food containing L-*glutamate*, such as meat extracts and aging cheese. The pleasurable

sensation of umami taste is thought to be important for nutrition by promoting ingestion of proteins.

THRESHOLD FOR TASTE

The molar threshold for stimulation of the sour taste by hydrochloric acid averages 0.0009 M; for stimulation of the salty taste by sodium chloride, 0.01 M; for the sweet taste by sucrose, 0.01 M; and for the bitter taste by quinine, 0.000008 M. Note especially that the bitter taste sense is much more sensitive than all the others, which provides an important protective function against many dangerous toxins in food.

Table 54.1 lists the relative taste indices (the reciprocals of the taste thresholds) of different substances. In this table, the intensities of four of the primary sensations of taste are referred, respectively, to the intensities of the taste of hydrochloric acid, quinine, sucrose, and sodium chloride, each of which is arbitrarily chosen to have a taste index of 1.

Taste Blindness. Some people are taste blind for certain substances, especially for different types of thiourea compounds. A substance used frequently by psychologists for demonstrating taste blindness is *phenylthiocarbamide*, for which about 15% to 30% of all people exhibit taste blindness; the exact percentage depends on the method of testing and the concentration of the substance.

TASTE BUDS AND THEIR FUNCTION

Fig. 54.1B shows a taste bud, which has a diameter of about 1/30 of a millimeter and a length of about 1/16 of a millimeter. The taste bud is composed of epithelial cells; some are supporting cells called *sustentacular cells* and others are called *taste cells*. There are about 100 taste cells in each taste bud. The taste cells are continually being replaced by mitotic division of surrounding epithelial cells, so some taste cells are young cells. Others are mature cells that lie toward the center of the bud; these cells soon break up and dissolve. The average life span of each taste cell is estimated to be about 10 days, although there is considerable variation, with some taste cells being eliminated in only 2 days while others may survive for over 3 weeks.

The outer tips of the taste cells are arranged around a minute *taste pore*, shown in **Fig. 54.1B**. From the tip of each taste cell, several *microvilli*, or *taste hairs*, protrude outward into the taste pore to approach the cavity of the mouth. These microvilli provide the receptor surface for taste.

Interwoven around the bodies of the taste cells is a branching terminal network of *taste nerve fibers* that are stimulated by the taste receptor cells. Some of these fibers invaginate into folds of the taste cell membranes. In some of the taste cells, many vesicles form beneath the cell membrane near the fibers. These vesicles contain neurotransmitter substances that are released through the cell membrane to excite the nerve fiber endings in response to taste stimulation. Sour taste cells have typical synapses and release the neurotransmitter *serotonin* (5-hydroxytryptamine; 5-HT). Sweet, salty, umami, and bitter taste cells do not appear to have typical synaptic vesicles, but upon stimulation they produce and release ATP, which serves as a neurotransmitter, distinct from its role in supplying energy for metabolic processes of the taste cells. Additional neurotransmitters, including acetylcholine, have also been implicated in transmission of nervous signals from taste cells.

Table 54.1 Relative Taste Indices of Different Substances

Sour Substances	Index	Bitter Substances	Index	Sweet Substances	Index	Salty Substances	Index
Hydrochloric acid	1	Quinine	1	Sucrose	1	NaCl	1
Formic acid	1.1	Brucine	11	1-Propoxy-2-amino-4-nitrobenzene	5000	NaF	2
Chloroacetic acid	0.9	Strychnine	3.1	Saccharin	675	$CaCl_2$	1
Acetoacetic acid	0.85	Nicotine	1.3	Chloroform	40	NaBr	0.4
Lactic acid	0.85	Phenylthiourea	0.9	Fructose	1.7	NaI	0.35
Tartaric acid	0.7	Caffeine	0.4	Alanine	1.3	LiCl	0.4
Malic acid	0.6	Veratrine	0.2	Glucose	0.8	NH_4Cl	2.5
Potassium H tartrate	0.58	Pilocarpine	0.16	Maltose	0.45	KCl	0.6
Acetic acid	0.55	Atropine	0.13	Galactose	0.32		
Citric acid	0.46	Cocaine	0.02	Lactose	0.3		
Carbonic acid	0.06	Morphine	0.02				

$CaCl_2$, Calcium chloride; *KCl*, potassium chloride; *LiCl*, lithium chloride; *NaBr*, sodium bromide; *NaCl*, sodium chloride; *NaF*, sodium fluoride; *NaI*, sodium iodide; *NH_4Cl*, ammonium chloride.
Data from Pfaffman C. *Handbook of Physiology*. Vol 1. Baltimore: Williams & Wilkins; 1959 [p. 507].

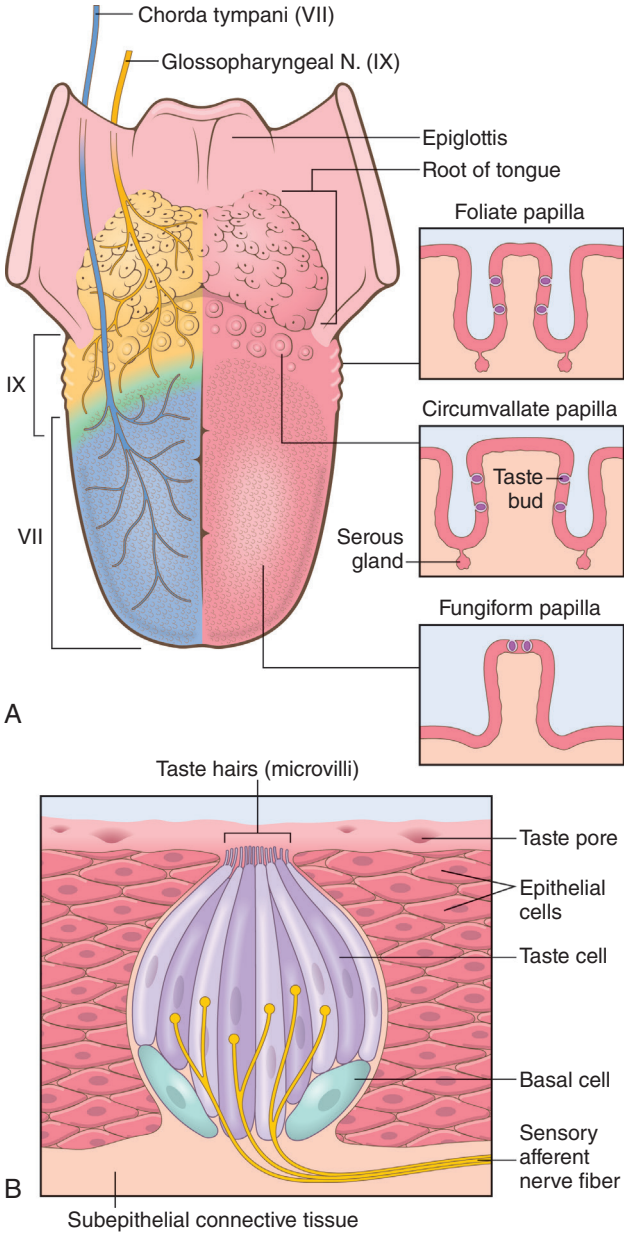

Figure 54.1 (A) Distribution of taste buds in papillae of the tongue and neuronal pathways for transmission of taste signals. (B) Structure of a taste bud. *N.*, Nerve.

Location of the Taste Buds. The taste buds are found on three types of papillae of the tongue, as follows (**Fig. 54.1A**): (1) a large number of taste buds are on the walls of the troughs that surround the *circumvallate papillae*, which form a V line on the surface of the posterior tongue; (2) moderate numbers are on the *foliate papillae*, located in the folds along the lateral surfaces of the tongue; and (3) moderate numbers of taste buds are on the *fungiform papillae* over the flat anterior surface of the tongue. Additional taste buds are located on the palate, and a few are found on the tonsillar pillars, on the epiglottis, and even in the proximal esophagus. Adults have 3000 to 10,000 taste buds, and children have a few more. Beyond the age of 45 years, many taste buds degenerate, causing taste sensitivity to decrease in older people.

Specificity of Taste Buds for a Primary Taste Stimulus. Microelectrode studies from single taste buds show that each taste bud usually *responds mostly to one of the five primary taste stimuli when the taste substance is in low concentration*. However, at high concentration, most buds can be excited by two or more of the primary taste stimuli, as well as by a few other taste stimuli that do not fit into the "primary" categories.

Mechanism of Stimulation of Taste Buds

Receptor Potential. The membrane of the taste cell, like that of most other sensory receptor cells, is negatively charged on the inside with respect to the outside. Application of a taste substance to the taste hairs causes partial loss of this negative potential—that is, the taste cell becomes *depolarized*. In most cases, the decrease in potential, within a wide range, is approximately proportional to the logarithm of concentration of the stimulating substance. This *change in electrical potential* in the taste cell is called the *receptor potential* for taste.

The mechanism whereby most stimulating substances react with the taste villi to initiate the receptor potential is by binding of the taste chemical to a protein receptor molecule that lies on the outer surface of the taste receptor cell, near to or protruding through a villus membrane. This action, in turn, opens ion channels, which allows positively charged sodium ions or hydrogen ions to enter and depolarize the normal negativity of the cell. Then, the taste chemical is gradually washed away from the taste villus by the saliva, which removes the stimulus.

The type of receptor protein in each taste villus determines the type of taste that will be perceived. For sodium ions and hydrogen ions, which elicit salty and sour taste sensations, respectively, the receptor proteins open specific ion channels, likely the epithelial sodium channel (ENaC), in the apical membranes of the taste cells, thereby activating the receptors. However, for the sweet and bitter taste sensations, the portions of the G-protein coupled receptors that protrude through the apical membranes activate *second-messenger transmitter substances* inside the taste cells; these second messengers cause intracellular chemical changes that elicit the taste signals.

Sweet-tasting compounds are detected by a combination of two closely related G-protein-coupled taste receptors, T1R2 and T1R3. The receptor responsible for umami taste is believed to be a complex of T1R1 and T1R3 proteins. Thus, T1R3 appears to function as a co-receptor for sweet and umami tastes.

Bitter taste is sensed by another family (T2R) of approximately 30 different G-protein coupled receptors. Individual bitter-sensing taste receptor cells express multiple T2Rs, each of which recognizes a unique set of bitter compounds. This pattern of receptor expression permits detection of a variety of bitter compounds through a single type of taste receptor cell.

Sour taste, associated with acidic food or drink, is believed to be sensed by ion channels that are opened

by hydrogen ions although the precise mechanisms are not fully understood. Current evidence suggests that an acid-sensitive potassium channel (KIR2.1) and a hydrogen ion–selective ion channel (*otopetrin 1*) may mediate acid responses in taste receptor cells.

Generation of Nerve Impulses By the Taste Bud. On first application of the taste stimulus, the rate of discharge of the nerve fibers from taste buds rises to a peak in a small fraction of a second but then adapts within the next few seconds back to a lower steady level as long as the taste stimulus remains. Thus, a strong immediate signal is transmitted by the taste nerve, and a weaker continuous signal is transmitted as the taste bud partially adapts to the taste stimulus.

TRANSMISSION OF TASTE SIGNALS INTO THE CENTRAL NERVOUS SYSTEM

Figs. 54.1 and 54.2 show the neuronal pathways for transmission of taste signals from the tongue and pharyngeal region into the central nervous system. Taste impulses from the anterior two-thirds of the tongue pass first into the *lingual nerve*, then through the *chorda tympani* into the *facial nerve*, and finally into the *tractus solitarius* in the brain stem. Taste sensations from the circumvallate papillae on the back of the tongue and from other posterior regions of the mouth and throat are transmitted through the *glossopharyngeal nerve* also into the tractus solitarius, but at a slightly more posterior level. Finally, a few taste signals are transmitted into the tractus solitarius from the base of the tongue and other parts of the pharyngeal region by way of the *vagus nerve*.

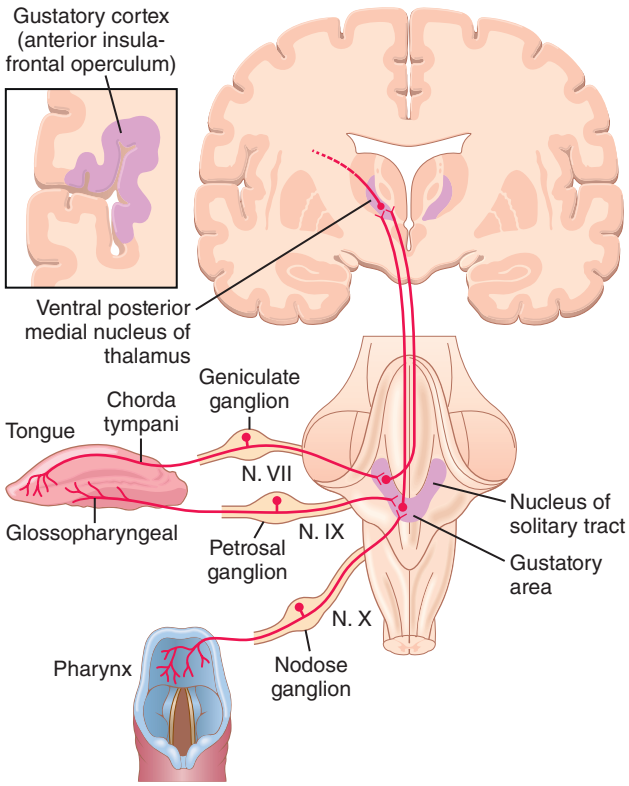

Figure 54.2 Transmission of taste signals into the central nervous system. *N.*, nerve.

All taste fibers synapse in the posterior brain stem in the nuclei of the tractus solitarius. These nuclei send second-order neurons to a small area of the *ventral posterior medial nucleus of the thalamus*, located slightly medial to the thalamic terminations of the facial regions of the dorsal column–medial lemniscal system. From the thalamus, third-order neurons are transmitted to the *lower tip of the postcentral gyrus in the parietal cerebral cortex*, where it curls *deep into the sylvian fissure*, and into the adjacent *opercular insular area*. This area lies slightly lateral, ventral, and rostral to the area for tongue tactile signals in cerebral somatic area I. From this description of the taste pathways, it is evident that they closely parallel the somatosensory pathways from the tongue.

Taste Reflexes Are Integrated in the Brain Stem. From the tractus solitarius, many taste signals are transmitted within the brain stem directly into the *superior* and *inferior salivatory nuclei*. These areas transmit signals to the submandibular, sublingual, and parotid glands to help control the secretion of saliva during the ingestion and digestion of food.

Rapid Adaptation of Taste. Taste sensations adapt rapidly, often almost completely, within a minute or so of continuous stimulation. Yet, from electrophysiological studies of taste nerve fibers, it is clear that adaptation of the taste buds usually accounts for no more than about half of this rapid taste adaptation. Therefore, the final extreme degree of adaptation that occurs in the sensation of taste almost certainly occurs in the central nervous system, although the mechanisms are not known. This mechanism of adaptation is different from that of many other sensory systems, which adapt mainly at the receptors.

TASTE PREFERENCE AND CONTROL OF THE DIET

Taste preference simply means that an animal will choose certain types of food in preference to others, and the animal automatically uses this preference to help control what it eats. Furthermore, its taste preferences often change in accord with the body's need for certain specific substances.

The following experiments demonstrate this ability of animals to choose food in accord with the needs of their bodies. First, adrenalectomized animals that become salt depleted automatically select drinking water with a high concentration of sodium chloride in preference to pure water, and the amount of sodium chloride in the water is often sufficient to supply the needs of the body and prevent death due to salt depletion. Second, an animal given injections of excessive amounts of insulin develops

a depleted blood sugar level, and the animal automatically chooses the sweetest food from among many samples. Third, calcium-depleted, parathyroidectomized animals choose drinking water with a high concentration of calcium chloride.

The same phenomena are also observed in everyday life. For example, the "salt licks" of desert regions are known to attract animals from far and wide. Also, human beings reject food that has an unpleasant affective sensation, which in many cases protects us from undesirable substances.

The phenomenon of taste preference almost certainly results from some mechanism located in the central nervous system and not directly from a mechanism in the taste receptors, although the receptors often become sensitized in favor of a needed nutrient. An important reason for believing that taste preference is mainly a central nervous system phenomenon is that previous experience with unpleasant or pleasant tastes plays a major role in determining one's taste preferences. For example, if a person becomes sick soon after eating a particular type of food, the person then generally develops a negative taste preference, or *taste aversion*, for that particular food; the same effect can be demonstrated in lower animals.

SENSE OF SMELL

Smell is perhaps the least understood of our senses, partly because the sense of smell is a subjective phenomenon that cannot be studied with ease in lower animals. Another complicating problem is that the sense of smell is poorly developed in human beings compared with many other mammals.

OLFACTORY MEMBRANE

The olfactory membrane, the histology of which is shown in **Fig. 54.3**, lies in the superior part of the nasal cavity. Medially, the olfactory membrane folds downward along the surface of the superior septum; laterally, it folds over the superior turbinate and even over a small portion of the upper surface of the middle turbinate. The olfactory membrane has a total surface area of about 5 square centimeters in humans.

Olfactory Cells Are the Receptor Cells for Smell Sensation. The *olfactory cells* (**Fig. 54.3**) are actually bipolar nerve cells derived originally from the central nervous system. There are about 100 million of these cells in the olfactory epithelium interspersed among *sustentacular cells*, also shown in **Fig. 54.3**. The mucosal end of the olfactory cell forms a knob from which 4 to 25 *olfactory hairs* (also called *olfactory cilia*), measuring 0.3 micrometer in diameter and up to 200 micrometers in length, project into the mucus that coats the inner surface of the nasal cavity. These projecting olfactory cilia form a dense mat in the mucus, and it is these cilia that react to odors in the air and stimulate the olfactory cells, as discussed later.

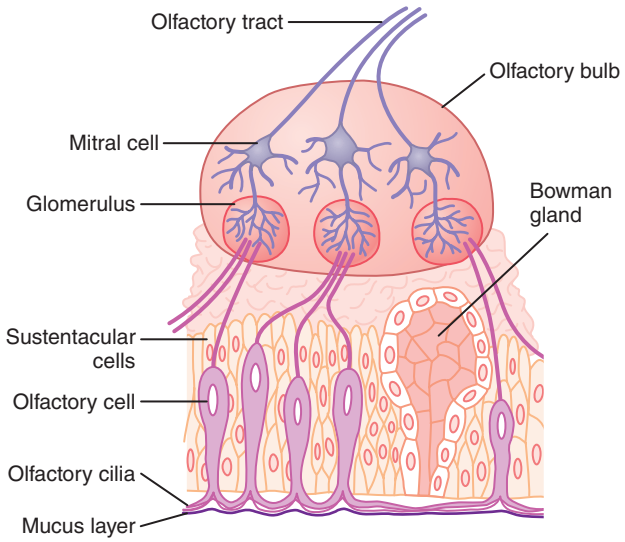

Figure 54.3 Organization of the olfactory membrane and olfactory bulb and connections to the olfactory tract.

Spaced among the olfactory cells in the olfactory membrane are many small *Bowman glands* that secrete mucus onto the surface of the olfactory membrane.

STIMULATION OF THE OLFACTORY CELLS

Mechanism of Excitation of the Olfactory Cells. The portion of each olfactory cell that responds to the olfactory chemical stimuli is the *olfactory cilia*. The odorant substance, on coming in contact with the olfactory membrane surface, first diffuses into the mucus that covers the cilia and then it binds with *receptor proteins* in the membrane of each cilium (**Fig. 54.4**). Each receptor protein is actually a long molecule that threads its way through the membrane about seven times, folding inward and outward. The odorant binds with the portion of the receptor protein that folds to the outside. The inside of the folding protein is coupled to a *G protein* comprised of three subunits.

On excitation of the receptor protein, an *alpha* subunit breaks away from the G protein and activates *adenylyl cyclase*, which is attached to the inside of the ciliary membrane near the receptor cell body. The activated cyclase, in turn, converts many molecules of intracellular *adenosine triphosphate* (ATP) into *cyclic adenosine monophosphate* (cAMP). Finally, this cAMP activates another nearby membrane protein, a *gated sodium ion channel*, which opens its "gate" and allows large numbers of sodium ions to pour through the membrane into the receptor cell cytoplasm. The sodium ions increase the electrical potential in the positive direction inside the cell membrane, thus exciting the olfactory neuron and transmitting action potentials into the central nervous system via the *olfactory nerve*.

The importance of this mechanism for activating olfactory nerves is that it greatly multiplies the excitatory effect

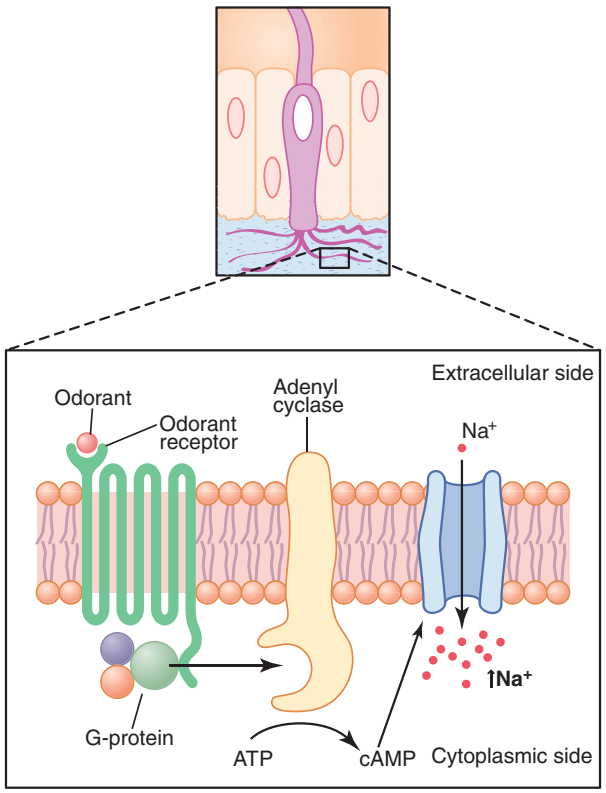

Figure 54.4 Summary of olfactory signal transduction. Binding of the odorant to a G-protein–coupled receptor causes the activation of adenylate cyclase, which converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). The cAMP activates a gated sodium channel that increases sodium influx and depolarizes the cell, exciting the olfactory neuron and transmitting action potentials to the central nervous system.

of even the weakest odorant. To summarize: (1) activation of the receptor protein by the odorant substance activates the G-protein complex, which (2) activates multiple molecules of adenylyl cyclase inside the olfactory cell membrane, which (3) causes the formation of many times more molecules of cAMP, and finally, (4) the cAMP opens still many times more sodium ion channels. Therefore, even a minute concentration of a specific odorant initiates a cascading effect that opens extremely large numbers of sodium channels. This process accounts for the exquisite sensitivity of the olfactory neurons to even the slightest amount of odorant.

In addition to the basic chemical mechanism whereby the olfactory cells are stimulated, several physical factors affect the degree of stimulation. First, only volatile substances that can be sniffed into the nasal cavity can be smelled. Second, the stimulating substance must be at least slightly water-soluble so that it can pass through the mucus to reach the olfactory cilia. Third, it is helpful for the substance to be at least slightly lipid-soluble, presumably because lipid constituents of the cilium are a weak barrier to non–lipid-soluble odorants.

Membrane Potentials and Action Potentials in Olfactory Cells. The membrane potential inside unstimulated olfactory cells, as measured by microelectrodes, averages about −55 millivolts. At this potential, most of the cells generate continuous action potentials at a very slow rate, varying from once every 20 seconds up to two or three per second.

Most odorants cause *depolarization* of the olfactory cell membrane, decreasing the negative potential in the cell from the normal level of −55 millivolts to −30 millivolts or less. Along with this, the number of action potentials increases to 20 to 30 per second, which is a high rate for the minute olfactory nerve fibers.

Over a wide range, the rate of olfactory nerve impulses changes approximately in proportion to the logarithm of the stimulus strength, indicating that the olfactory receptors obey principles of transduction similar to those of other sensory receptors.

Rapid Adaptation of Olfactory Sensations. The olfactory receptors adapt about 50% in the first second or so after stimulation. Thereafter, they adapt very little and very slowly. Yet, we all know from our own experience that smell sensations adapt almost to extinction within a minute or so after entering a strongly odorous atmosphere. Because this psychological adaptation is far greater than the degree of adaptation of the receptors, it is almost certain that most of the additional adaptation occurs in the central nervous system, which seems to be true for the adaptation of taste sensations as well.

The following neuronal mechanism for the adaptation is postulated: large numbers of centrifugal nerve fibers pass from the olfactory regions of the brain backward along the olfactory tract and terminate on special inhibitory cells in the olfactory bulb, the *granule cells*. After the onset of an olfactory stimulus, the central nervous system quickly develops strong feedback inhibition to suppress relay of the smell signals through the olfactory bulb.

Search for the Primary Sensations of Smell

In the past, most physiologists were convinced that the many smell sensations are subserved by a few rather discrete primary sensations in the same way that vision and taste are subserved by a few select primary sensations. On the basis of psychological studies, one attempt to classify these sensations is the following:

1. Camphoraceous
2. Musky
3. Floral
4. Pepperminty
5. Ethereal
6. Pungent
7. Putrid

It is certain that this list does not represent the true primary sensations of smell. Multiple clues, including studies of the genes that encode for the receptor proteins, suggest the existence of at least 100 primary sensations of smell—a marked contrast to only three primary sensations of color detected by the eyes and only five primary

sensations of taste detected by the tongue. Some studies suggest that there may be as many as 1000 different types of odorant receptors. Further support for the many primary sensations of smell is that people have been found who have *odor blindness* for single substances; such discrete odor blindness has been identified for more than 50 different substances. It is presumed that odor blindness for each substance represents lack of the appropriate receptor protein in olfactory cells for that particular substance.

Affective Nature of Smell. Smell, even more so than taste, has the affective quality of either *pleasantness* or *unpleasantness*, and thus smell is probably even more important than taste for selection of food. A person who has previously eaten food that was unpleasant is often nauseated by the smell of that same food on a second occasion. Conversely, perfume of the right quality can be a powerful stimulant of human emotions. In addition, in some animals, odors are the primary excitant of sexual drive.

Threshold for Smell. One of the principal characteristics of smell is the minute quantity of stimulating agent in the air that can elicit a smell sensation. For example, the substance *methylmercaptan* can be smelled when only one 25-trillionth of a gram is present in each milliliter of air. Because of this very low threshold, this substance is mixed with natural gas to give the gas an odor that can be detected when even small amounts of gas leak from a pipeline.

Gradations of Smell Intensities. Although the threshold concentrations of substances that evoke smell are extremely slight, for many (if not most) odorants, concentrations only 10 to 50 times above the threshold evoke maximum intensity of smell. This range of intensity discrimination is in contrast to most other sensory systems of the body, in which the ranges of intensity discrimination are tremendous—for example, 500,000 to 1 for the eyes and 1 trillion to 1 for the ears. This difference might be explained by the fact that smell is concerned more with detecting the presence or absence of odors rather than with quantitative detection of their intensities.

TRANSMISSION OF SMELL SIGNALS INTO THE CENTRAL NERVOUS SYSTEM

The olfactory portions of the brain were among the first brain structures developed in primitive animals, and much of the remainder of the brain appears to have developed around these olfactory beginnings. In fact, part of the brain that originally subserved olfaction later evolved into the basal brain structures that control emotions and other aspects of human behavior; we call this system the *limbic system*, as discussed in Chapter 59.

Transmission of Olfactory Signals Into the Olfactory Bulb. The *olfactory bulb* is shown in **Fig. 54.5**. The olfactory nerve fibers leading backward from the bulb are called *cranial nerve I*, or the *olfactory tract*. In reality, both the tract and the bulb are anterior outgrowths of brain tissue from the base of the brain; the bulbous enlargement at its end, the *olfactory bulb*, lies over the *cribriform plate*, separating the brain cavity from the upper reaches of the nasal cavity. The cribriform plate has multiple small perforations through which an equal number of small nerves pass upward from the olfactory membrane in the nasal cavity to enter the olfactory bulb in the cranial cavity.

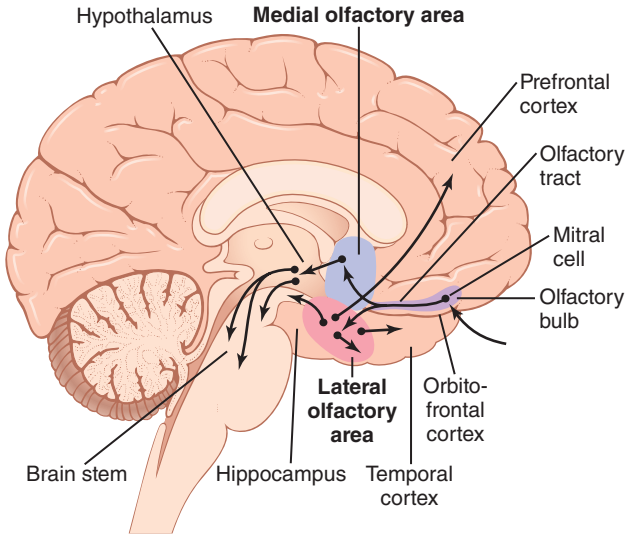

Figure 54.5 Neural connections of the olfactory system.

Fig. 54.3 illustrates the close relation between the *olfactory cells* in the olfactory membrane and the olfactory bulb, showing short axons from the olfactory cells terminating in multiple globular structures in the olfactory bulb called *glomeruli*. Each bulb has several thousand glomeruli, each of which is the terminus for about 25,000 axons from olfactory cells. Each glomerulus also is the terminus for dendrites from about 25 large *mitral cells* and about 60 smaller *tufted cells*, the cell bodies of which lie in the olfactory bulb superior to the glomeruli. These dendrites receive synapses from the olfactory cell neurons; the mitral and tufted cells send axons through the olfactory tract to transmit olfactory signals to higher levels in the central nervous system.

Some research has suggested that different glomeruli respond to different odors. It is possible that specific glomeruli are the real clue to the analysis of different odor signals transmitted into the central nervous system.

Primitive and Newer Olfactory Pathways Into the Central Nervous System

The olfactory tract enters the brain at the anterior junction between the mesencephalon and cerebrum; there, the tract divides into two pathways, as shown in **Fig. 54.5**, one passing medially into the *medial olfactory area* of the brain stem and the other passing laterally into the *lateral olfactory area*. The medial olfactory area represents a

primitive olfactory system, whereas the lateral olfactory area is the input to the following: (1) a less old olfactory system; and (2) a newer system.

The Primitive Olfactory System—The Medial Olfactory Area. The medial olfactory area consists of a group of nuclei located in the midbasal portions of the brain immediately anterior to the hypothalamus. Most conspicuous are the *septal nuclei*, which are midline nuclei that feed into the hypothalamus and other primitive portions of the brain's limbic system. This is the brain area most concerned with basic behavior (as described in Chapter 59).

The importance of this medial olfactory area is best understood by considering what happens in animals when the lateral olfactory areas on both sides of the brain are removed, and only the medial system remains. The removal of these areas hardly affects the more basic responses to olfaction, such as licking the lips, salivation, and other feeding responses caused by the smell of food or by basic emotional drives associated with smell. Conversely, removal of the lateral areas abolishes the more complicated olfactory conditioned reflexes.

The Less Old Olfactory System—The Lateral Olfactory Area. The lateral olfactory area is composed mainly of the *prepyriform* and *pyriform cortex* plus the *cortical portion of the amygdaloid nuclei*. From these areas, signal pathways pass into almost all portions of the limbic system, especially into less primitive portions such as the hippocampus, which seem to be most important for learning to like or dislike certain foods, depending on one's experiences with them. For example, it is believed that this lateral olfactory area and its many connections with the limbic behavioral system cause a person to develop an absolute aversion to foods that have caused nausea and vomiting.

An important feature of the lateral olfactory area is that many signal pathways from this area also feed directly into an *older part of the cerebral cortex* called the *paleocortex* in the *anteromedial portion of the temporal lobe*. This area is the only area of the entire cerebral cortex where sensory signals pass directly to the cortex without passing first through the thalamus.

The Newer Pathway. A newer olfactory pathway that passes through the thalamus, passing to the dorsomedial thalamic nucleus and then to the lateroposterior quadrant of the orbitofrontale cortex, has been found. On the basis of studies in monkeys, this newer system probably helps in the conscious analysis of odor.

Summary. Thus, there appear to be a *primitive* olfactory system that subserves the basic olfactory reflexes, a *less old* system that provides automatic but partially learned control of food intake and aversion to toxic and unhealthy foods, and a *newer* system that is comparable to most of the other cortical sensory systems and is used for conscious perception and analysis of olfaction.

Centrifugal Control of Activity in the Olfactory Bulb By the Central Nervous System. Many nerve fibers that originate in the olfactory portions of the brain pass from the brain in the outward direction into the olfactory tract to the olfactory bulb (i.e., centrifugally from the brain to the periphery). These nerve fibers terminate on a large number of small *granule cells* located among the mitral and tufted cells in the olfactory bulb. The granule cells send inhibitory signals to the mitral and tufted cells. This inhibitory feedback may be a means for sharpening a person's specific ability to distinguish one odor from another.

CHAPTER 55

Spinal Cord Motor Functions; The Cord Reflexes

Sensory information is integrated at all levels of the nervous system and causes appropriate motor responses that begin in the spinal cord with relatively simple muscle reflexes, extend into the brain stem with more complicated responses, and finally extend to the cerebrum, where the most complicated muscle skills are controlled.

In this chapter, we discuss spinal cord control of muscle function. Without the special neuronal circuits of the cord, even the most complex motor control systems in the brain could not cause any purposeful muscle movement. For example, there is no neuronal circuit anywhere in the brain that causes the specific to-and-fro movements of the legs that are required in walking. Instead, the circuits for these movements are in the cord, and the brain simply sends *command* signals to the spinal cord to set into motion the walking process.

The brain gives directions that control the sequential cord activities—for example, to promote turning movements when they are required, to lean the body forward during acceleration, to change the movements from walking to jumping as needed, and to monitor continuously and control equilibrium. All this is done through "analytical" and "command" signals generated in the brain. However, the many neuronal circuits of the spinal cord that are the objects of the commands are also required. These circuits provide all but a small fraction of the direct control of the muscles.

ORGANIZATION OF THE SPINAL CORD FOR MOTOR FUNCTIONS

The cord gray matter is the integrative area for the cord reflexes. **Fig. 55.1** shows the typical organization of the cord gray matter in a single cord segment. Sensory signals enter the cord almost entirely through the sensory roots, also known as the *posterior* or *dorsal roots*. After entering the cord, every sensory signal travels to two separate destinations: one branch of the sensory nerve terminates almost immediately in the gray matter of the cord and elicits local segmental cord reflexes and other local effects; another branch transmits signals to higher levels of the nervous system—that is, to higher levels in the cord, to the brain stem, or even to the cerebral cortex, as described in earlier chapters.

Each segment of the spinal cord (at the level of each spinal nerve) has several million neurons in its gray matter. Aside from the sensory relay neurons discussed in Chapters 48 and 49, the other neurons are of two types: (1) *anterior motor neurons* and (2) *interneurons*.

Anterior Motor Neurons. Located in each segment of the anterior horns of the cord gray matter are several thousand neurons that are 50% to 100% larger than most of the others and are called *anterior motor neurons* (**Fig. 55.2**). They give rise to the nerve fibers that leave the cord by way of the anterior roots and directly innervate the skeletal muscle fibers. The neurons are of two types, *alpha motor neurons* and *gamma motor neurons*.

Alpha Motor Neurons. The alpha motor neurons give rise to large type A alpha (Aα) motor nerve fibers, averaging 14 micrometers in diameter; these fibers branch many times after they enter the muscle and innervate the large skeletal muscle fibers. Stimulation of a single alpha

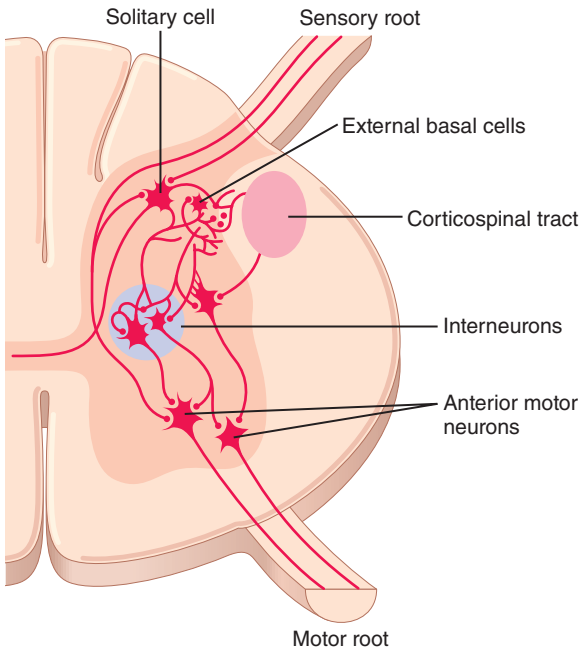

Figure 55.1 Connections of peripheral sensory fibers and corticospinal fibers with the interneurons and anterior motor neurons of the spinal cord.

nerve fiber excites from three to several hundred skeletal muscle fibers, which are collectively called the *motor unit*. Transmission of nerve impulses into skeletal muscles and their stimulation of the muscle motor units are discussed in Chapters 6 and 7.

Gamma Motor Neurons. Along with the alpha motor neurons, which excite contraction of the skeletal muscle fibers, about one-half as many much smaller *gamma motor neurons* are located in the spinal cord anterior horns. These gamma motor neurons transmit impulses through much smaller type A gamma (Aγ) motor nerve fibers, averaging 5 micrometers in diameter, which go to small, special skeletal muscle fibers called *intrafusal fibers*, shown in **Figs. 55.2** and **55.3**. These fibers constitute the middle of the *muscle spindle*, which helps control basic muscle "tone," as discussed later in this chapter.

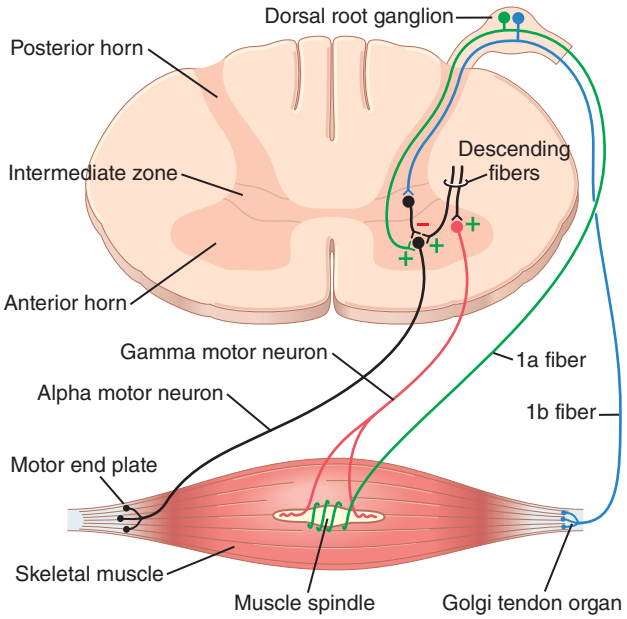

Figure 55.2 Peripheral sensory fibers and anterior motor neurons innervating skeletal muscle.

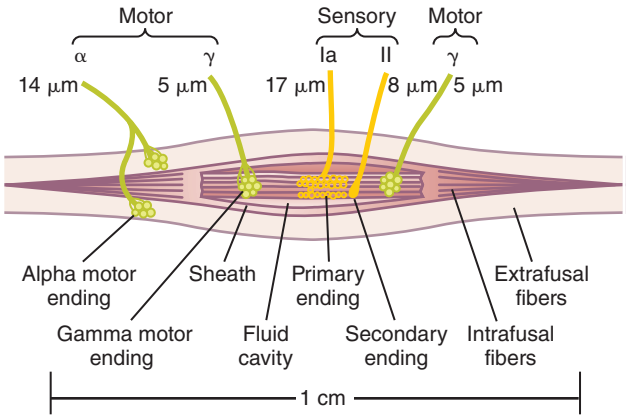

Figure 55.3 Muscle spindle, showing its relationship to the large extrafusal skeletal muscle fibers. Note also both motor and sensory innervation of the muscle spindle.

Interneurons. Interneurons are present in all areas of the cord gray matter—in the dorsal horns, the anterior horns, and the intermediate areas between them, as shown in **Fig. 55.1**. These cells are about 30 times as numerous as the anterior motor neurons. They are small and highly excitable, often exhibiting spontaneous activity and capable of firing as rapidly as 1500 times per second. They have many interconnections with one another, and many of them also synapse directly with the anterior motor neurons, as shown in **Fig. 55.1**. The interconnections among the interneurons and anterior motor neurons are responsible for most of the integrative functions of the spinal cord that are discussed in the remainder of this chapter.

Essentially all the different types of neuronal circuits described in Chapter 47 are found in the interneuron pool of cells of the spinal cord, including *diverging, converging, repetitive-discharge*, and other types of circuits. In this chapter, we examine many applications of these different circuits in performing specific reflex actions by the spinal cord.

Only a few incoming sensory signals from the spinal nerves or signals from the brain terminate directly on the anterior motor neurons. Instead, almost all these signals are transmitted first through interneurons, where they are appropriately processed. Thus, in **Fig. 55.1**, the corticospinal tract from the brain is shown to terminate almost entirely on spinal interneurons, where signals from this tract are combined with signals from other spinal tracts or spinal nerves before finally converging on anterior motor neurons to control muscle function.

Renshaw Cells Transmit Inhibitory Signals to Surrounding Motor Neurons. Also located in the anterior horns of the spinal cord, in close association with the motor neurons, are a large number of small neurons called *Renshaw cells*. Almost immediately after the anterior motor neuron axon leaves the body of the neuron, collateral branches from the axon pass to adjacent Renshaw cells. Renshaw cells are *inhibitory cells* that transmit inhibitory signals to the surrounding motor neurons. Thus, stimulation of each motor neuron tends to inhibit adjacent motor neurons, an effect called *lateral inhibition*. The motor system uses this lateral inhibition to focus, or sharpen, its signals in the same way that the sensory system uses the same principle to allow unabated transmission of the primary signal in the desired direction while suppressing the tendency for signals to spread laterally.

Propriospinal Fibers Provide Multisegmental Connections From One Spinal Cord Level to Other Levels. More than half of all the nerve fibers that ascend and descend in the spinal cord are *propriospinal fibers*. These fibers run from one segment of the cord to another. In addition, as the sensory fibers enter the cord from the posterior cord roots, they bifurcate and branch both up and down the spinal cord; some of the branches transmit signals to only a segment or two, whereas others transmit signals to many segments. These ascending and descending propriospinal fibers of the cord provide pathways for the *multisegmental reflexes* described later in this chapter, including reflexes that coordinate simultaneous movements in the forelimbs and hindlimbs.

MUSCLE SENSORY RECEPTORS—MUSCLE SPINDLES AND GOLGI TENDON ORGANS—AND THEIR ROLES IN MUSCLE CONTROL

Proper control of muscle function requires not only excitation of the muscle by spinal cord anterior motor neurons but also continuous feedback of sensory information from each muscle to the spinal cord, indicating the functional status of each muscle at each instant. That is, what is the length of the muscle, what is its instantaneous tension, and how rapidly is its length or tension changing? To provide this information, the muscles and their tendons are supplied abundantly with two special types of sensory receptors: (1) *muscle spindles* (**Fig. 55.2**), which are distributed throughout the belly of the muscle and send information to the nervous system about muscle length or rate of change of length, and (2) *Golgi tendon organs* (**Figs. 55.2** and **55.8**), which are located in the muscle tendons and transmit information about tendon tension or rate of change of tension.

The signals from these two receptors are almost entirely for the purpose of intrinsic muscle control. They operate almost completely at a subconscious level. Even so, they transmit tremendous amounts of information not only to the spinal cord but also to the cerebellum and even to the cerebral cortex, helping these portions of the nervous system function to control muscle contraction.

RECEPTOR FUNCTION OF THE MUSCLE SPINDLE

Structure and Motor Innervation of the Muscle Spindle. The organization of the muscle spindle is shown in **Fig. 55.3**. Each spindle is 3 to 10 millimeters long. It is built around 3 to 12 tiny *intrafusal muscle fibers* that are pointed at their ends and attached to the glycocalyx of the surrounding large *extrafusal* skeletal muscle fibers (**Video 55.1**).

Each intrafusal muscle fiber is a tiny skeletal muscle fiber. However, the central region of each of these fibers has few or no actin and myosin filaments. Therefore, this central portion does not contract when the ends do. Instead, it functions as a sensory receptor, as described later. The end portions that do contract are excited by small *gamma motor nerve fibers* that originate from small type A gamma motor neurons in the anterior horns of the spinal cord, as described earlier. These gamma motor nerve fibers are also called *gamma efferent fibers*, in contradistinction to the large *alpha efferent fibers* (type Aα nerve fibers) that innervate the extrafusal skeletal muscle.

Sensory Innervation of the Muscle Spindle. The receptor portion of the muscle spindle is its central portion. As shown in **Fig. 55.3** and in more detail in **Fig. 55.4**, sensory fibers originate in this area and are stimulated by

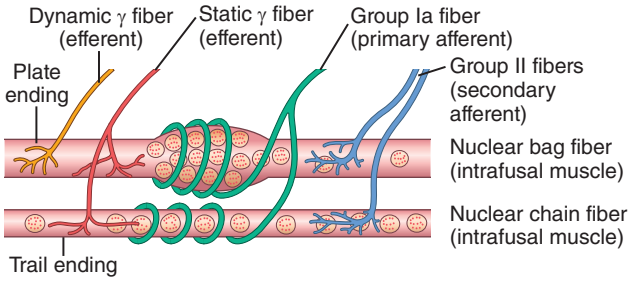

Figure 55.4 Details of nerve connections from the nuclear bag and nuclear chain muscle spindle fibers. *(Modified from Stein RB. Peripheral control of movement.* Physiol Rev. *1974;54:225.)*

stretching of this midportion of the spindle. The muscle spindle receptor can be excited in two ways:

1. Lengthening the whole muscle stretches the midportion of the spindle and, therefore, excites the receptor.
2. Even if the length of the entire muscle does not change, contraction of the end portions of the spindle's intrafusal fibers stretches the midportion of the spindle and therefore excites the receptor.

Two types of sensory endings, the *primary afferent* and *secondary afferent endings*, are found in this central receptor area of the muscle spindle.

Primary Afferent Ending. In the center of the receptor area, a large sensory nerve fiber encircles the central portion of each intrafusal fiber, forming the *primary afferent ending* or *annulospiral ending*. This nerve fiber is a type Ia fiber averaging 17 micrometers in diameter, and it transmits sensory signals to the spinal cord at a velocity of 70 to 120 m/sec, as rapidly as any type of nerve fiber in the entire body.

Secondary Afferent Ending. Usually one but sometimes two smaller sensory nerve fibers—type II fibers with an average diameter of 8 micrometers—innervate the receptor region on one or both sides of the primary ending, as shown in **Figs. 55.3** and **55.4**. This sensory ending is called the *secondary afferent ending;* sometimes it encircles the intrafusal fibers in the same way as the type Ia fiber, but often it spreads like branches on a bush.

Nuclear Bag and Nuclear Chain Intrafusal Fibers of the Muscle Spindle. There are also two types of muscle spindle intrafusal fibers: (1) *nuclear bag muscle fibers* (one to three in each spindle), in which several muscle fiber nuclei are congregated in expanded "bags" in the central portion of the receptor area, as shown by the top fiber in **Fig. 55.4**, and (2) *nuclear chain fibers* (three to nine), which are about half as large in diameter and half as long as the nuclear bag fibers and have nuclei aligned in a chain throughout the receptor area, as shown by the bottom fiber in the figure. The primary sensory nerve ending is excited by both the nuclear bag intrafusal fibers *and* the nuclear chain fibers. Conversely, the secondary ending is

usually excited only by nuclear chain fibers. These relations are shown in **Fig. 55.4**.

The Primary and the Secondary Afferent Endings Both Respond to the Length of the Receptor—"Static" Response. When the receptor portion of the muscle spindle is stretched *slowly*, the number of impulses transmitted from both the primary and secondary endings increases almost directly in proportion to the degree of stretching, and the endings continue to transmit these impulses for several minutes. This effect is called the *static response* of the spindle receptor, meaning that both the primary and secondary endings continue to transmit their signals for at least several minutes if the muscle spindle remains stretched.

The Primary (But Not the Secondary) Afferent Ending Responds to Rate of Change of Receptor Length—"Dynamic" Response. When the length of the spindle receptor increases suddenly, the primary ending (but not the secondary ending) is stimulated powerfully. This stimulus of the primary ending is called the *dynamic response*, which means that the primary ending actively responds to a rapid *rate of change* in spindle length. Even when the length of a spindle receptor increases only a fraction of a micrometer for only a fraction of a second, the primary receptor transmits tremendous numbers of excess impulses to the large 17-micrometer sensory nerve fiber, *but only while the length is actually increasing*. As soon as the length stops increasing, this extra rate of impulse discharge returns to the level of the much smaller static response that is still present in the signal.

Conversely, when the spindle receptor shortens, exactly opposite sensory signals occur. Thus, the primary ending sends extremely strong signals, either positive or negative, to the spinal cord to apprise it of any change in length of the spindle receptor.

Control of Intensity of the Static and Dynamic Responses By the Gamma Motor Nerves. The gamma motor nerves to the muscle spindle can be divided into two types: *gamma-dynamic (gamma-d)* and *gamma-static (gamma-s)*. The first of these gamma motor nerves excites mainly the nuclear bag intrafusal fibers, and the second excites mainly the nuclear chain intrafusal fibers. When the gamma-d fibers excite the nuclear bag fibers, the dynamic response of the muscle spindle becomes tremendously enhanced, whereas the static response is hardly affected. Conversely, stimulation of the gamma-s fibers, which excite the nuclear chain fibers, enhances the static response while having little influence on the dynamic response. Subsequent paragraphs illustrate that these two types of muscle spindle responses are important in different types of muscle control.

Continuous Discharge of the Muscle Spindles Under Normal Conditions. Normally, when there is some degree of gamma nerve excitation, the muscle spindles emit sensory nerve impulses continuously. Stretching the muscle spindles increases the rate of firing, whereas shortening the spindle decreases the rate of firing. Thus, the spindles can send to the spinal cord either *positive signals* (increased numbers of impulses to indicate stretch of a muscle) or *negative signals* (reduced numbers of impulses) to indicate that the muscle is unstretched.

MUSCLE STRETCH REFLEX (MYOTATIC REFLEX)

The simplest manifestation of muscle spindle function is the *muscle stretch reflex*, also called the *myotatic reflex*. Whenever a muscle is stretched suddenly, excitation of the spindles causes reflex contraction of the large skeletal muscle fibers of the stretched muscle and of closely allied synergistic muscles.

Neuronal Circuitry of the Stretch Reflex. **Fig. 55.5** illustrates the basic circuit of the muscle spindle stretch reflex, showing a type Ia proprioceptor nerve fiber originating in a muscle spindle and entering a dorsal root of the spinal cord. A branch of this fiber then goes directly to the anterior horn of the cord gray matter and synapses with anterior motor neurons that send motor nerve fibers back to the same muscle from which the muscle spindle fiber originated. Thus, this *monosynaptic pathway* allows a reflex signal to return with the shortest possible time delay back to the muscle after excitation of the spindle. Most type II fibers from the muscle spindle terminate on multiple interneurons in the cord gray matter, and these transmit delayed signals to the anterior motor neurons or serve other functions.

Dynamic Stretch Reflex and Static Stretch Reflexes. The stretch reflex can be divided into two components: the dynamic stretch reflex and the static stretch reflex. The *dynamic stretch reflex* is elicited by potent dynamic signals transmitted from the primary

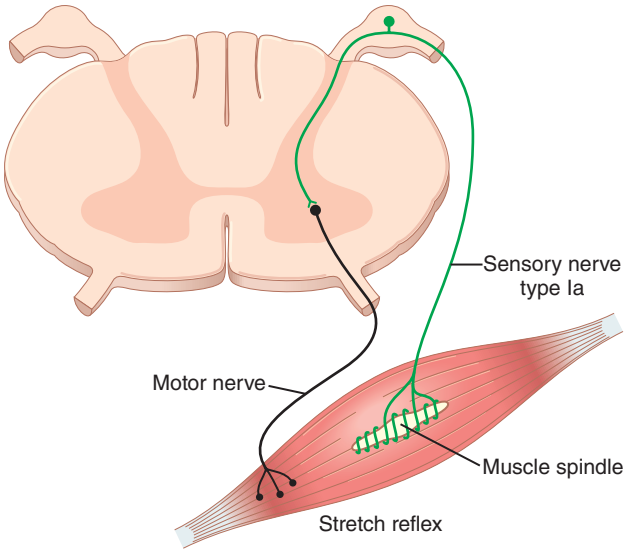

Figure 55.5 Neuronal circuit of the stretch reflex.

sensory endings of the muscle spindles, caused by rapid stretch or unstretch. That is, when a muscle is suddenly stretched or unstretched, a strong signal is transmitted to the spinal cord, which causes an instantaneous strong reflex contraction (or decrease in contraction) of the same muscle from which the signal originated. Thus, *the reflex functions to oppose sudden changes in muscle length.*

The dynamic stretch reflex is over within a fraction of a second after the muscle has been stretched (or unstretched) to its new length, but then a weaker *static stretch reflex* continues for a prolonged period thereafter. This reflex is elicited by the continuous static receptor signals transmitted by both primary and secondary endings. The importance of the static stretch reflex is that it causes the degree of muscle contraction to remain reasonably constant, except when the person's nervous system specifically wills otherwise.

"Damping" Function of the Dynamic and Static Stretch Reflexes in Smoothing Muscle Contraction. An especially important function of the stretch reflex is its *damping* (or smoothing) function, which prevents oscillation or jerkiness of body movements.

Signals from the spinal cord are often transmitted to a muscle in an unsmooth form, increasing in intensity for a few milliseconds, then decreasing in intensity, then changing to another intensity level, and so forth. When the muscle spindle apparatus is not functioning satisfactorily, the muscle contraction is jerky during the course of such a signal. This effect is shown in **Fig. 55.6**. In part A, the muscle spindle reflex of the excited muscle is intact. Note that the contraction is relatively smooth, even though the motor nerve to the muscle is excited at a slow frequency of only eight signals per second. Part B illustrates the same experiment in an animal whose muscle spindle sensory nerves had been sectioned 3 months earlier. Note the unsmooth muscle contraction. Thus,

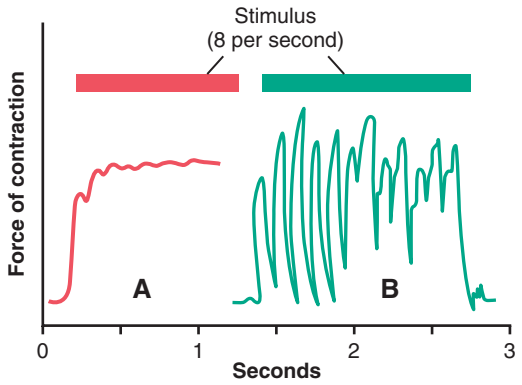

Figure 55.6 Muscle contraction caused by a spinal cord signal under two conditions. Depicted are curve A, in a normal muscle, and curve B, in a muscle whose muscle spindles were denervated by section of the posterior roots of the cord 82 days previously. Note the smoothing effect of the muscle spindle reflex in curve A. *(Modified from Creed RS, Denney-Brown D, Eccles JC, et al.* Reflex Activity of the Spinal Cord. *New York: Oxford University Press; 1932.)*

Fig. 55.6A graphically demonstrates the damping mechanism's ability to smooth muscle contractions, even though the primary input signals to the muscle motor system may themselves be jerky. This effect can also be called a *signal averaging* function of the muscle spindle reflex.

ROLE OF THE MUSCLE SPINDLE IN VOLUNTARY MOTOR ACTIVITY

Approximately 31% of all the motor nerve fibers to the muscle are the small type A gamma efferent fibers. Whenever signals are transmitted from the motor cortex or from any other area of the brain to the alpha motor neurons, in most instances the gamma motor neurons are stimulated simultaneously, an effect called *coactivation* of the alpha and gamma motor neurons. This effect causes both the extrafusal skeletal muscle fibers and the muscle spindle intrafusal muscle fibers to contract at the same time.

The purpose of contracting the muscle spindle intrafusal fibers at the same time that the large skeletal muscle fibers contract is 2-fold: First, it keeps the length of the receptor portion of the muscle spindle from changing during the course of the whole muscle contraction. Therefore, coactivation keeps the muscle spindle reflex from opposing the muscle contraction. Second, it maintains the proper damping function of the muscle spindle, regardless of changes in muscle length. For instance, if the muscle spindle did not contract and relax along with the large muscle fibers, the receptor portion of the spindle would sometimes be flailing and sometimes be overstretched, in neither instance operating under optimal conditions for spindle function.

Brain Areas for Control of the Gamma Motor System

The gamma efferent system is excited specifically by signals from the *bulboreticular facilitatory* region of the brain stem and, secondarily, by impulses transmitted into the bulboreticular area from the following: (1) the *cerebellum;* (2) the *basal ganglia;* and (3) the *cerebral cortex.*

Because the bulboreticular facilitatory area is particularly concerned with antigravity contractions, and because the antigravity muscles have an especially high density of muscle spindles, the gamma efferent mechanism is believed to be important for damping the movements of the different body parts during walking and running.

The Muscle Spindle System Stabilizes Body Position During Tense Action. One of the most important functions of the muscle spindle system is to stabilize body position during tense motor action. To perform this function, the bulboreticular facilitatory region and its allied areas of the brain stem transmit excitatory signals through the gamma nerve fibers to the intrafusal muscle fibers of the muscle spindles. This action shortens the ends of the spindles and stretches the central receptor regions, thus increasing their signal output. However, if the spindles on both sides of each joint are activated at the same time,

reflex excitation of the skeletal muscles on both sides of the joint also increases, producing tight, tense muscles opposing each other at the joint. The net effect is that the position of the joint becomes strongly stabilized, and any force that tends to move the joint from its current position is opposed by highly sensitized stretch reflexes operating on both sides of the joint.

When a person must perform a muscle function that requires a high degree of delicate and exact positioning, excitation of the appropriate muscle spindles by signals from the bulboreticular facilitatory region of the brain stem stabilizes the positions of the major joints. This stabilization aids tremendously in performing the additional detailed voluntary movements (of fingers or other body parts) required for intricate motor procedures.

Clinical Applications of the Stretch Reflex

When clinicians perform a physical examination on a patient, they often elicit multiple stretch reflexes to determine how much background excitation, or "tone," the brain is sending to the spinal cord. This reflex is elicited as follows.

Knee Jerk and Other Muscle Jerks Can Be Used to Assess Sensitivity of Stretch Reflexes. The knee jerk can be elicited by simply striking the patellar tendon lightly with a reflex hammer; this action instantaneously stretches the quadriceps muscle and excites a *dynamic stretch reflex* that causes the lower leg to "jerk" forward (**Video 55.2**). The upper part of **Fig. 55.7** shows a myogram from the quadriceps muscle recorded during a knee jerk.

Similar reflexes can be obtained from almost any muscle of the body either by striking the tendon of the muscle or by striking the belly of the muscle itself. In other words, sudden stretch of muscle spindles is all that is required to elicit a dynamic stretch reflex.

The muscle jerks are used by neurologists to assess the degree of facilitation of spinal cord centers. When large numbers of facilitatory impulses are being transmitted from the upper regions of the central nervous system into the cord, the muscle jerks are greatly exaggerated. Conversely, if the facilitatory impulses are depressed or abrogated, the muscle jerks are considerably weakened or absent. These reflexes are used most frequently in determining the presence or absence of muscle spasticity caused by lesions in the motor areas of the brain or diseases that excite the bulboreticular facilitatory area of the brain stem. Ordinarily, large *lesions in the motor areas of the cerebral cortex* but not in the lower motor control areas (especially lesions caused by strokes or brain tumors) cause greatly exaggerated muscle jerks in the muscles on the opposite side of the body.

Clonus—Oscillation of Muscle Jerks. Under some conditions, the muscle jerks can oscillate, a phenomenon called *clonus* (see lower myogram, **Fig. 55.7**). Oscillation can be explained particularly well in relation to ankle clonus, as follows.

If a person standing on the tip ends of the feet suddenly drops their body downward and stretches the gastrocnemius muscles, stretch reflex impulses are transmitted from the muscle spindles into the spinal cord. These impulses reflexively excite the stretched muscle, which lifts the body up again. After a fraction of a second, the reflex contraction of the muscle dies out and the body falls again, thus stretching the spindles a second time. Again, a dynamic stretch reflex lifts the body, but this too dies out after a fraction of a second, and the body falls once more to begin a new cycle. In this way, the stretch reflex of the gastrocnemius muscle continues to oscillate, often for long periods, which is clonus.

Clonus ordinarily occurs only when the stretch reflex is highly sensitized by facilitatory impulses from the brain. For instance, in a decerebrate animal in which the stretch reflexes are highly facilitated, clonus develops readily. To determine the degree of facilitation of the spinal cord, neurologists test patients for clonus by suddenly stretching a muscle and applying a steady stretching force to it. If clonus occurs, the degree of facilitation is certain to be high.

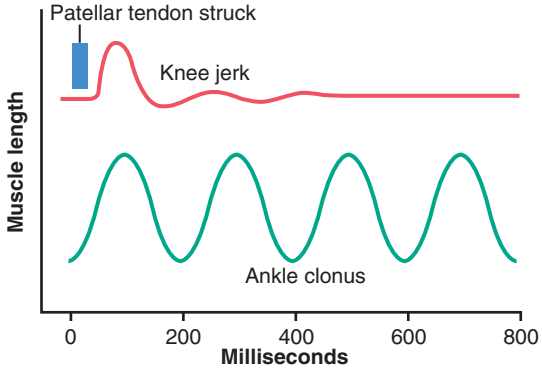

Figure 55.7 Myograms recorded from the quadriceps muscle during elicitation of the knee jerk *(above)* and from the gastrocnemius muscle during ankle clonus *(below)*.

GOLGI TENDON REFLEX

Golgi Tendon Organ Helps Control Muscle Tension. The Golgi tendon organ, shown in **Fig. 55.8**, is an encapsulated sensory receptor through which muscle tendon fibers pass. About 10 to 15 muscle fibers are usually connected to each Golgi tendon organ, and the organ is stimulated when this small bundle of muscle fibers is "tensed" by contracting or stretching the muscle. Thus, the major difference in excitation of the Golgi tendon organ versus the muscle spindle is that *the spindle detects muscle length and changes in muscle length*, whereas *the tendon organ detects muscle tension* as reflected by the tension in itself.

The tendon organ, like the primary receptor of the muscle spindle, has both a *dynamic response* and a *static response*, reacting intensely when the muscle tension suddenly increases (the dynamic response) but settling down within a fraction of a second to a lower level of steady-state firing that is almost directly proportional to the muscle tension (the static response). Thus, Golgi tendon organs provide the nervous system with instantaneous

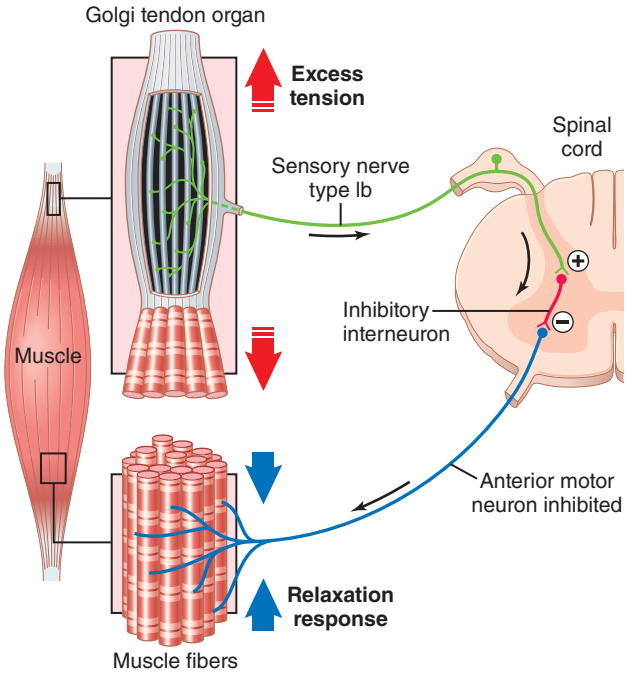

Figure 55.8 Golgi tendon reflex. Excessive tension of the muscle stimulates sensory receptors in the Golgi tendon organ. Signals from the receptors are transmitted through a sensory afferent nerve fiber that excites an inhibitory interneuron in the spinal cord, inhibiting anterior motor neuron activity, causing muscle relaxation, and protecting the muscle against excessive tension.

information on the degree of tension in each small segment of each muscle.

Transmission of Impulses From the Tendon Organ Into the Central Nervous System. Signals from the tendon organ are transmitted through large, rapidly conducting type Ib nerve fibers that average 16 micrometers in diameter, only slightly smaller than those from the primary endings of the muscle spindle. These fibers, like those from the primary spindle endings, transmit signals into local areas of the cord and, after synapsing in a dorsal horn of the cord, through long fiber pathways such as the spinocerebellar tracts into the cerebellum and through still other tracts to the cerebral cortex. The local cord signal excites a single *inhibitory* interneuron that inhibits the anterior motor neuron. This local circuit directly inhibits the individual muscle without affecting adjacent muscles. The relation between signals to the brain and function of the cerebellum and other parts of the brain for muscle control is discussed in Chapter 57.

The Tendon Reflex Prevents Excessive Tension on the Muscle. When the Golgi tendon organs of a muscle tendon are stimulated by increased tension in the connecting muscle, signals are transmitted to the spinal cord to cause reflex effects in the respective muscle. This reflex is entirely *inhibitory*. Thus, this reflex provides a *negative feedback* mechanism that prevents the development of too much tension on the muscle.

When tension on the muscle—and therefore on the tendon—becomes extreme, the inhibitory effect from the tendon organ can be so great that it leads to a sudden reaction in the spinal cord that causes instantaneous relaxation of the entire muscle. This effect is called the *lengthening reaction;* it is probably a protective mechanism to prevent tearing of the muscle or avulsion of the tendon from its attachments to the bone.

The Tendon Reflex Helps to Equalize Contractile Forces Among the Muscle Fibers. Another likely function of the Golgi tendon reflex is to equalize contractile forces of the separate muscle fibers. That is, the fibers that exert excess tension become inhibited by the reflex, whereas those that exert too little tension become more excited because of the absence of reflex inhibition. This phenomenon spreads the muscle load over all the fibers and prevents damage in isolated areas of a muscle where small numbers of fibers might be overloaded.

Function of the Muscle Spindles and Golgi Tendon Organs in Motor Control By Higher Levels of the Brain

Although we have emphasized the function of the muscle spindles and Golgi tendon organs in spinal cord control of motor function, these two sensory organs also apprise the higher motor control centers of instantaneous changes taking place in the muscles. For instance, the *dorsal spinocerebellar tracts* carry instantaneous information from the muscle spindles and the Golgi tendon organs directly to the cerebellum at conduction velocities approaching 120 m/sec, the most rapid conduction anywhere in the brain or spinal cord. Additional pathways transmit similar information into the reticular regions of the brain stem and, to a lesser extent, all the way to the motor areas of the cerebral cortex. As discussed in Chapters 56 and 57, the information from these receptors is crucial for feedback control of motor signals that originate in all these areas.

FLEXOR REFLEX AND THE WITHDRAWAL REFLEXES

In the spinal or decerebrate animal, almost any type of cutaneous sensory stimulus from a limb is likely to cause the flexor muscles of the limb to contract, thereby withdrawing the limb from the stimulating object. This reflex is called the *flexor reflex*.

In its classic form, the flexor reflex is elicited most powerfully by stimulation of pain endings, such as by a pinprick, heat, or a wound. For this reason, it is also called a *nociceptive reflex*, or simply a *pain reflex*. Stimulation of touch receptors can also elicit a weaker and less prolonged flexor reflex.

If some part of the body other than one of the limbs is painfully stimulated, that part will similarly be *withdrawn from the stimulus*, but the reflex may not be confined to

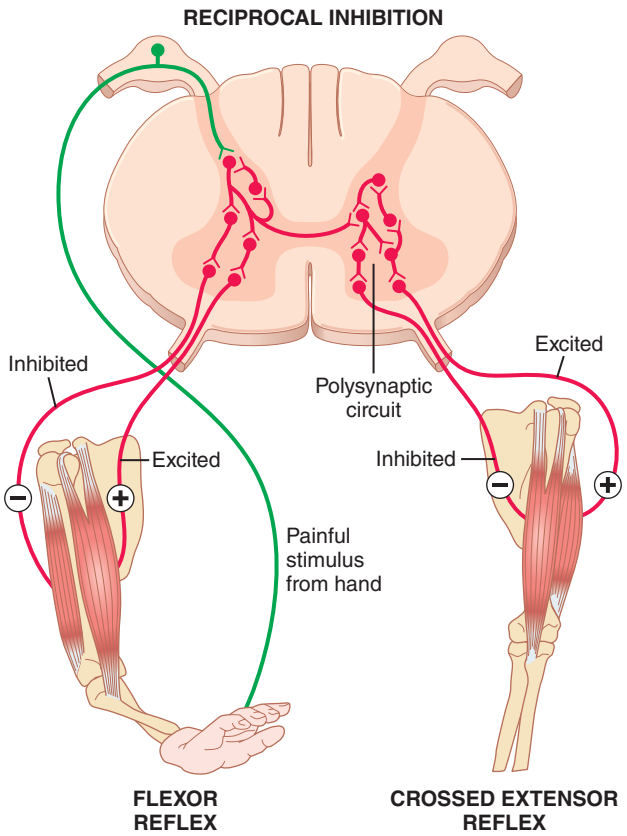

Figure 55.9 Flexor reflex, crossed extensor reflex, and reciprocal inhibition.

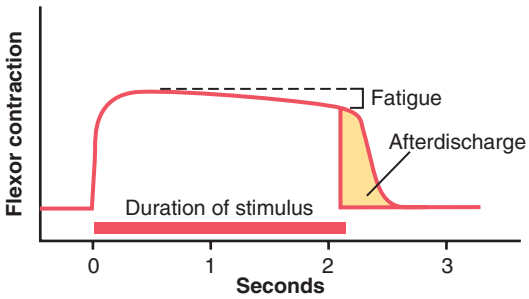

Figure 55.10 Myogram of the flexor reflex showing rapid onset of the reflex, an interval of fatigue, and, finally, afterdischarge after the input stimulus is over.

flexor muscles, even though it is basically the same type of reflex. Therefore, the many patterns of these reflexes in the different areas of the body are called *withdrawal reflexes*.

Neuronal Mechanism of the Flexor Reflex. The left-hand portion of **Fig. 55.9** shows the neuronal pathways for the flexor reflex. When a painful stimulus is applied to the hand, for example, the flexor muscles of the upper arm become excited and withdraw the hand from the painful stimulus.

The pathways for eliciting the flexor reflex do not pass directly to the anterior motor neurons but instead pass first into the spinal cord pool of interneurons and only secondarily to the motor neurons. The shortest possible circuit is a three- or four-neuron pathway; however, most of the signals of the reflex traverse many more neurons and involve the following basic types of circuits: (1) diverging circuits to spread the reflex to the necessary muscles for withdrawal; (2) circuits to inhibit the antagonist muscles, called *reciprocal inhibition circuits;* and (3) circuits to cause *afterdischarge* that lasts many fractions of a second after the stimulus is over.

Fig. 55.10 shows a typical myogram from a flexor muscle during a flexor reflex. Within a few milliseconds after a pain sensory nerve begins to be stimulated, the flexor response appears. Then, in the next few seconds, the reflex begins to *fatigue*, which is characteristic of essentially all complex integrative reflexes of the spinal cord. Finally, after the stimulus is over, the contraction of the muscle returns toward the baseline, but because of afterdischarge, it takes many milliseconds for this contraction to occur. The duration of afterdischarge depends on the intensity of the sensory stimulus that elicited the reflex; a weak tactile stimulus causes almost no afterdischarge, but after a strong pain stimulus, the afterdischarge may last for a second or more.

The afterdischarge that occurs in the flexor reflex almost certainly results from both types of repetitive discharge circuits discussed in Chapter 47. Electrophysiological studies indicate that immediate afterdischarge, lasting for about 6 to 8 milliseconds, results from repetitive firing of the excited interneurons. Also, prolonged afterdischarge occurs after strong pain stimuli, almost certainly resulting from recurrent pathways that initiate oscillation in reverberating interneuron circuits. These, in turn, transmit impulses to the anterior motor neurons, sometimes for several seconds after the incoming sensory signal is over.

Thus, the flexor reflex is appropriately organized to withdraw a pained or otherwise irritated part of the body from a stimulus. Further, because of afterdischarge, the reflex can hold the irritated part away from the stimulus for 0.1 to 3 seconds after the irritation is over. During this time, other reflexes and actions commanded by the central nervous system can move the entire body away from the painful stimulus.

The Pattern of Withdrawal During a Flexor Reflex Depends on Which Sensory Nerve Is Stimulated. A pain stimulus on the inward side of the arm elicits not only contraction of the flexor muscles of the arm but also contraction of abductor muscles to pull the arm outward. In other words, the cord integrative centers cause contraction of the muscles that can most effectively remove the pained part of the body away from the object causing the pain. Although this principle applies to any part of the body, it is especially applicable to the limbs because of their highly developed flexor reflexes.

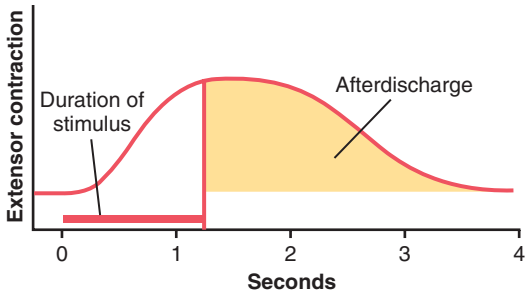

Figure 55.11 Myogram of a crossed extensor reflex showing slow onset but prolonged afterdischarge.

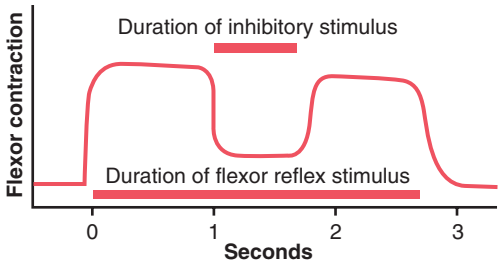

Figure 55.12 Myogram of a flexor reflex showing reciprocal inhibition caused by an inhibitory stimulus from a stronger flexor reflex on the opposite side of the body.

CROSSED EXTENSOR REFLEX

About 0.2 to 0.5 second after a stimulus elicits a flexor reflex in one limb, the opposite limb begins to extend. This reflex is called the *crossed extensor reflex*. Extension of the opposite limb can push the entire body away from the object that is causing the painful stimulus in the withdrawn limb.

Neuronal Mechanism of the Crossed Extensor Reflex. The right-hand portion of **Fig. 55.9** shows the neuronal circuit responsible for the crossed extensor reflex, demonstrating that signals from sensory nerves cross to the opposite side of the cord to excite extensor muscles. Because the crossed extensor reflex usually does not begin until 200 to 500 milliseconds after onset of the initial pain stimulus, it is certain that many interneurons are involved in the circuit between the incoming sensory neuron and the motor neurons of the opposite side of the cord responsible for the crossed extension.

After the painful stimulus is removed, the crossed extensor reflex has an even longer period of afterdischarge than does the flexor reflex. Again, this prolonged afterdischarge likely results from reverberating circuits among the interneuronal cells.

Fig. 55.11 shows a typical myogram recorded from a muscle involved in a crossed extensor reflex. This myogram demonstrates the relatively long latency before the reflex begins and the long afterdischarge at the end of the stimulus. The prolonged afterdischarge helps hold the pained area of the body away from the painful object until other nervous reactions cause the entire body to move away.

RECIPROCAL INHIBITION AND RECIPROCAL INNERVATION

We previously pointed out that excitation of one group of muscles is often associated with inhibition of another group. For instance, when a stretch reflex excites one muscle, it often simultaneously inhibits the antagonist muscles. This phenomenon is called *reciprocal inhibition*, and the neuronal circuit that causes this reciprocal relation is called *reciprocal innervation*. Likewise, reciprocal relations often exist between the muscles on the two sides of the body, as exemplified by the flexor and extensor muscle reflexes described earlier.

Fig. 55.12 shows an example of reciprocal inhibition. In this instance, a moderate but prolonged flexor reflex is elicited from one limb of the body; while this reflex is still being elicited, a stronger flexor reflex is elicited in the limb on the opposite side of the body. This stronger reflex sends reciprocal inhibitory signals to the first limb and depresses its degree of flexion. Finally, removal of the stronger reflex allows the original reflex to reassume its previous intensity.

REFLEXES OF POSTURE AND LOCOMOTION

Postural and Locomotive Reflexes of the Cord

Positive Supportive Reaction. Pressure on the footpad of a decerebrate animal causes the limb to extend against the pressure applied to the foot. Indeed, this reflex is so strong that if an animal whose spinal cord has been transected for several months—after the reflexes have become exaggerated—is placed on its feet, the reflex often stiffens the limbs sufficiently to support the weight of the body. This reflex is called the *positive supportive reaction*.

The positive supportive reaction involves a complex circuit in the interneurons similar to the circuits responsible for the flexor and crossed extensor reflexes. The locus of the pressure on the pad of the foot determines the direction in which the limb will extend; pressure on one side causes extension in that direction, an effect called the *magnet reaction*. This reaction helps keep an animal from falling to that side.

Cord "Righting" Reflexes. When a spinal animal is laid on its side, it will make uncoordinated movements to try to raise itself to the standing position. This reflex is called the *cord righting reflex*. Such a reflex demonstrates that some relatively complex reflexes associated with posture are integrated in the spinal cord. Indeed, an animal with a well-healed transected thoracic cord between the levels for forelimb and hindlimb innervation can right itself from the lying position and even walk using its hindlimbs in addition to its forelimbs. In the case of an opossum with a similar transection of the thoracic cord, the walking movements of

the hindlimbs are hardly different from those in a normal opossum, except that the hindlimb walking movements are not synchronized with those of the forelimbs.

Stepping and Walking Movements

Rhythmical Stepping Movements of a Single Limb. Rhythmical stepping movements are frequently observed in the limbs of spinal animals. Indeed, even when the lumbar portion of the spinal cord is separated from the remainder of the cord and a longitudinal section is made down the center of the cord to block neuronal connections between the two sides of the cord and between the two limbs, each hindlimb can still perform individual stepping functions. Forward flexion of the limb is followed a second or so later by backward extension. Then flexion occurs again, and the cycle is repeated over and over.

This oscillation back and forth between flexor and extensor muscles can occur even after the sensory nerves have been cut, and results mainly from mutually reciprocal inhibition circuits within the matrix of the cord, oscillating between the neurons controlling agonist and antagonist muscles.

The sensory signals from the footpads and from the position sensors around the joints play a strong role in controlling foot pressure and frequency of stepping when the foot is allowed to walk along a surface. In fact, the cord mechanism for control of stepping can be even more complex. For instance, if the top of the foot encounters an obstruction during forward thrust, the forward thrust will stop temporarily; then, in rapid sequence, the foot will be lifted higher and proceed forward to be placed over the obstruction. This is the *stumble reflex*. Thus, the cord is an intelligent walking controller.

Reciprocal Stepping of Opposite Limbs. If the lumbar spinal cord is not split down its center, every time stepping occurs in the forward direction in one limb, the opposite limb ordinarily moves backward. This effect results from reciprocal innervation between the two limbs.

Diagonal Stepping of All Four Limbs—"Mark Time" Reflex. If a well-healed spinal animal (with spinal transection in the neck above the forelimb area of the cord) is held up from the floor and its legs are allowed to dangle, the stretch on the limbs occasionally elicits stepping reflexes that involve all four limbs. In general, stepping occurs diagonally between the forelimbs and hindlimbs. This diagonal response is another manifestation of reciprocal innervation, this time occurring the entire distance up and down the cord between the forelimbs and hindlimbs. Such a walking pattern is called a *mark time reflex*.

Scratch Reflex

An especially important cord reflex in some animals is the scratch reflex, which is initiated by an *itch* or *tickle sensation*. This reflex involves two functions: (1) a *position sense* that allows the paw to find the exact point of irritation on the surface of the body; and (2) a *to-and-fro scratching movement.*

The *position sense* of the scratch reflex is a highly developed function. If a flea is crawling as far forward as the shoulder of a spinal animal, the hind paw can still find its position, even though 19 muscles in the limb must be contracted simultaneously in a precise pattern to bring the paw to the position of the crawling flea. To make the reflex even more complicated, when the flea crosses the midline, the first paw stops scratching and the opposite paw begins the to-and-fro motion and eventually finds the flea.

The *to-and-fro movement*, like the stepping movements of locomotion, involves reciprocal innervation circuits that cause oscillation.

Spinal Cord Reflexes That Cause Muscle Spasm

In human beings, local muscle spasm is often observed. In many instances, localized pain is the cause of the local spasm.

Muscle Spasm Resulting From a Broken Bone. One important type of spasm occurs in muscles that surround a broken bone. The spasm results from pain impulses initiated from the broken edges of the bone, which cause the muscles that surround the area to contract tonically. Pain relief obtained by injecting a local anesthetic at the broken edges of the bone relieves the spasm; a deep general anesthetic of the entire body, such as ether anesthesia, also relieves the spasm.

Abdominal Muscle Spasm Associated With Peritonitis. Another type of local spasm caused by cord reflexes is abdominal spasm resulting from irritation of the parietal peritoneum by peritonitis. Here again, relief of the pain caused by the peritonitis allows the spastic muscle to relax. The same type of spasm often occurs during surgical operations; for instance, during abdominal operations, pain impulses from the parietal peritoneum often cause the abdominal muscles to contract extensively, sometimes extruding the intestines through the surgical wound. For this reason, deep anesthesia is usually required for intraabdominal operations.

Muscle Cramps. Another type of local spasm is the typical muscle cramp. Any local irritating factor or metabolic abnormality of a muscle, such as severe cold, lack of blood flow, or overexercise, can elicit pain or other sensory signals transmitted from the muscle to the spinal cord, which in turn cause reflex feedback muscle contraction. The contraction is believed to stimulate the same sensory receptors even more, which causes the spinal cord to increase the intensity of contraction. Thus, positive feedback develops, so a small amount of initial irritation causes more and more contraction until a full-blown muscle cramp ensues.

Autonomic Reflexes in the Spinal Cord. Many types of segmental autonomic reflexes are integrated in the spinal cord, most of which are discussed in other chapters. Briefly, these reflexes include (1) changes in vascular tone resulting from changes in local skin heat (Chapter 74); (2) sweating, which results from localized heat on the surface of the body (Chapter 74); (3) intestinointestinal reflexes that control some motor functions of the gut (Chapter 63); (4) peritoneointestinal reflexes that inhibit gastrointestinal motility in response to peritoneal irritation (Chapter 67); and

(5) evacuation reflexes for emptying the full bladder (Chapter 26) or the colon (Chapter 64). In addition, all the segmental reflexes can at times be elicited simultaneously in the form of the so-called *mass reflex*, described next.

Mass Reflex. In a spinal animal or person, sometimes the spinal cord suddenly becomes excessively active, causing massive discharge in large portions of the cord. The usual stimulus that causes this excess activity is a strong pain stimulus to the skin or excessive filling of a viscus, such as overdistention of the bladder or the gut. Regardless of the type of stimulus, the resulting reflex, called the *mass reflex*, involves large portions or even all of the cord. The effects are as follows: (1) a major portion of the body's skeletal muscles goes into strong flexor spasm; (2) the colon and bladder are likely to evacuate; (3) the arterial pressure often rises to high levels, sometimes to a systolic pressure well over 200 mm Hg; and (4) large areas of the body break out into profuse sweating.

Because the mass reflex can last for minutes, it presumably results from activation of large numbers of reverberating circuits that excite large areas of the cord at once. This mechanism is similar to the mechanism of epileptic seizures, which involve reverberating circuits that occur in the brain instead of in the cord.

Spinal Cord Transection and Spinal Shock

When the spinal cord is suddenly transected in the upper neck, essentially all cord functions, including the cord reflexes, immediately become depressed to the point of total silence, a reaction called *spinal shock*. The reason for this reaction is that normal activity of the cord neurons depends to a great extent on continual tonic excitation by the discharge of nerve fibers entering the cord from higher centers, particularly discharge transmitted through the reticulospinal tracts, vestibulospinal tracts, and corticospinal tracts.

After a few hours to a few weeks, the spinal neurons gradually regain their excitability. This phenomenon seems to be a natural characteristic of neurons everywhere in the nervous system; after they lose their source of facilitatory impulses, they increase their own natural degree of excitability to make up at least partially for the loss. In most nonprimates, excitability of the cord centers returns essentially to normal within a few hours to a day or so, but in humans, the return is often delayed for several weeks and occasionally is never complete; however, recovery is sometimes excessive, with resultant hyperexcitability of some or all cord functions.

Some of the spinal functions specifically affected during or after spinal shock are the following:

1. At onset of spinal shock, the arterial blood pressure falls almost instantly and drastically—sometimes to as low as 40 mm Hg—thus demonstrating that sympathetic nervous system activity becomes blocked almost to extinction. The pressure ordinarily returns to normal within a few days, even in humans.
2. All skeletal muscle reflexes integrated in the spinal cord are blocked during the initial stages of shock. In lower animals, a few hours to a few days are required for these reflexes to return to normal; in humans, 2 weeks to several months are sometimes required. In both animals and humans, some reflexes may eventually become hyperexcitable, particularly if a few facilitatory pathways remain intact between the brain and the cord while the remainder of the spinal cord is transected. The first reflexes to return are the stretch reflexes, followed in order by the progressively more complex reflexes: flexor reflexes, postural antigravity reflexes, and remnants of stepping reflexes.
3. The sacral reflexes for control of bladder and colon evacuation are suppressed in humans for the first few weeks after cord transection, but in most cases they eventually return. These effects are discussed in Chapters 26 and 67.

CHAPTER 56

Cortical and Brain Stem Control of Motor Function

Most "voluntary" movements initiated by the cerebral cortex are achieved when the cortex activates "patterns" of function stored in lower brain areas—the spinal cord, brain stem, basal ganglia, and cerebellum. These lower centers, in turn, send specific control signals to the muscles.

For a few types of movements, however, the cortex has almost a direct pathway to the anterior motor neurons of the cord, bypassing some motor centers on the way. This is especially true for control of the fine dexterous movements of the fingers and hands. This chapter and Chapter 57 explain the interplay among the different motor areas of the brain and spinal cord to provide overall synthesis of voluntary motor function.

MOTOR CORTEX AND CORTICOSPINAL TRACT

Fig. 56.1 shows the functional areas of the cerebral cortex. Anterior to the central cortical sulcus, occupying approximately the posterior one-third of the frontal lobes, is the *motor cortex*. Posterior to the central sulcus is the *somatosensory cortex* (an area discussed in detail in earlier chapters), which feeds the motor cortex many of the signals that initiate motor activities.

The motor cortex is divided into three subareas, each of which has its own topographical representation of muscle groups and specific motor functions: (1) the *primary motor cortex;* (2) the *premotor area;* and (3) the *supplementary motor area*.

PRIMARY MOTOR CORTEX

The primary motor cortex, shown in **Fig. 56.1**, lies in the first convolution of the frontal lobes anterior to the central sulcus. It begins laterally in the sylvian fissure, spreads superiorly to the uppermost portion of the brain, and then dips deep into the longitudinal fissure. (This area is the same as area 4 in the Brodmann classification of the brain's cortical areas, shown in **Fig. 48.5**.)

Fig. 56.1 lists the approximate topographical representations of the different muscle areas of the body in the primary motor cortex, beginning with the face and mouth region near the sylvian fissure; the arm and hand area, in the midportion of the primary motor cortex; the trunk, near the apex of the brain; and the leg and foot areas in the part of the primary motor cortex that dips into the longitudinal fissure. This topographical organization is demonstrated even more graphically in **Fig. 56.2**, which shows the degrees of representation of the different muscle areas as mapped by Penfield and Rasmussen. This mapping was done by electrically stimulating the different areas of the motor cortex in human beings who were undergoing neurosurgery. Note that more than half of the entire primary motor cortex is concerned with controlling the muscles of the hands and the muscles of speech. Point stimulation in these hand and speech motor areas on rare occasion causes contraction of a single muscle, but stimulation usually contracts a group of muscles. To express this in another way, excitation of a single motor cortex neuron usually excites a specific movement rather than one specific muscle. To do this, it excites a "pattern" of separate muscles, each of which contributes its own direction and strength of muscle movement.

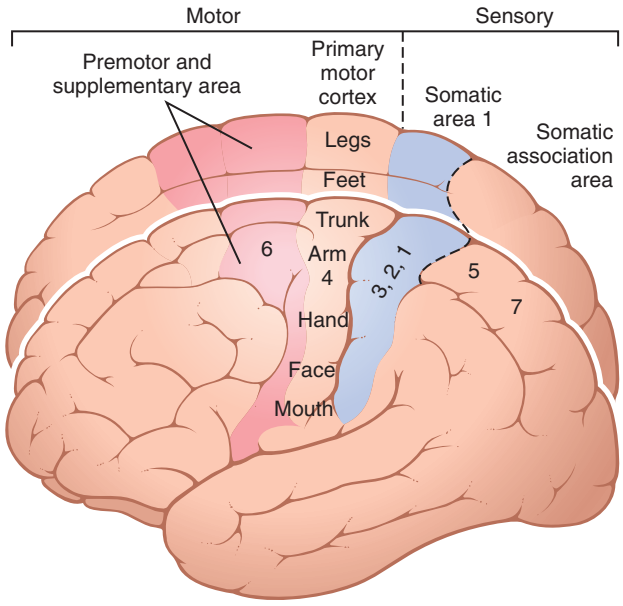

Figure 56.1 Motor and somatosensory functional areas of the cerebral cortex. The numbers 4, 5, 6, and 7 are Brodmann cortical areas, as explained in Chapter 48.

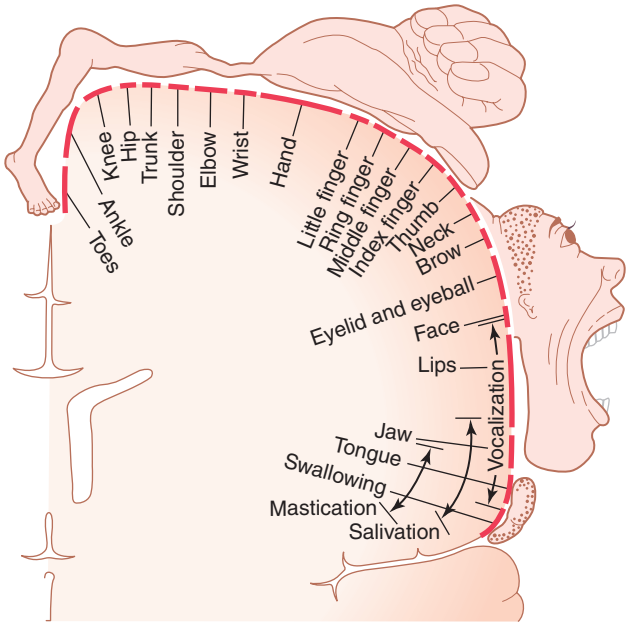

Figure 56.2 Degree of representation of the different muscles of the body in the motor cortex. *(Modified from Penfield W, Rasmussen T.* The Cerebral Cortex of Man: A Clinical Study of Localization of Function. *New York: Hafner; 1968.)*

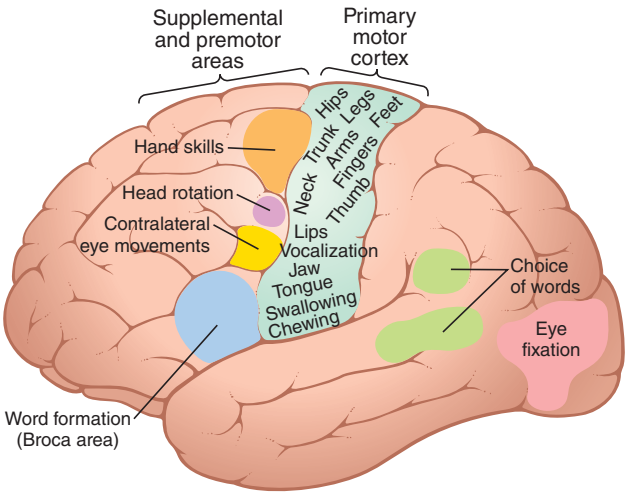

Figure 56.3 Representation of the different muscles of the body in the motor cortex and location of other cortical areas responsible for specific types of motor movements.

PREMOTOR AREA

The premotor area, also shown in **Fig. 56.1**, lies 1 to 3 centimeters anterior to the primary motor cortex. It extends inferiorly into the sylvian fissure and superiorly into the longitudinal fissure, where it abuts the supplementary motor area, which has functions similar to those of the premotor area. The topographical organization of the premotor cortex is roughly the same as that of the primary motor cortex, with the mouth and face areas located most laterally; as one moves upward, the hand, arm, trunk, and leg areas are encountered.

Nerve signals generated in the premotor area cause much more complex "patterns" of movement than the discrete patterns generated in the primary motor cortex. For example, the pattern may be to position the shoulders and arms so that the hands are properly oriented to perform specific tasks. To achieve these results, the most anterior part of the premotor area first develops a "motor image" of the total muscle movement that is to be performed. Then, in the posterior premotor cortex, this image excites each successive pattern of muscle activity required to achieve the image. This posterior part of the premotor cortex sends its signals either directly to the primary motor cortex to excite specific muscles or, often, by way of the basal ganglia and thalamus back to the primary motor cortex.

A special class of neurons called *mirror neurons* becomes active when a person performs a specific motor task or when they observe the same task performed by others. Thus, the activity of these neurons "mirrors" the behavior of another person as though the observer was performing the specific motor task. Brain imaging studies indicate that these neurons transform sensory representations of acts that are heard or seen into motor representations of these acts. Many neurophysiologists believe that these mirror neurons may be important for understanding the actions of other people and for learning new skills by imitation. Thus, the premotor cortex, basal ganglia, thalamus, and primary motor cortex constitute a complex overall system for the control of complex patterns of coordinated muscle activity.

SUPPLEMENTARY MOTOR AREA

The supplementary motor area has yet another topographical organization for controlling motor function. It lies mainly in the longitudinal fissure but extends a few centimeters onto the superior frontal cortex. Contractions elicited by stimulating this area are often bilateral rather than unilateral. For example, stimulation frequently leads to bilateral grasping movements of both hands simultaneously; these movements are perhaps rudiments of the hand functions required for climbing. In general, this area functions in concert with the premotor area to provide body-wide attitudinal movements, fixation movements of the different segments of the body, positional movements of the head and eyes, and so forth, as background for the finer motor control of the arms and hands by the premotor area and primary motor cortex.

SOME SPECIALIZED AREAS OF MOTOR CONTROL FOUND IN THE HUMAN MOTOR CORTEX

A few highly specialized motor regions of the human cerebral cortex (shown in **Fig. 56.3**) control specific motor functions. These regions have been localized either by electrical stimulation or by noting the loss of motor function when destructive lesions occur in specific cortical

areas. Some of the more important regions are described in the following sections.

Broca Area (Motor Speech Area). Fig. 56.3 shows a premotor area labeled "word formation" lying immediately anterior to the primary motor cortex and immediately above the sylvian fissure. This region is called the *Broca area*. Damage to this area, often associated with a "stroke" caused by blockage or rupture of the middle cerebral artery, may not prevent a person from vocalizing but makes it impossible to generate fluent speech. A person with *Broca aphasia* is usually able to comprehend spoken language but may speak only with uncoordinated utterances or an occasional simple word such as "no" or "yes," depending on the severity of the damage.

A closely associated cortical area also causes appropriate respiratory function, so respiratory activation of the vocal cords can occur simultaneously with the movements of the mouth and tongue during speech. Thus, the premotor neuronal activities related to speech are highly complex.

"Voluntary" Eye Movement Field. In the premotor area immediately above the Broca area is a locus for controlling voluntary eye movements. Damage to this area prevents a person from *voluntarily* moving the eyes toward different objects. Instead, the eyes tend to lock involuntarily onto specific objects, an effect controlled by signals from the occipital visual cortex, as explained in Chapter 52. This frontal area also controls eyelid movements such as blinking.

Head Rotation Area. Slightly higher in the motor association area, electrical stimulation elicits head rotation. This area is closely associated with the eye movement field; it directs the head toward different objects.

Area for Hand Skills. In the premotor area immediately anterior to the primary motor cortex for the hands and fingers is a region that is important for "hand skills." That is, when tumors or other lesions cause destruction in this area, hand movements become uncoordinated and nonpurposeful, a condition called *motor apraxia*.

TRANSMISSION OF SIGNALS FROM THE MOTOR CORTEX TO THE MUSCLES

Motor signals are transmitted directly from the cortex to the spinal cord through the *corticospinal tract* and indirectly through multiple accessory pathways that involve the *basal ganglia, cerebellum*, and various *nuclei of the brain stem*. In general, the direct pathways are concerned with discrete and detailed movements, especially of the distal segments of the limbs, particularly the hands and fingers.

Corticospinal (Pyramidal) Tract

The most important output pathway from the motor cortex is the *corticospinal tract*, also called the *pyramidal tract*, shown in Fig. 56.4. The corticospinal tract originates about 30% from the primary motor cortex, 30% from the premotor and supplementary motor areas, and 40% from the somatosensory areas posterior to the central sulcus.

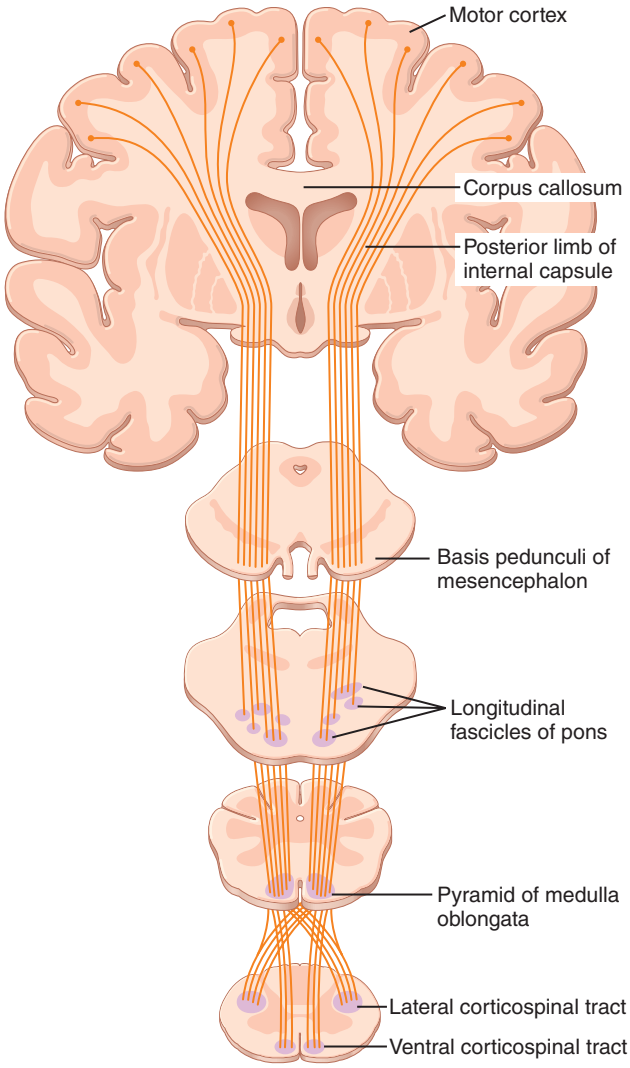

Figure 56.4 Corticospinal (pyramidal) tract. *(Modified from Ranson SW, Clark SL. Anatomy of the Nervous System. Philadelphia: WB Saunders; 1959.)*

After leaving the cortex, it passes through the posterior limb of the internal capsule (between the caudate nucleus and the putamen of the basal ganglia) and then downward through the brain stem, forming the *pyramids of the medulla*. Most of the pyramidal fibers then cross in the lower medulla to the opposite side and descend into the *lateral corticospinal tracts* of the cord, finally terminating principally on the interneurons in the intermediate regions of the cord gray matter. A few terminate on sensory relay neurons in the dorsal horn, and a very few terminate directly on the anterior motor neurons that cause muscle contraction.

A few of the fibers do not cross to the opposite side in the medulla but pass ipsilaterally down the cord in the *ventral corticospinal tracts*. Many, if not most, of these

fibers eventually cross to the opposite side of the cord either in the neck or in the upper thoracic region. These fibers may be concerned with control of bilateral postural movements by the supplementary motor cortex.

The most impressive fibers in the pyramidal tract are a population of large myelinated fibers with a mean diameter of about 16 micrometers. These fibers originate from *giant pyramidal cells*, called *Betz cells*, that are found only in the primary motor cortex. The Betz cells are about 60 micrometers in diameter, and their fibers transmit nerve impulses to the spinal cord at a velocity of about 70 m/sec, the most rapid rate of transmission of any signals from the brain to the cord. There are about 34,000 of these large Betz cell fibers in each corticospinal tract. The total number of fibers in each corticospinal tract is more than 1 million, so these large fibers represent only 3% of the total. The other 97% are mainly fibers smaller than 4 micrometers in diameter that conduct background tonic signals to the motor areas of the cord.

Other Fiber Pathways From the Motor Cortex

The motor cortex gives rise to large numbers of additional (mainly small) fibers that go to deep regions in the cerebrum and brain stem, including the following:

1. The axons from the giant Betz cells send short collaterals back to the cortex. These collaterals are believed to inhibit adjacent regions of the cortex when the Betz cells discharge, thereby "sharpening" the boundaries of the excitatory signal.
2. A large number of fibers pass from the motor cortex into the *caudate nucleus* and *putamen*. From there, additional pathways extend into the brain stem and spinal cord, as discussed in Chapter 57, mainly to control body postural muscle contractions.
3. A moderate number of motor fibers pass to *red nuclei* of the midbrain. From these nuclei, additional fibers pass down the cord through the *rubrospinal tract*.
4. A moderate number of motor fibers deviate into the *reticular substance* and *vestibular nuclei* of the brain stem; from there, signals go to the cord via *reticulospinal* and *vestibulospinal tracts*, and others go to the cerebellum via *reticulocerebellar* and *vestibulocerebellar tracts*.
5. A tremendous number of motor fibers synapse in the pontile nuclei, which give rise to the *pontocerebellar fibers*, carrying signals into the cerebellar hemispheres.
6. Collaterals also terminate in the *inferior olivary nuclei*, and from there, secondary *olivocerebellar fibers* transmit signals to multiple areas of the cerebellum.

Thus, the basal ganglia, brain stem, and cerebellum all receive strong motor signals from the corticospinal system every time a signal is transmitted down the spinal cord to cause a motor activity.

Incoming Sensory Fiber Pathways to the Motor Cortex

The functions of the motor cortex are controlled mainly by nerve signals from the somatosensory system but also, to some degree, from other sensory systems such as hearing and vision. Once the sensory information is received, the motor cortex operates in association with the basal ganglia and cerebellum to excite appropriate motor actions. Important incoming fiber pathways to the motor cortex include the following:

1. Subcortical fibers from adjacent regions of the cerebral cortex, especially from (a) somatosensory areas of the parietal cortex, (b) adjacent areas of the frontal cortex anterior to the motor cortex, and (c) visual and auditory cortices.
2. Subcortical fibers that arrive through the corpus callosum from the opposite cerebral hemisphere. These fibers connect corresponding areas of the cortices in the two sides of the brain.
3. Somatosensory fibers that arrive directly from the ventrobasal complex of the thalamus. These fibers relay mainly cutaneous tactile signals and joint and muscle signals from the peripheral body.
4. Tracts from the ventrolateral and ventroanterior nuclei of the thalamus, which in turn receive signals from the cerebellum and basal ganglia. These tracts provide signals that are necessary for coordination among the motor control functions of the motor cortex, basal ganglia, and cerebellum.
5. Fibers from the intralaminar nuclei of the thalamus. These fibers control the general level of excitability of the motor cortex in the same way they control the general level of excitability of most other regions of the cerebral cortex.

THE RED NUCLEUS SERVES AS AN ALTERNATIVE PATHWAY FOR TRANSMITTING CORTICAL SIGNALS TO THE SPINAL CORD

The *red nucleus*, located in the mesencephalon, functions in close association with the corticospinal tract. As shown in **Fig. 56.5**, it receives a large number of direct fibers from the primary motor cortex through the *corticorubral tract*,

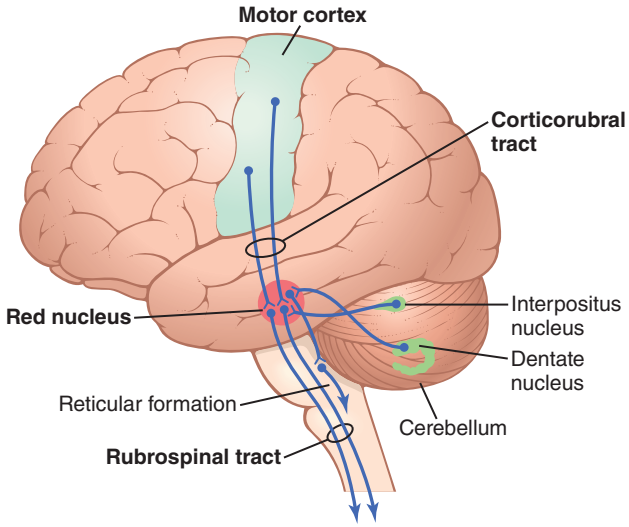

Figure 56.5 The corticorubrospinal pathway for motor control, also showing the relation of this pathway to the cerebellum.

as well as branching fibers from the corticospinal tract as it passes through the mesencephalon. These fibers synapse in the lower portion of the red nucleus, the *magnocellular portion*, which contains large neurons similar in size to the Betz cells in the motor cortex. These large neurons then give rise to the *rubrospinal tract*, which crosses to the opposite side in the lower brain stem and follows a course immediately adjacent and anterior to the corticospinal tract into the lateral columns of the spinal cord.

The rubrospinal fibers terminate mostly on the interneurons of the intermediate areas of the cord gray matter, along with the corticospinal fibers, but some of the rubrospinal fibers terminate directly on anterior motor neurons, along with some corticospinal fibers. The red nucleus also has close connections with the cerebellum, similar to the connections between the motor cortex and the cerebellum.

The Corticorubrospinal System Is an Accessory Pathway for Transmitting Relatively Discrete Signals From the Motor Cortex to the Spinal Cord. The magnocellular portion of the red nucleus has a somatographic representation of all the muscles of the body, as does the motor cortex. Therefore, stimulation of a single point in this portion of the red nucleus causes contraction of either a single muscle or a small group of muscles. However, the fineness of representation of the different muscles is far less developed than in the motor cortex, especially in human beings, who have relatively small red nuclei.

The corticorubrospinal pathway serves as an accessory route for transmission of relatively discrete signals from the motor cortex to the spinal cord. When the corticospinal fibers are destroyed but the corticorubrospinal pathway is intact, discrete movements can still occur, except that the movements for fine control of the fingers and hands are considerably impaired. Wrist movements are still functional, which is not the case when the corticorubrospinal pathway is also blocked.

Therefore, the pathway through the red nucleus to the spinal cord is associated with the corticospinal system. Furthermore, the rubrospinal tract lies in the lateral columns of the spinal cord, along with the corticospinal tract, and terminates on the interneurons and motor neurons that control the more distal muscles of the limbs. Therefore, the corticospinal and rubrospinal tracts together are called the *lateral motor system of the cord*, in contradistinction to a vestibuloreticulospinal system, which lies mainly medially in the cord and is called the *medial motor system of the cord*, as discussed later in this chapter.

EXCITATION OF THE SPINAL CORD MOTOR CONTROL AREAS BY THE PRIMARY MOTOR CORTEX AND RED NUCLEUS

Neurons in the Motor Cortex Are Arranged in Vertical Columns. In Chapters 48 and 52, we pointed out that the cells in the somatosensory cortex and visual cortex are organized in *vertical columns of cells*. The cells of the motor cortex are also organized in vertical columns a fraction of a millimeter in diameter, with thousands of neurons in each column.

Each column of cells functions as a unit, usually stimulating a group of synergistic muscles, but sometimes stimulating just a single muscle. Also, each column has six distinct layers of cells, as is true throughout nearly all the cerebral cortex. The pyramidal cells that give rise to the corticospinal fibers all lie in the fifth layer of cells from the cortical surface. The input signals all enter via layers 2 through 4, and the sixth layer gives rise mainly to fibers that communicate with other regions of the cerebral cortex.

Each Column of Neurons Functions as an Integrative Processing System. The neurons of each column operate as an integrative processing system, using information from multiple input sources to determine the output response from the column. In addition, each column can function as an amplifying system to stimulate large numbers of pyramidal fibers to the same muscle or to synergistic muscles simultaneously. This ability is important because stimulation of a single pyramidal cell seldom excites a muscle. Usually, 50 to 100 pyramidal cells need to be excited simultaneously or in rapid succession to achieve definitive muscle contraction.

Dynamic and Static Signals Are Transmitted By the Pyramidal Neurons. If a strong signal is sent to a muscle to cause initial rapid contraction, then a much weaker continuing signal can maintain the contraction for long periods thereafter. This process is the usual manner in which excitation is provided to cause muscle contractions. To provide this excitation, each column of cells excites two populations of pyramidal cell neurons, one called *dynamic neurons* and the other *static neurons*. The dynamic neurons are excited at a high rate for a short period at the beginning of a contraction, causing the initial rapid *development of force*. The static neurons then fire at a much slower rate, but they continue firing at this slow rate to *maintain the force of contraction* as long as the contraction is required.

The neurons of the red nucleus have similar dynamic and static characteristics, except that a greater percentage of dynamic neurons is in the red nucleus and a greater percentage of static neurons is in the primary motor cortex. This may be related to the fact that the red nucleus is closely allied with the cerebellum, and the cerebellum plays an important role in rapid initiation of muscle contraction, as explained in the next chapter.

Somatosensory Feedback to the Motor Cortex Helps Control Precision of Muscle Contraction

When nerve signals from the motor cortex cause a muscle to contract, somatosensory signals return all the way from the activated region of the body to the neurons in

the motor cortex that are initiating the action. Most of these somatosensory signals arise in the following: (1) the muscle spindles; (2) the muscle tendon organs; or (3) the tactile receptors of the skin overlying the muscles.

These somatic signals often cause positive feedback enhancement of the muscle contraction. In the case of the muscle spindles, if the fusimotor muscle fibers in the spindles contract more than the large skeletal muscle fibers contract, the central portions of the spindles become stretched and, therefore, excited. Signals from these spindles then return rapidly to the pyramidal cells in the motor cortex and signal them that the large muscle fibers have not contracted enough. The pyramidal cells further excite the muscle, helping its contraction to catch up with the contraction of the muscle spindles.

In the case of the tactile receptors, if the muscle contraction causes compression of the skin against an object, such as compression of the fingers around an object being grasped, the signals from the skin receptors can, if necessary, cause further excitation of the muscles and, therefore, increase the tightness of the hand grasp.

Stimulation of the Spinal Motor Neurons

Fig. 56.6 shows a cross section of a spinal cord segment illustrating the following: (1) multiple motor and sensorimotor control tracts entering the cord segment; and (2) a representative anterior motor neuron in the middle of the anterior horn gray matter. The corticospinal tract and the rubrospinal tract lie in the dorsal portions of the lateral white columns. Their fibers terminate mainly on interneurons in the intermediate area of the cord gray matter.

In the cervical enlargement of the cord where the hands and fingers are represented, large numbers of both corticospinal and rubrospinal fibers also terminate directly on the anterior motor neurons, allowing a direct route from the brain to activate muscle contraction. This mechanism is in keeping with the fact that the primary motor cortex has an extremely high degree of representation for fine control of hand, finger, and thumb actions.

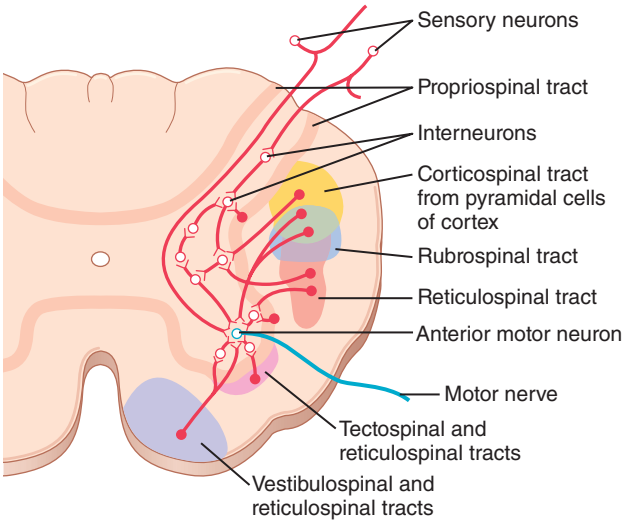

Figure 56.6 Convergence of different motor control pathways on the anterior motor neurons.

Patterns of Movement Elicited By Spinal Cord Centers. From Chapter 55, recall that the spinal cord can provide certain specific reflex patterns of movement in response to sensory nerve stimulation. Many of these same patterns are also important when the cord's anterior motor neurons are excited by signals from the brain. For example, the stretch reflex is functional at all times, helping to damp any oscillations of the motor movements initiated from the brain. This reflex probably also provides at least part of the motive power required to cause muscle contractions when the intrafusal fibers of the muscle spindles contract more than the large skeletal muscle fibers, thus eliciting reflex "servo-assist" stimulation of the muscle, in addition to the direct stimulation by the corticospinal fibers.

Also, when a brain signal excites a muscle, it is usually unnecessary to transmit an inverse signal to relax the antagonist muscle at the same time; this relaxation is achieved by the *reciprocal innervation* circuit that is always present in the cord for coordinating the function of antagonistic pairs of muscles.

Finally, other cord reflex mechanisms, such as withdrawal, stepping and walking, scratching, and postural mechanisms, can each be activated by "command" signals from the brain. Thus, command signals from the brain can initiate many normal motor activities, particularly for such functions as walking and attaining different postures of the body.

Effect of Lesions in the Motor Cortex or in the Corticospinal Pathway.

Reduced Brain Blood Supply Caused By a Stroke. The motor control system can be damaged by a stroke due to a ruptured blood vessel that hemorrhages into the brain or a thrombosis of one of the major arteries supplying blood to the brain. In either case, the result is loss of blood supply to the cortex or to the corticospinal tract where it passes through the internal capsule between the caudate nucleus and the putamen.

Removal of the Primary Motor Cortex (Area Pyramidalis). Surgical removal of a portion of the primary motor cortex—the area that contains the giant Betz pyramidal cells—causes varying degrees of paralysis of the represented muscles. If the sublying caudate nucleus and adjacent premotor and supplementary motor areas are not damaged, gross postural and limb "fixation" movements can still occur, but there is *loss of voluntary control of discrete movements of the distal segments of the limbs, especially of the hands and fingers*. This does not mean that the hand and finger muscles cannot contract; rather, the *ability to control the fine movements is gone*. From these observations, one can conclude that the area pyramidalis is essential for voluntary initiation of finely controlled movements, especially of the hands and fingers.

Muscle Spasticity Caused By Lesions That Damage Large Areas Adjacent to the Motor Cortex. The primary motor cortex normally exerts a continual tonic stimulatory effect on the motor neurons of the spinal cord; when this stimulatory effect is removed, *hypotonia* results. Most lesions of the motor cortex, especially those caused by a *stroke*, involve not only the primary motor cortex but also adjacent parts of the brain, such as the basal ganglia. In these cases, *muscle spasm* almost invariably occurs in the afflicted muscle areas on the *opposite side* of the body (because the motor pathways cross to the opposite side). This spasm results mainly from damage to accessory pathways from the nonpyramidal portions of the motor cortex. These pathways normally inhibit the vestibular and reticular brain stem motor nuclei. When these nuclei cease their state of inhibition (i.e., are "disinhibited"), they become spontaneously active and cause excessive spastic tone in the involved muscles, as we discuss more fully later in this chapter. This spasticity often accompanies a stroke in a human being.

CONTROL OF MOTOR FUNCTIONS BY THE BRAIN STEM

The brain stem consists of the *medulla, pons*, and *mesencephalon (or midbrain)*. In one sense, it is an extension of the spinal cord upward into the cranial cavity because it contains motor and sensory nuclei that perform motor and sensory functions for the face and head regions in the same way that the spinal cord performs these functions from the neck down. In another sense, however, the brain stem is its own master because it provides many special control functions, such as the following:

1. Control of respiration
2. Control of the cardiovascular system
3. Partial control of gastrointestinal function
4. Control of many stereotyped movements of the body
5. Control of equilibrium
6. Control of eye movements

Finally, the brain stem serves as a way station for "command signals" from higher neural centers. Many of these functions are discussed in other chapters in this text. In the following sections, we discuss the role of the brain stem in controlling whole-body movement and equilibrium. Especially important for these purposes are the brain stem's *reticular nuclei* and *vestibular nuclei*.

SUPPORT OF THE BODY AGAINST GRAVITY—ROLES OF THE RETICULAR AND VESTIBULAR NUCLEI

Fig. 56.7 shows the locations of the reticular and vestibular nuclei in the brain stem.

Excitatory-Inhibitory Antagonism Between Pontine and Medullary Reticular Nuclei

The reticular nuclei are divided into two major groups: (1) *pontine reticular nuclei*, located slightly posteriorly and laterally in the pons and extending into the mesencephalon; and (2) *medullary reticular nuclei*, which extend through the entire medulla, lying ventrally and medially near the midline. These two sets of nuclei function mainly antagonistically to each other, with the pontine exciting the antigravity muscles and the medullary relaxing these same muscles.

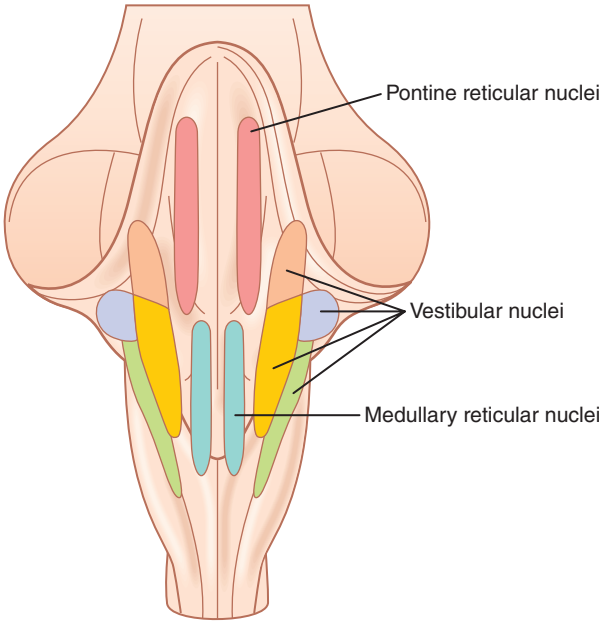

Figure 56.7 Locations of the reticular and vestibular nuclei in the brain stem.

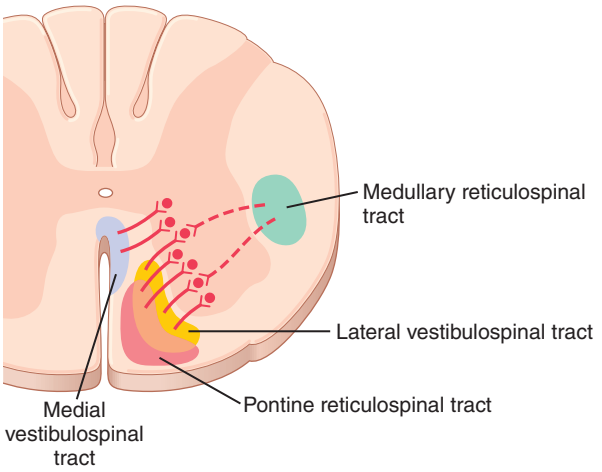

Figure 56.8 Vestibulospinal and reticulospinal tracts descending in the spinal cord to excite *(solid lines)* or inhibit *(dashed lines)* the anterior motor neurons that control the body's axial musculature.

Pontine Reticular System Transmits Excitatory Signals. The pontine reticular nuclei transmit excitatory signals downward into the cord through the *pontine reticulospinal tract* in the anterior column of the cord, as shown in **Fig. 56.8**. The fibers of this pathway terminate on the medial anterior motor neurons that excite the axial muscles of the body, which support the body against gravity—that is, the muscles of the vertebral column and the extensor muscles of the limbs.

The pontine reticular nuclei have a high degree of natural excitability. In addition, they receive strong excitatory signals from the vestibular nuclei, as well as from deep nuclei of the cerebellum. Therefore, when the pontine reticular excitatory system is unopposed by the medullary reticular system, it causes powerful excitation of antigravity muscles throughout the body, so much so that four-legged animals can be placed in a standing position, supporting the body against gravity without any signals from higher levels of the brain.

Medullary Reticular System Transmits Inhibitory Signals. The medullary reticular nuclei transmit inhibitory signals to the same antigravity anterior motor neurons via a different tract, the *medullary reticulospinal tract*, located in the lateral column of the cord, as also shown in **Fig. 56.8**. The medullary reticular nuclei receive strong input collaterals from the following: (1) the corticospinal tract; (2) the rubrospinal tract; and (3) other motor pathways. These tracts and pathways normally activate the medullary reticular inhibitory system to counterbalance the excitatory signals from the pontine reticular system, so under normal conditions the body muscles are not abnormally tense.

Yet, some signals from higher areas of the brain can "disinhibit" the medullary system when the brain wishes to excite the pontine system to cause standing. At other times, excitation of the medullary reticular system can inhibit antigravity muscles in certain portions of the body to allow those portions to perform special motor activities. The excitatory and inhibitory reticular nuclei constitute a controllable system that is manipulated by motor signals from the cerebral cortex and elsewhere to provide necessary background muscle contractions for standing against gravity and to inhibit appropriate groups of muscles as needed so that other functions can be performed.

Role of the Vestibular Nuclei to Excite the Antigravity Muscles

All the *vestibular nuclei*, shown in **Fig. 56.7**, function in association with the pontine reticular nuclei to control the antigravity muscles. The vestibular nuclei transmit strong excitatory signals to the antigravity muscles via the *lateral* and *medial vestibulospinal tracts* in the anterior columns of the spinal cord, as shown in **Fig. 56.8**. Without this support of the vestibular nuclei, the pontine reticular system would lose much of its excitation of the axial antigravity muscles.

The specific role of the vestibular nuclei, however, is to *selectively* control the excitatory signals to the different antigravity muscles to maintain equilibrium *in response to signals from the vestibular apparatus*. We discuss this concept more fully later in this chapter.

The Decerebrate Animal Develops Spastic Rigidity. When the brain stem is sectioned below the midlevel of the mesencephalon but the pontine and medullary reticular systems, as well as the vestibular system, are left intact, a condition called *decerebrate rigidity* develops. This rigidity does not occur in all the muscles of the body, but it does occur in the antigravity muscles—the muscles of the neck and trunk and the extensors of the legs.

The cause of decerebrate rigidity is blockage of normally strong input to the medullary reticular nuclei from the cerebral cortex, the red nuclei, and the basal ganglia. Lacking this input, the medullary reticular inhibitor system becomes nonfunctional, full overactivity of the pontine excitatory system occurs, and rigidity develops. We shall see later that other causes of rigidity occur in other neuromotor diseases, especially lesions of the basal ganglia.

VESTIBULAR SENSATIONS AND MAINTENANCE OF EQUILIBRIUM

VESTIBULAR APPARATUS

The vestibular apparatus, shown in **Fig. 56.9**, is the sensory organ for detecting sensations of equilibrium. It is encased in a system of bony tubes and chambers located in the petrous portion of the temporal bone, called the *bony labyrinth*. Within this system are membranous tubes and chambers called the *membranous labyrinth*.

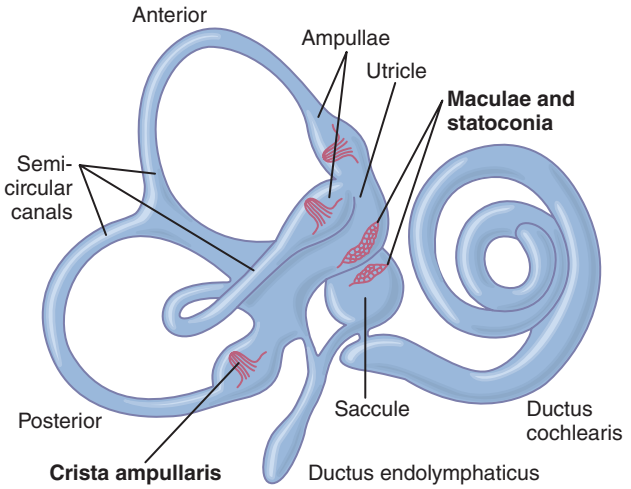

Figure 56.9 Membranous labyrinth and organization of the crista ampullaris and the macula.

The membranous labyrinth is the functional part of the vestibular apparatus.

The top of **Fig. 56.9** shows the membranous labyrinth. It is composed mainly of the *cochlea* (ductus cochlearis), three *semicircular canals*, and two large chambers, the *utricle* and *saccule*. The cochlea is the major sensory organ for hearing (see Chapter 53) and has little to do with equilibrium. However, the *semicircular canals*, the *utricle*, and the *saccule* are all integral parts of the equilibrium mechanism.

Maculae in the Utricle and Saccule Are Sensory Organs for Detecting Orientation of the Head With Respect to Gravity. Located on the inside surface of each utricle and saccule, shown in the top diagram of **Fig. 56.9**, is a small sensory area slightly greater than 2 millimeters in diameter called a *macula*. The *macula of the utricle* lies mainly in the *horizontal plane* on the inferior surface of the utricle and plays an important role in determining orientation of the head when the head is upright. Conversely, the *macula of the saccule* is located mainly in a *vertical plane* and signals head orientation when the person is lying down.

Each macula is covered by a gelatinous layer in which many small calcium carbonate crystals called *statoconia* are embedded. Also in the macula are thousands of *hair cells*, one of which is shown in **Fig. 56.10**; these hair cells project *cilia* up into the gelatinous layer. The bases and sides of the hair cells synapse with sensory endings of the *vestibular nerve*.

The calcified statoconia have a *specific gravity* two to three times the specific gravity of the surrounding fluid and tissues. The weight of the statoconia bends the cilia in the direction of gravitational pull.

Directional Sensitivity of the Hair Cells—Kinocilium. Each hair cell has about 100 small cilia called *stereocilia*, plus one large cilium, the *kinocilium*, as shown in **Fig. 56.10**. The kinocilium is always located to one side, and the stereocilia become progressively shorter toward the other side of the cell. Minute filamentous attachments, almost invisible even to the electron microscope, connect the tip of each stereocilium to the next longer stereocilium and, finally, to the kinocilium.

Because of these attachments, when the stereocilia bend in the direction of the kinocilium, the filamentous attachments tug in sequence on the stereocilia, pulling them outward from the cell body. This movement opens several hundred cation channels in the neuronal cell membrane around the bases of the stereocilia, and these channels are capable of conducting large numbers of positive ions. Therefore, positive ions pour into the cell from the surrounding endolymphatic fluid, causing *receptor membrane depolarization*. Conversely, bending the pile of stereocilia in the opposite direction (backward, away from the kinocilium) reduces the tension on the attachments; this movement closes the ion channels, thus causing *receptor hyperpolarization*.

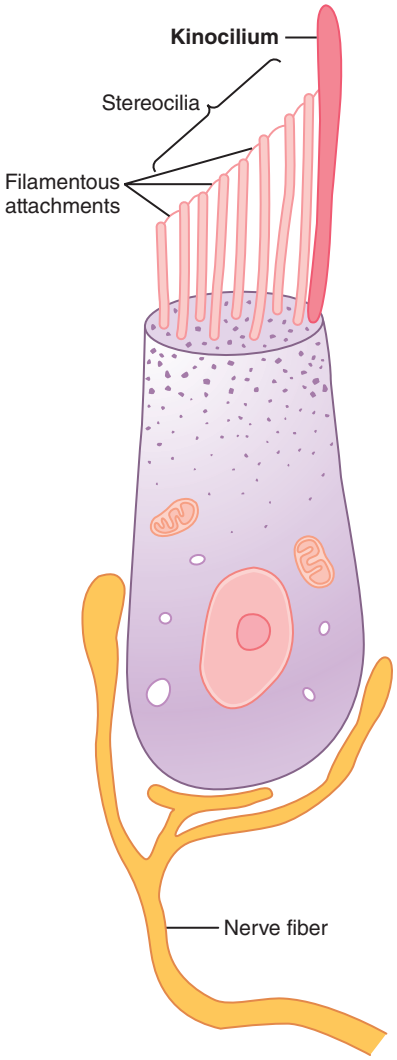

Figure 56.10 A hair cell of the equilibrium apparatus and its synapses with the vestibular nerve.

Under normal resting conditions, the nerve fibers leading from the hair cells transmit continuous nerve impulses at a rate of about 100 per second. When the stereocilia are bent toward the kinocilium, the impulse traffic increases, often to several hundred per second; conversely, bending the cilia away from the kinocilium decreases the impulse traffic, often turning it off completely. Therefore, as the orientation of the head in space changes and the weight of the statoconia bends the cilia, appropriate signals are transmitted to the brain to control equilibrium.

In each macula, each of the hair cells is oriented in a different direction so that some of the hair cells are stimulated when the head bends forward, some are stimulated when it bends backward, others are stimulated when it bends to one side, and so forth. Therefore, a different pattern of excitation occurs in the macular nerve fibers for each orientation of the head in the gravitational field. It is this "pattern" that apprises the brain of the head's orientation in space.

Semicircular Ducts. The three semicircular ducts in each vestibular apparatus, known as the *anterior, posterior*, and *lateral (horizontal) semicircular ducts*, are arranged at right angles to one another so that they represent all three planes in space. When the head is bent forward about 30 degrees, the lateral semicircular ducts are approximately horizontal with respect to the surface of the Earth; the anterior ducts are in vertical planes that project *forward and 45 degrees outward*, whereas the posterior ducts are in vertical planes that project *backward and 45 degrees outward*.

Each semicircular duct has an enlargement at one of its ends called the *ampulla*, and the ducts and ampulla are filled with a fluid called *endolymph*. Flow of this fluid through one of the ducts and through its ampulla excites the sensory organ of the ampulla. **Fig. 56.11** shows a small crest in each ampulla called a *crista ampullaris*. On top of this crista is a loose gelatinous tissue mass, the *cupula*. When a person's head begins to rotate in any direction, the inertia of the fluid in one or more of the semicircular ducts causes the fluid to remain stationary while the semicircular duct rotates with the head. This process causes fluid to flow from the duct and through the ampulla, bending the cupula to one side, as demonstrated by the position of the colored cupula in **Fig. 56.11**. Rotation of the head in the opposite direction causes the cupula to bend to the opposite side.

Hundreds of cilia from hair cells located on the ampullary crest are projected into the cupula. The kinocilia of these hair cells are all oriented in the same direction in the cupula, and bending the cupula in that direction causes depolarization of the hair cells, whereas bending it in the opposite direction hyperpolarizes the cells. Then, from the hair cells, appropriate signals are sent via the *vestibular nerve* to apprise the central nervous system of a *change in rotation* of the head and the *rate of change* in each of the three planes of space.

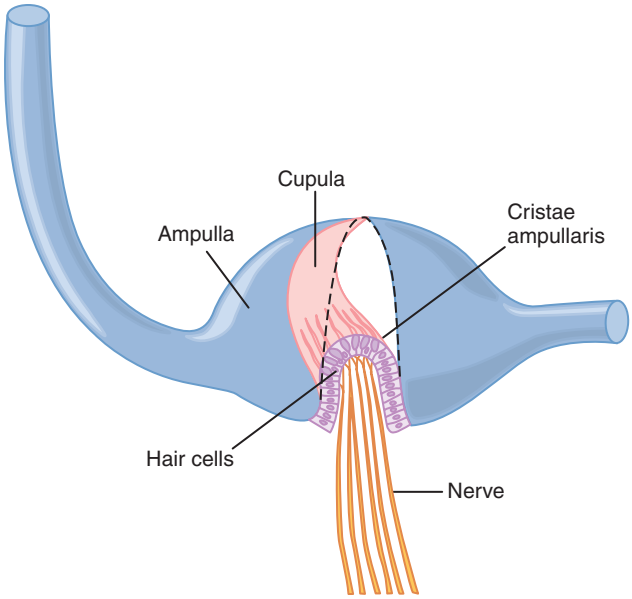

Figure 56.11 Movement of the cupula and its embedded hairs at the onset of rotation.

FUNCTION OF THE UTRICLE AND SACCULE IN THE MAINTENANCE OF STATIC EQUILIBRIUM

It is especially important that the hair cells are all oriented in different directions in the maculae of the utricles and saccules so that with different positions of the head, different hair cells become stimulated. The "patterns" of stimulation of the different hair cells apprise the brain of the position of the head with respect to the pull of gravity. In turn, the vestibular, cerebellar, and reticular motor nerve systems of the brain excite appropriate postural muscles to maintain proper equilibrium.

This utricle and saccule system functions extremely effectively for maintaining equilibrium when the head is in the near-vertical position. Indeed, a person can determine as little as half a degree of disequilibrium when the body leans from the precise upright position.

Detection of Linear Acceleration By the Utricle and Saccule Maculae. When the body is suddenly thrust forward—that is, when the body accelerates—the statoconia, which have greater mass inertia than the surrounding fluid, fall backward on the hair cell cilia, and information of disequilibrium is sent into the nervous centers, causing the person to feel as though they are falling backward. This sensation automatically causes the person to lean forward until the resulting anterior shift of the statoconia equals the tendency for the statoconia to fall backward because of the acceleration. At this point, the nervous system senses a state of proper equilibrium and leans the body forward no farther. Thus, the maculae operate to maintain equilibrium during linear acceleration in the same manner as they operate during static equilibrium.

The maculae *do not* operate for the detection of linear *velocity*. When runners first begin to run, they must lean far forward to keep from falling backward because of initial *acceleration*, but once they have achieved running speed, they would not have to lean forward if they were running in a vacuum. However, when running in air, they usually lean forward slightly to maintain equilibrium only because of air resistance against their bodies; in this case, it is not the maculae that make them lean but air pressure acting on pressure end-organs in the skin, which initiate appropriate equilibrium adjustments to prevent falling.

DETECTION OF HEAD ROTATION BY THE SEMICIRCULAR DUCTS

When the head suddenly begins to rotate in any direction (called *angular acceleration*), the endolymph in the semicircular ducts, because of its inertia, tends to remain stationary while the semicircular ducts turn. This mechanism causes relative fluid flow in the ducts in the direction opposite to head rotation.

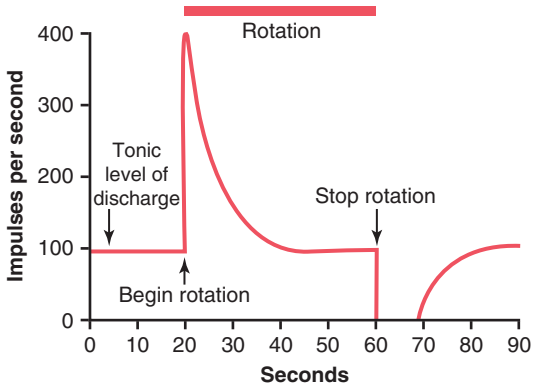

Figure 56.12 Response of a hair cell when a semicircular canal is stimulated first by the onset of head rotation and then by stopping rotation.

Fig. 56.12 shows a typical discharge signal from a single hair cell in the crista ampullaris when an animal is rotated for 40 seconds, demonstrating the following: (1) even when the cupula is in its resting position, the hair cell emits a tonic discharge of about 100 impulses per second; (2) when the animal begins to rotate, the hairs bend to one side, and the rate of discharge increases greatly; and (3) with continued rotation, the excess discharge of the hair cell gradually subsides back to the resting level during the next few seconds.

The reason for this adaptation of the receptor is that within the first few seconds of rotation, back resistance to the flow of fluid in the semicircular duct and past the bent cupula causes the endolymph to begin rotating as rapidly as the semicircular canal itself. Then, in another 5 to 20 seconds, the cupula slowly returns to its resting position in the middle of the ampulla because of its own elastic recoil.

When the rotation suddenly stops, exactly opposite effects take place: The endolymph continues to rotate while the semicircular duct stops. This time, the cupula bends in the opposite direction, causing the hair cell to stop discharging entirely. After another few seconds, the endolymph stops moving and the cupula gradually returns to its resting position, thus allowing hair cell discharge to return to its normal tonic level, as shown at the right in **Fig. 56.12**. Thus, the semicircular duct transmits a signal of one polarity when the head *begins* to rotate and of opposite polarity when it *stops* rotating.

"Predictive" Function of the Semicircular Duct System in the Maintenance of Equilibrium. Because the semicircular ducts do not detect that the body is off balance in the forward direction, in the side direction, or in the backward direction, one might question the role of semicircular ducts in the maintenance of equilibrium. All they detect is that the person's head is *beginning* or *stopping* to rotate in one direction or another. Therefore, the function of the semicircular ducts is not to maintain static equilibrium or to maintain equilibrium during steady directional or rotational movements. Yet, loss of function of the semicircular ducts does cause a person to have poor equilibrium when attempting to perform *rapid, intricate changing* body movements.

The function of the semicircular ducts can be explained by the following illustration: if a person is running forward rapidly and then suddenly begins to turn to one side, *they will fall off balance a fraction of a second later* unless appropriate corrections are made *ahead of time*. However, the maculae of the utricle and saccule cannot detect that the person is off balance until *after* the loss of balance has occurred. The semicircular ducts, however, will have already detected that the person is turning, and this information apprises the central nervous system of the fact that the person *will* fall off balance within the next fraction of a second or so unless some *anticipatory correction* is made.

In other words, the semicircular duct mechanism *predicts* that disequilibrium is going to occur and thereby causes the equilibrium centers to make appropriate anticipatory preventive adjustments, which helps the person maintain balance.

Removal of the *flocculonodular lobes* of the cerebellum prevents normal detection of semicircular duct signals but has less effect on detecting macular signals. It is especially interesting that the cerebellum serves as a "predictive" organ for most rapid movements of the body, as well as for those involving equilibrium. These other functions of the cerebellum are discussed in Chapter 57.

Vestibular Mechanisms for Stabilizing the Eyes

When a person changes direction of movement rapidly or even leans the head sideways, forward, or backward, it would be impossible to maintain a stable image on the retinas unless the person had some automatic control mechanism to stabilize the direction of the eyes' gaze. In addition, the eyes would be of little use in detecting an image unless they remained fixed on each object long enough to gain a clear image. Fortunately, each time the head is suddenly rotated, signals from the semicircular ducts cause the eyes to rotate in a direction equal and opposite to the rotation of the head. This movement results from reflexes transmitted through the *vestibular nuclei* and the *medial longitudinal fasciculus* to the *oculomotor nuclei*. These reflexes are described in Chapter 52.

Additional Mechanisms for Maintaining Equilibrium

Neck Proprioceptors. The vestibular apparatus detects the orientation and movement *only of the head*. Therefore, it is essential that the nervous centers also receive appropriate information about the orientation of the head with respect to the body. This information is transmitted from the proprioceptors of the neck and body directly to the vestibular and reticular nuclei in the brain stem and indirectly by way of the cerebellum.

Among the most important proprioceptive information needed for the maintenance of equilibrium is that transmitted by *joint receptors of the neck*. When the head is leaned in one direction by bending the neck, impulses from the

neck proprioceptors keep the signals originating in the vestibular apparatus from giving the person a sense of disequilibrium. They perform this function by transmitting signals that exactly oppose the signals transmitted from the vestibular apparatus. However, *when the entire body* leans in one direction, the impulses from the vestibular apparatus *are not opposed* by signals from the neck proprioceptors; therefore, in this case, the person does perceive a change in equilibrium status of the entire body.

Proprioceptive and Exteroceptive Information From Other Parts of the Body. Proprioceptive information from parts of the body other than the neck is also important for maintaining equilibrium. For example, pressure sensations from the footpads tell one (1) whether weight is distributed equally between the two feet and (2) whether weight on the feet is more forward or backward.

Exteroceptive information is especially necessary for maintaining equilibrium when a person is running. The air pressure against the front of the body signals that a force is opposing the body in a direction different from that caused by gravitational pull; as a result, the person leans forward to oppose this force.

Importance of Visual Information for Maintaining Equilibrium. After destruction of the vestibular apparatus, and even after loss of most proprioceptive information from the body, a person can still use visual mechanisms for maintaining equilibrium. Even a slight linear or rotational movement of the body instantaneously shifts the visual images on the retina, and this information is relayed to the equilibrium centers. Some people with bilateral destruction of the vestibular apparatus have almost normal equilibrium as long as their eyes are open, and all motions are performed slowly. However, when moving rapidly or when the eyes are closed, equilibrium is immediately lost.

Neuronal Connections of the Vestibular Apparatus With the Central Nervous System

Fig. 56.13 shows the connections in the hindbrain of the vestibular nerve. Most of the vestibular nerve fibers terminate in the brain stem in the *vestibular nuclei*, which are located approximately at the junction of the medulla and the pons. Some fibers pass directly to the brain stem reticular nuclei without synapsing and also to the cerebellar fastigial, uvular, and flocculonodular lobe nuclei. The fibers that end in the brain stem vestibular nuclei synapse with second-order neurons that also send fibers into the cerebellum, the vestibulospinal tracts, the medial longitudinal fasciculus, and other areas of the brain stem, particularly the reticular nuclei.

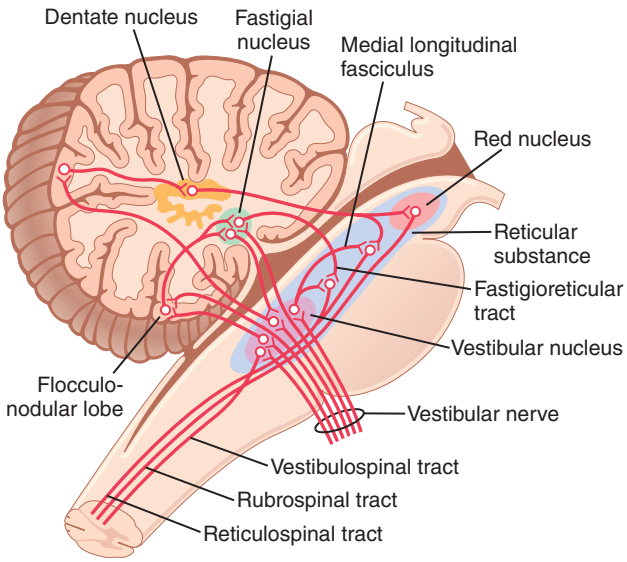

Figure 56.13 Connections of vestibular nerves through the vestibular nuclei *(large pink oval area)* with other areas of the central nervous system.

The primary pathway for the equilibrium reflexes begins in the vestibular nerves, where the nerves are excited by the vestibular apparatus. The pathway then passes to the vestibular nuclei and cerebellum. Next, signals are sent into the reticular nuclei of the brain stem, as well as down the spinal cord via the vestibulospinal and reticulospinal tracts. The signals to the cord control the interplay between facilitation and inhibition of the many antigravity muscles, thus automatically controlling equilibrium.

The *flocculonodular* lobes of the cerebellum are especially concerned with dynamic equilibrium signals from the semicircular ducts. In fact, destruction of these lobes results in almost exactly the same clinical symptoms as destruction of the semicircular ducts. That is, severe injury to either the lobes or the ducts causes loss of dynamic equilibrium during *rapid changes in direction of motion* but does not seriously disturb equilibrium under static conditions. It is believed that the *uvula* of the cerebellum plays a similar important role in static equilibrium.

Signals transmitted upward in the brain stem from both the vestibular nuclei and the cerebellum via the *medial longitudinal fasciculus* cause corrective movements of the eyes every time the head rotates, so the eyes remain fixed on a specific visual object. Signals also pass upward (either through this same tract or through reticular tracts) to the cerebral cortex, terminating in a primary cortical center for equilibrium located in the parietal lobe deep in the sylvian fissure on the opposite side of the fissure from the auditory area of the superior temporal gyrus. These signals apprise the psyche of the equilibrium status of the body.

Functions of Brain Stem Nuclei in Controlling Subconscious, Stereotyped Movements

Rarely, a baby is born without brain structures above the mesencephalic region, a condition called *anencephaly*. Some of these babies have been kept alive for many months. They are able to perform some stereotyped movements for feeding, such as suckling, extrusion of unpleasant food from the mouth, and moving the hands to the mouth to suck the fingers. In addition, they can yawn and stretch. They can cry and can follow objects with movements of the eyes and head. Also, placing pressure on the upper anterior parts of their legs causes them to pull toward the sitting position. It is clear that many of the stereotyped motor functions of the human being are integrated in the brain stem.

CHAPTER 57

Cerebellum and Basal Ganglia Contributions to Overall Motor Control

In addition to areas in the cerebral cortex that stimulate muscle contraction, two other brain structures are essential for normal motor function—the *cerebellum* and the *basal ganglia*. Neither of these structures can control muscle function by itself. Instead, these structures always function in association with other systems of motor control.

The cerebellum plays major roles in timing of motor activities and in rapid, smooth progression from one muscle movement to the next. It also helps control the intensity of muscle contraction when the muscle load changes, and it controls the necessary instantaneous interplay between agonist and antagonist muscle groups.

The basal ganglia help plan and control complex patterns of muscle movement. They control relative intensities of the separate movements, directions of movements, and sequencing of multiple successive and parallel movements to achieve specific complicated motor goals. This chapter summarizes the basic functions of the cerebellum and basal ganglia and discusses the overall brain mechanisms for achieving intricate coordination of total motor activity.

THE CEREBELLUM AND ITS MOTOR FUNCTIONS

The cerebellum, illustrated in **Figs. 57.1 and 57.2**, has long been called a *silent area* of the brain, principally because electrical excitation of the cerebellum does not cause any conscious sensation and rarely causes any motor movement. Removal of the cerebellum, however, causes body movements to become highly abnormal. The cerebellum is especially vital during rapid muscular activities such as running, typing, playing the piano, and even talking. Loss of this area of the brain can cause almost total lack of coordination of these activities, even though its loss does not cause paralysis of any muscles.

How can the cerebellum be so important when it has no direct ability to cause muscle contraction? The answer is that it helps sequence and monitor motor activities and makes corrective adjustments while activities are being executed so that they will conform to the motor signals directed by the cerebral motor cortex and other parts of the brain.

The cerebellum receives continuously updated information about the desired sequence of muscle contractions from the brain motor control areas; it also receives continuous sensory information from the peripheral parts of the body, providing sequential changes in the status of each part of the body—its position, rate of movement, forces acting on it, and so forth. The cerebellum then *compares* the actual movements as depicted by the peripheral sensory feedback information with the movements intended by the motor system. If the two do not compare favorably, then instantaneous subconscious corrective signals are transmitted back into the motor system to increase or decrease the levels of activation of specific muscles.

The cerebellum also aids the cerebral cortex in planning the next sequential movement a fraction of a second in advance while the current movement is still being executed, thus helping the person to progress smoothly from one movement to the next. Also, it learns by its mistakes. If a movement does not occur exactly as intended, the cerebellar circuit learns to make a stronger or weaker movement the next time. To make these adjustments, changes occur in the excitability of appropriate cerebellar neurons, thus bringing subsequent muscle contractions into better correspondence with the intended movements.

Anatomical and Functional Areas of the Cerebellum

Two deep fissures divide the cerebellum into three lobes, as shown in **Figs. 57.1** and **57.2**: (1) the *anterior lobe*, (2) the *posterior lobe*, and (3) the *flocculonodular lobe*. The flocculonodular lobe is the oldest portion of the cerebellum; it developed along with (and functions with) the vestibular system in controlling body equilibrium, as discussed in Chapter 56.

Longitudinal Functional Divisions of the Anterior and Posterior Lobes. From a functional point of view, the anterior and posterior lobes are organized not by lobes but along the longitudinal axis, as illustrated in **Fig. 57.2**, which shows a posterior view of the human cerebellum after the lower end of the posterior cerebellum has been rolled downward from its normally hidden position. Note, down the center of the cerebellum, a narrow band called the *vermis*, which is separated from the remainder of the cerebellum by shallow grooves. Most cerebellar functions for muscle movements of the *axial body*, *neck*, *shoulders*, *and hips* are controlled by this area.

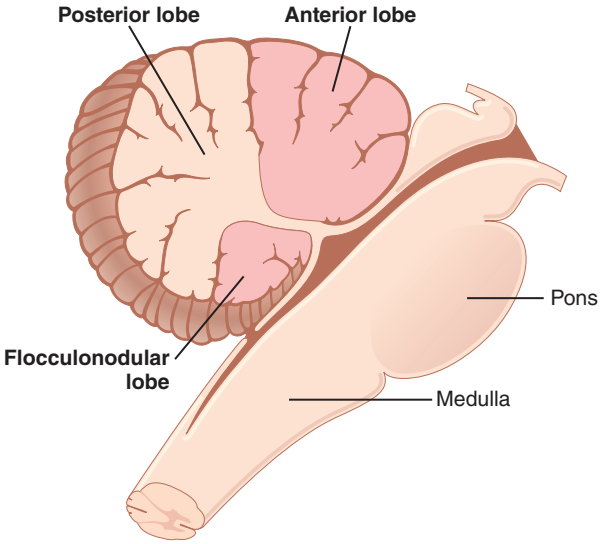

Figure 57.1 Anatomical lobes of the cerebellum as seen from the lateral side.

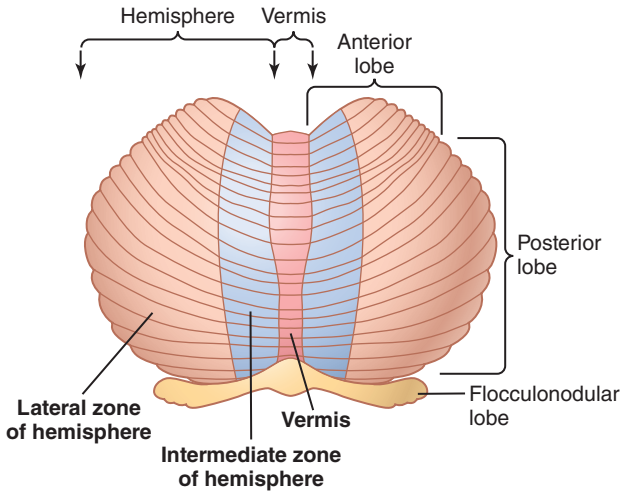

Figure 57.2 Functional parts of the cerebellum as seen from the posteroinferior view, with the inferiormost portion of the cerebellum rolled outward to flatten the surface.

To each side of the vermis is a large, laterally protruding *cerebellar hemisphere;* each of these hemispheres is divided into an *intermediate zone* and a *lateral zone*. The intermediate zone of the hemisphere controls muscle contractions in the distal portions of the upper and lower limbs, especially the hands, fingers, feet, and toes. The lateral zone of the hemisphere operates at a much more remote level because this area joins with the cerebral cortex in the overall planning of sequential motor movements. Without this lateral zone, most discrete motor activities of the body lose their appropriate timing and sequencing and therefore become uncoordinated, as we discuss more fully later in this chapter.

Topographical Representation of the Body in the Vermis and Intermediate Zones. In the same manner that the cerebral sensory cortex, motor cortex, basal ganglia, red nuclei, and reticular formation all have topographical

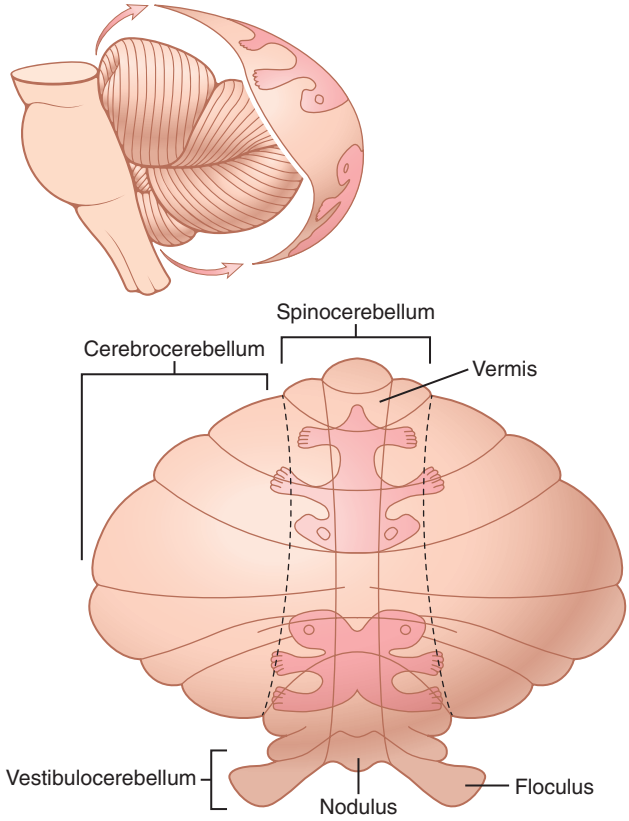

Figure 57.3 Flattened view of the cerebellar cortex shows the somatosensory projection areas and the major subdivisions.

representations of the different parts of the body, so do the vermis and intermediate zones of the cerebellum. **Fig. 57.3** shows two such representations. Note that the axial portions of the body lie in the vermis part of the cerebellum, whereas the limbs and facial regions lie in the intermediate zones.

These topographical representations receive afferent nerve signals from all the respective parts of the body, as well as from corresponding topographical motor areas in the cerebral cortex and brain stem. In turn, they send motor signals back to the same respective topographical areas of the cerebral motor cortex, as well as to topographical areas of the red nucleus and reticular formation in the brain stem.

Note that the large lateral portions of the cerebellar hemispheres *do not* have topographical representations of the body. These areas of the cerebellum receive input signals almost exclusively from the cerebral cortex, especially the premotor areas of the frontal cortex, and from somatosensory and other sensory association areas of the parietal cortex. This connectivity with the cerebral cortex allows the lateral portions of the cerebellar hemispheres to play important roles in planning and coordinating the body's *rapid* sequential muscular activities that occur one after another within fractions of a second.

Neuronal Circuits of the Cerebellum

The human cerebellar cortex is actually a large folded sheet, about 17 centimeters wide by 120 centimeters long, with

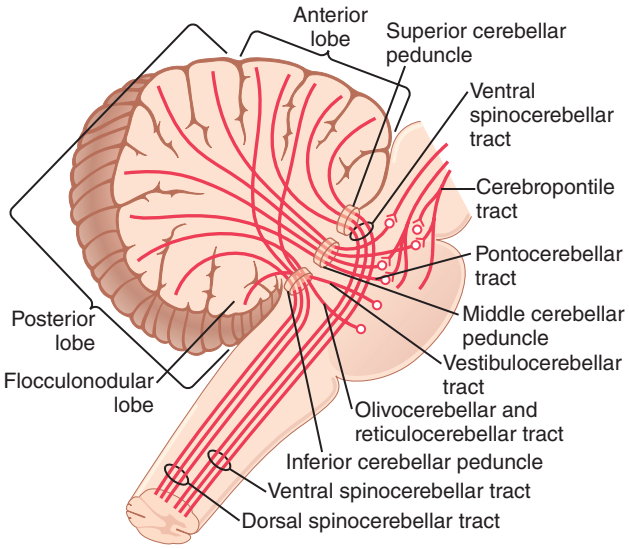

Figure 57.4 Principal *afferent* tracts to the cerebellum.

the folds lying crosswise, as shown in **Figs. 57.2** and **57.3**. Each fold is called a *folium*. Lying deep beneath the folded mass of cerebellar cortex are *deep cerebellar nuclei.*

Afferent Pathways From Other Parts of the Brain to the Cerebellum. The basic input pathways to the cerebellum are shown in **Fig. 57.4**. An extensive and important afferent pathway is the *corticopontocerebellar pathway*, which originates in the cerebral motor and premotor cortices and also in the cerebral somatosensory cortex. It passes by way of the pontile nuclei and pontocerebellar tracts mainly to the lateral divisions of the cerebellar hemispheres on the opposite side of the brain from the cerebral areas.

In addition, important afferent tracts originate in each side of the brain stem. These tracts include the following: (1) an extensive *olivocerebellar tract*, which passes from the inferior olive to all parts of the cerebellum and is excited in the olive by fibers from the cerebral motor cortex, basal ganglia, widespread areas of the reticular formation, and spinal cord; (2) *vestibulocerebellar fibers*, some of which originate in the vestibular apparatus itself and others from the brain stem vestibular nuclei, with almost all of these fibers terminating in the flocculonodular lobe and fastigial nucleus of the cerebellum; and (3) *reticulocerebellar fibers*, which originate in different portions of the brain stem reticular formation and terminate in the midline cerebellar areas (mainly in the vermis).

Afferent Pathways From the Periphery to the Cerebellum. The cerebellum also receives important sensory signals directly from the peripheral parts of the body, mainly through four tracts on each side, two of which are located dorsally in the cord and two ventrally. The two most important of these tracts are shown in **Figs. 57.4 and 57.5**, the *dorsal spinocerebellar tract* and the *ventral spinocerebellar tract*. The dorsal tract enters the cerebellum through the inferior cerebellar peduncle and terminates in the vermis and intermediate zones of the cerebellum on the same side as its origin. The ventral tract enters the cerebellum through the superior cerebellar peduncle, but it terminates in both sides of the cerebellum.

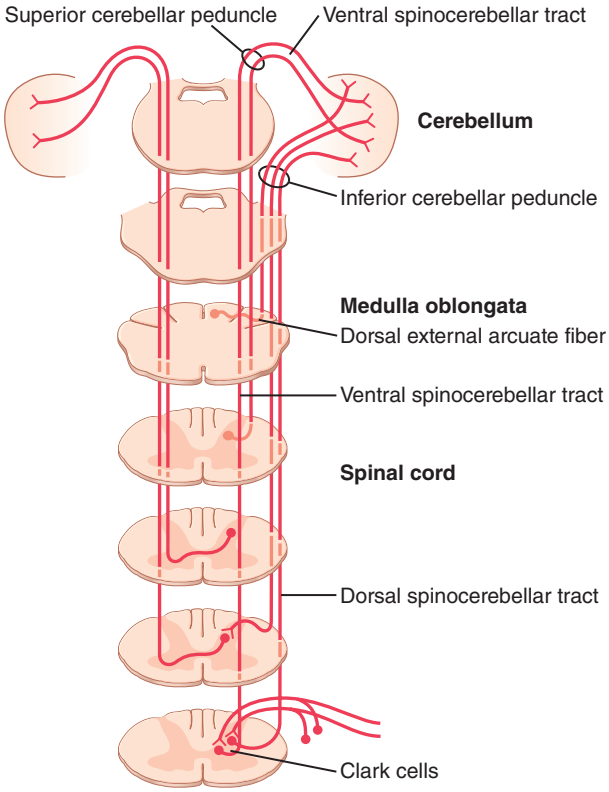

Figure 57.5 Spinocerebellar tracts.

The signals transmitted in the dorsal spinocerebellar tracts come mainly from the muscle spindles and to a lesser extent from other somatic receptors throughout the body, such as Golgi tendon organs, large tactile receptors of the skin, and joint receptors. All these signals apprise the cerebellum of the momentary status of (1) muscle contraction, (2) degree of tension on the muscle tendons, (3) positions and rates of movement of the parts of the body, and (4) forces acting on the surfaces of the body.

The ventral spinocerebellar tracts receive much less information from the peripheral receptors. Instead, they are excited mainly by motor signals arriving in the anterior horns of the spinal cord from (1) the brain through the corticospinal and rubrospinal tracts and (2) the internal motor pattern generators in the cord itself. Thus, this ventral fiber pathway tells the cerebellum which motor signals have arrived at the anterior horns; this feedback is called the *efference copy* of the anterior horn motor drive.

The spinocerebellar pathways can transmit impulses at velocities up to 120 m/sec, which is the most rapid conduction in any pathway in the central nervous system. This speed is important for instantaneous apprisal of the cerebellum of changes in peripheral muscle actions.

In addition to signals from the spinocerebellar tracts, signals are transmitted into the cerebellum from the body periphery through the spinal dorsal columns to the dorsal column nuclei of the medulla and are then relayed to the cerebellum. Likewise, signals are transmitted up the spinal cord through the *spinoreticular pathway* to the reticular formation of the brain stem and also through the *spino-olivary pathway* to the inferior olivary nucleus. Signals

are then relayed from both of these areas to the cerebellum. Thus, the cerebellum continually collects information about the movements and positions of all parts of the body even though it is operating at a subconscious level.

Deep Cerebellar Nuclei and the Efferent Pathways. Located deep in the cerebellar mass on each side are three *deep cerebellar nuclei*—the *dentate, interposed*, and *fastigial*. The *vestibular nuclei* in the medulla also function in some respects as if they were deep cerebellar nuclei because of their direct connections with the cortex of the flocculonodular lobe. All the deep cerebellar nuclei receive signals from two sources: (1) the cerebellar cortex and (2) the deep sensory afferent tracts to the cerebellum.

Each time an input signal arrives in the cerebellum, it divides and goes in two directions: (1) directly to one of the cerebellar deep nuclei and (2) to a corresponding area of the cerebellar cortex overlying the deep nucleus. Then, a fraction of a second later, the cerebellar cortex relays an *inhibitory* output signal to the deep nucleus. Thus, all input signals that enter the cerebellum eventually end in the deep nuclei in the form of initial excitatory signals followed a fraction of a second later by inhibitory signals. From the deep nuclei, output signals leave the cerebellum and are distributed to other parts of the brain.

The general plan of the major efferent pathways leading out of the cerebellum is shown in **Fig. 57.6** and consists of the following pathways:

1. A pathway that originates in the *midline structures of the cerebellum* (the *vermis*) and then passes through the *fastigial nuclei* into the *medullary* and *pontile regions of the brain stem*. This circuit functions in close association with the equilibrium apparatus and brain stem vestibular nuclei to control equilibrium, as well as in association with the reticular formation of the brain stem to control the postural attitudes of the body, as discussed in detail in Chapter 56 in relation to equilibrium.
2. A pathway that originates in (1) the intermediate zone of the cerebellar hemisphere and then passes through (2) the interposed nucleus to (3) the ventrolateral and ventroanterior nuclei of the thalamus and then to (4) the cerebral cortex to (5) several midline structures of the thalamus and then to (6) the basal ganglia and (7) the red nucleus and reticular formation of the upper portion of the brain stem. This complex circuit mainly helps coordinate the reciprocal contractions of agonist and antagonist muscles in the peripheral portions of the limbs, especially in the hands, fingers, and thumbs.
3. A pathway that begins in the cerebellar cortex of the lateral zone of the cerebellar hemisphere and then passes to the dentate nucleus, next to the ventrolateral and ventroanterior nuclei of the thalamus, and, finally, to the cerebral cortex. This pathway plays an important role in helping coordinate sequential motor activities initiated by the cerebral cortex.

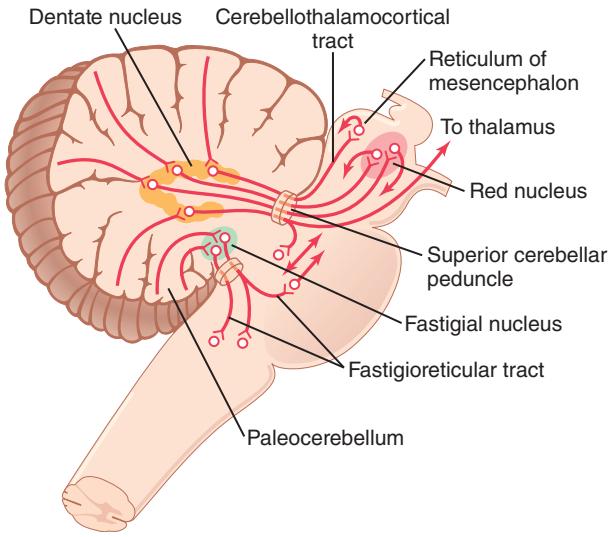

Figure 57.6 Principal *efferent* tracts from the cerebellum.

FUNCTIONAL UNIT OF THE CEREBELLAR CORTEX—THE PURKINJE AND DEEP NUCLEAR CELLS

The cerebellum has about 30 million nearly identical functional units, one of which is illustrated to the left in **Fig. 57.7**. This functional unit centers on a single, very large *Purkinje cell* and on a corresponding *deep nuclear cell*.

To the top and right in **Fig. 57.7**, the three major layers of the cerebellar cortex are shown: the *molecular layer*, *Purkinje cell layer*, and *granule cell layer*. Beneath these cortical layers, in the center of the cerebellar mass, are the deep cerebellar nuclei that send output signals to other parts of the nervous system.

Neuronal Circuit of the Functional Unit. Also shown in the left half of **Fig. 57.7** is the neuronal circuit of the functional unit, which is repeated with little variation 30 million times in the cerebellum. The output from the functional unit is from a *deep nuclear cell*. This cell is

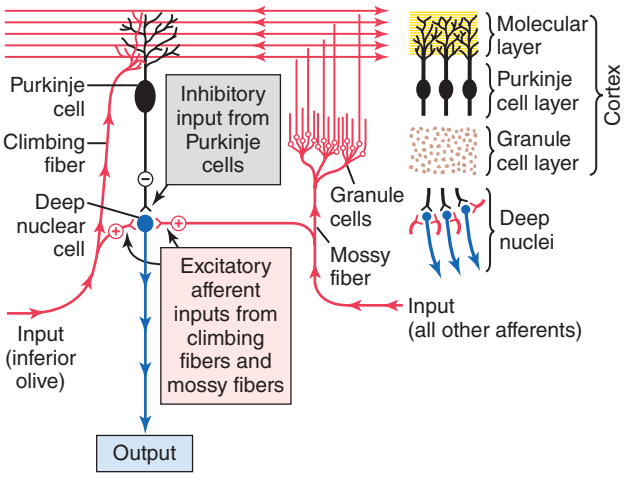

Figure 57.7 Deep nuclear cells receive excitatory and inhibitory inputs. The *left side* of this figure shows the basic neuronal circuit of the cerebellum, with excitatory neurons shown in *red* and the Purkinje cell (an inhibitory neuron) shown in *black*. To the *right* is shown the physical relationship of the deep cerebellar nuclei to the cerebellar cortex with its three layers.

continually under both excitatory and inhibitory influences. The excitatory influences arise from direct connections with afferent fibers that enter the cerebellum from the brain or the periphery. The inhibitory influence arises entirely from the Purkinje cell in the cortex of the cerebellum.

The afferent inputs to the cerebellum are mainly of two types, one called the *climbing fiber type* and the other called the *mossy fiber type*.

The climbing fibers *all originate from the inferior olives of the medulla*. There is one climbing fiber for about 5 to 10 Purkinje cells. After sending branches to several deep nuclear cells, the climbing fiber continues all the way to the outer layers of the cerebellar cortex, where it makes about 300 synapses with the soma and dendrites of each Purkinje cell. This climbing fiber is distinguished by the fact that a single impulse in it causes a single, prolonged (up to 1 second), peculiar type of action potential in each Purkinje cell with which it connects, beginning with a strong spike and followed by a trail of weakening secondary spikes. This action potential is called the *complex spike*.

The mossy fibers are all the other fibers that enter the cerebellum from multiple sources—the higher brain, brain stem, and spinal cord. These fibers also send collaterals to excite the deep nuclear cells. They then proceed to the granule cell layer of the cortex, where they also synapse with hundreds to thousands of *granule cells*. In turn, the granule cells send extremely small axons, less than 1 micrometer in diameter, up to the molecular layer on the outer surface of the cerebellar cortex. Here the axons divide into two branches that extend 1 to 2 millimeters in each direction parallel to the folia. Many millions of these *parallel nerve fibers* exist because there are some 500 to 1000 granule cells for every 1 Purkinje cell. It is into this molecular layer that the dendrites of the Purkinje cells project and 80,000 to 200,000 of the parallel fibers synapse with each Purkinje cell.

The mossy fiber input to the Purkinje cell is quite different from the climbing fiber input because the synaptic connections are weak, so large numbers of mossy fibers must be stimulated simultaneously to excite the Purkinje cell. Furthermore, activation usually takes the form of a much weaker, short-duration Purkinje cell action potential called a *simple spike*, rather than the prolonged complex action potential caused by climbing fiber input.

Purkinje Cells and Deep Nuclear Cells Fire Continuously Under Normal Resting Conditions. One characteristic of Purkinje cells and deep nuclear cells is that normally both of them fire continuously; the Purkinje cell fires at about 50 to 100 action potentials per second, and the deep nuclear cells fire at much higher rates. Furthermore, the output activity of both these cells can be modulated upward or downward.

Balance Between Excitation and Inhibition at the Deep Cerebellar Nuclei. Referring again to the circuit of **Fig. 57.7**, note that direct stimulation of the deep nuclear cells by both the climbing and the mossy fibers excites them. By contrast, signals arriving from the Purkinje cells inhibit them. Normally, the balance between these two effects is slightly in favor of excitation so that under quiet conditions, output from the deep nuclear cells remains relatively constant at a moderate level of continuous stimulation.

In execution of a rapid motor movement, the initiating signal from the cerebral motor cortex or brain stem at first greatly increases deep nuclear cell excitation. Then, another few milliseconds later, feedback inhibitory signals from the Purkinje cell circuit arrive. In this way, there is first a rapid excitatory signal sent by the deep nuclear cells into the motor output pathway to enhance the motor movement, followed within a small fraction of a second by an inhibitory signal. This inhibitory signal resembles a "delay line" negative feedback signal that provides *damping*. That is, when the motor system is excited, a negative feedback signal occurs after a short delay to stop the muscle movement from overshooting its mark. Otherwise, oscillation of the movement would occur.

Basket Cells and Stellate Cells Cause Lateral Inhibition of Purkinje Cells in the Cerebellum. In addition to the deep nuclear cells, granule cells, and Purkinje cells, two other types of neurons are located in the cerebellum, *basket cells* and *stellate cells*, which are inhibitory cells with short axons. Both the basket cells and the stellate cells are located in the molecular layer of the cerebellar cortex, lying among and stimulated by the small parallel fibers. These cells in turn send their axons at right angles across the parallel fibers and cause *lateral inhibition* of adjacent Purkinje cells, thus sharpening the signal in the same manner that lateral inhibition sharpens contrast of signals in many other neuronal circuits of the nervous system.

Turn-On/Turn-Off and Turn-Off/Turn-On Output Signals From the Cerebellum

The typical function of the cerebellum is to help provide rapid turn-on signals for the agonist muscles and simultaneous reciprocal turn-off signals for the antagonist muscles at the onset of a movement. Then, on approaching termination of the movement, the cerebellum is mainly responsible for timing and executing the turn-off signals to the agonists and the turn-on signals to the antagonists. Although the exact details are not fully known, we can speculate from the basic cerebellar circuit of **Fig. 57.7** how this process might work, as follows.

Let us suppose that the turn-on/turn-off pattern of agonist/antagonist contraction at the onset of movement begins with signals from the cerebral cortex. These signals pass through noncerebellar brain stem and cord pathways directly to the agonist muscle to begin the initial contraction.

At the same time, parallel signals are sent by way of the pontile mossy fibers into the cerebellum. One branch of

each mossy fiber goes directly to deep nuclear cells in the dentate or other deep cerebellar nuclei, which instantly sends an excitatory signal back into the cerebral corticospinal motor system, either by way of return signals through the thalamus to the cerebral cortex or by way of neuronal circuitry in the brain stem, to support the muscle contraction signal that had already been begun by the cerebral cortex. As a consequence, the turn-on signal, after a few milliseconds, becomes even more powerful than it was at the start because it becomes the sum of both the cortical and the cerebellar signals. This is the normal effect when the cerebellum is intact, but in the absence of the cerebellum, the secondary extra supportive signal is missing. This cerebellar support makes the turn-on muscle contraction much stronger than it would be if the cerebellum did not exist.

What causes the turn-off signal for the agonist muscles at the termination of the movement? Remember that all mossy fibers have a second branch that transmits signals by way of the granule cells to the cerebellar cortex and, eventually, by way of "parallel" fibers, to the Purkinje cells. The Purkinje cells in turn *inhibit* the deep nuclear cells. This pathway passes through some of the smallest, slowest-conducting nerve fibers in the nervous system, the parallel fibers of the cerebellar cortical molecular layer, which have diameters of only a fraction of a millimeter. Also, the signals from these fibers are weak, so they require a finite period to build up enough excitation in the dendrites of the Purkinje cell to excite it. However, once the Purkinje cell is excited, it sends a strong *inhibitory signal* to the same deep nuclear cell that originally turned on the movement. Therefore, this signal helps *turn off* the movement after a short time.

Thus, one can see how the complete cerebellar circuit could cause a rapid turn-on agonist muscle contraction at the beginning of a movement and yet also cause a *precisely timed* turn-off of the same agonist contraction after a given period.

Now, let us speculate on the circuit for the antagonist muscles. Most important, remember that there are reciprocal agonist-antagonist circuits throughout the spinal cord for virtually every movement that the cord can initiate. Therefore, these circuits are important for antagonist turn-off at the onset of movement and then turn-on at termination of movement, mirroring whatever occurs in the agonist muscles. But also remember that the cerebellum contains several other types of inhibitory cells besides Purkinje cells. The functions of some of these cells are still to be determined; they, too, could play roles in the initial inhibition of the antagonist muscles at onset of a movement and subsequent excitation at the end of a movement.

These mechanisms are still partly speculation. They are presented here to illustrate ways by which the cerebellum could cause exaggerated turn-on and turn-off signals, thus controlling the agonist and antagonist muscles, as well as the timing.

The Purkinje Cells "Learn" to Correct Motor Errors—Role of the Climbing Fibers

The degree to which the cerebellum supports onset and offset of muscle contractions, as well as timing of contractions, must be learned by the cerebellum. Typically, when a person first performs a new motor act, the degree of motor enhancement by the cerebellum at the onset of contraction, the degree of inhibition at the end of contraction, and the timing of these are almost always incorrect for precise movements. However, after the act has been performed many times, the individual events become progressively more precise, sometimes requiring only a few movements before the desired result is achieved, but at other times requiring hundreds of movements.

How do these adjustments come about? The exact answer is not known, although it is known that sensitivity levels of cerebellar circuits progressively adapt during the training process, especially the sensitivity of the Purkinje cells to respond to the granule cell excitation. Furthermore, this sensitivity change is brought about by signals from the climbing fibers entering the cerebellum from the inferior olivary complex.

Under resting conditions, the climbing fibers fire about once per second, but they cause extreme depolarization of the entire dendritic tree of the Purkinje cell, lasting for up to 1 second, each time they fire. During this time, the Purkinje cell fires with one initial strong output spike, followed by a series of diminishing spikes. When a person performs a new movement for the first time, feedback signals from the muscle and joint proprioceptors will usually denote to the cerebellum how much the actual movement fails to match the intended movement, and the climbing fiber signals alter the long-term sensitivity of the Purkinje cells in some way. Over a period, this change in sensitivity, along with other possible "learning" functions of the cerebellum, is believed to make the timing and other aspects of cerebellar control of movements approach perfection. When this state has been achieved, the climbing fibers no longer need to send "error" signals to the cerebellum to cause further change.

FUNCTION OF THE CEREBELLUM IN OVERALL MOTOR CONTROL

The nervous system uses the cerebellum to coordinate motor control functions at three levels:

1. The *vestibulocerebellum*. This level consists principally of the small flocculonodular cerebellar lobes that lie under the posterior cerebellum and adjacent portions of the vermis. It provides neural circuits for most of the body's equilibrium movements.
2. The *spinocerebellum*. This level consists of most of the vermis of the posterior and anterior cerebellum plus the adjacent intermediate zones on both sides of the vermis. It provides the circuitry for coordinating mainly movements of the distal portions of the limbs, especially the hands and fingers.

3. The *cerebrocerebellum*. This level consists of the large lateral zones of the cerebellar hemispheres, lateral to the intermediate zones. It receives virtually all its input from the cerebral motor cortex and adjacent premotor and somatosensory cortices of the cerebrum. It transmits its output information in the upward direction, back to the brain, functioning in a feedback manner with the cerebral cortical sensorimotor system to plan sequential voluntary body and limb movements. These movements are planned as much as tenths of a second in advance of the actual movements. This process is called development of "*motor imagery*" of movements to be performed.

The Vestibulocerebellum Functions in Association With the Brain Stem and Spinal Cord to Control Equilibrium and Postural Movements

The vestibulocerebellum originated phylogenetically at about the same time that the vestibular apparatus in the inner ear developed. Furthermore, as discussed in Chapter 56, loss of the flocculonodular lobes and adjacent portions of the vermis of the cerebellum, which constitute the vestibulocerebellum, causes extreme disturbance of equilibrium and postural movements.

In people with vestibulocerebellar dysfunction, equilibrium is far more disturbed *during performance of rapid motions* than during inactivity, especially when these movements involve *changes in direction* of movement and stimulate the semicircular ducts. This phenomenon suggests that the vestibulocerebellum is important in controlling balance between agonist and antagonist muscle contractions of the spine, hips, and shoulders during *rapid changes* in body positions as required by the vestibular apparatus.

One of the major problems in controlling balance is the amount of time required to transmit position signals and velocity of movement signals from the different parts of the body to the brain. Even when the most rapidly conducting sensory pathways are used, up to 120 m/sec in the spinocerebellar afferent tracts, the delay for transmission from the feet to the brain is still 15 to 20 milliseconds. The feet of a person running rapidly can move as much as 10 inches during that time. Therefore, it is never possible for return signals from the peripheral parts of the body to reach the brain at the same time that the movements actually occur.

How, then, is it possible for the brain to know when to stop a movement and to perform the next sequential act when the movements are performed rapidly? The answer is that the signals from the periphery tell the brain how rapidly and in which directions the body parts are moving. It is then the function of the vestibulocerebellum to *calculate in advance* from these rates and directions where the different parts will be during the next few milliseconds. The results of these calculations are the key to the brain's progression to the next sequential movement.

Thus, during control of equilibrium, information from both the body periphery and the vestibular apparatus is presumably used in a typical feedback control circuit to provide *anticipatory correction* of postural motor signals necessary for maintaining equilibrium even during extremely rapid motion, including rapidly changing directions of motion.

Spinocerebellum—Feedback Control of Distal Limb Movements Via the Intermediate Cerebellar Cortex and the Interposed Nucleus

As shown in **Fig. 57.8**, the intermediate zone of each cerebellar hemisphere receives two types of information when a movement is performed: (1) information from the cerebral motor cortex and from the midbrain red nucleus, telling the cerebellum the *intended sequential plan of movement* for the next few fractions of a second; and (2) feedback information from the peripheral parts of the body, especially from the distal proprioceptors of the limbs, telling the cerebellum what *actual movements* result.

After the intermediate zone of the cerebellum has compared the intended movements with the actual movements, the deep nuclear cells of the interposed nucleus send *corrective* output signals (1) back to the *cerebral motor cortex* through relay nuclei in the *thalamus* and (2) to the *magnocellular portion* (the lower portion) *of the red nucleus* that gives rise to the *rubrospinal tract*. The rubrospinal tract, in turn, joins the corticospinal tract in

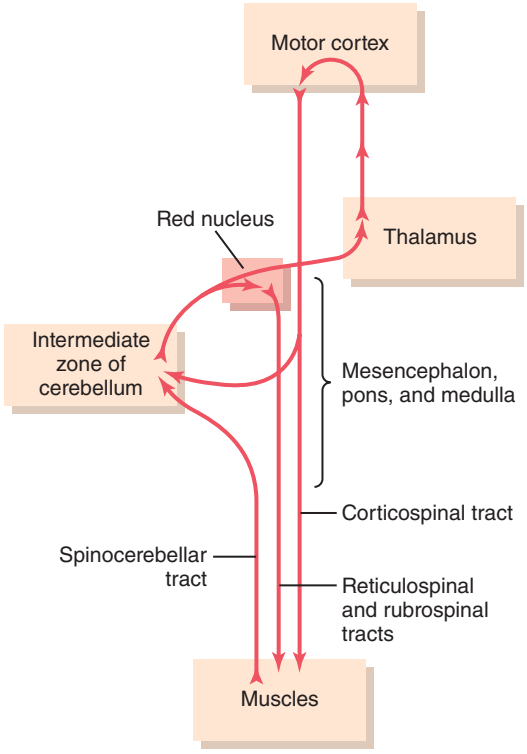

Figure 57.8 Cerebral and cerebellar control of voluntary movements, involving especially the intermediate zone of the cerebellum.

innervating the lateralmost motor neurons in the anterior horns of the spinal cord gray matter, the neurons that control the distal parts of the limbs, particularly the hands and fingers.

This part of the cerebellar motor control system provides smooth, coordinated movements of the agonist and antagonist muscles of the distal limbs for performing acute purposeful patterned movements. The cerebellum seems to compare the "intentions" of the higher levels of the motor control system, as transmitted to the intermediate cerebellar zone through the corticopontocerebellar tract, with the "performance" by the respective parts of the body, as transmitted back to the cerebellum from the periphery. In fact, the ventral spinocerebellar tract even transmits back to the cerebellum an "*efference*" *copy* of the actual motor control signals that reach the anterior motor neurons, and this information is also integrated with the signals arriving from the muscle spindles and other proprioceptor sensory organs, transmitted principally in the dorsal spinocerebellar tract. Similar comparator signals also go to the inferior olivary complex; if the signals do not compare favorably, the olivary–Purkinje cell system, along with possibly other cerebellar learning mechanisms, eventually corrects the motions until they perform the desired function.

Function of the Cerebellum to Prevent Overshoot and to "Damp" Movements. Almost all movements of the body are "pendular." For example, when an arm is moved, momentum develops, and the momentum must be overcome before the movement can be stopped. Because of momentum, all pendular movements tend to *overshoot*. If overshooting occurs in a person whose cerebellum has been destroyed, the conscious centers of the cerebrum eventually recognize this error and initiate a movement in the reverse direction to attempt to bring the arm to its intended position. However, the arm, by virtue of its momentum, overshoots once more in the opposite direction, and appropriate corrective signals must again be instituted. Thus, the arm oscillates back and forth past its intended point for several cycles before it finally fixes on its mark. This effect is called an *action tremor* or *intention tremor*.

If the cerebellum is intact, appropriate learned, subconscious signals stop the movement precisely at the intended point, thereby preventing the overshoot and the tremor. *This activity is the basic characteristic of a damping system*. All control systems regulating pendular elements that have inertia must have damping circuits built into the mechanisms. For motor control by the nervous system, the cerebellum provides most of this damping function.

Cerebellar Control of Ballistic Movements. Most rapid movements of the body, such as the movements of the fingers in typing, occur so rapidly that it is not possible to receive feedback information either from the periphery to the cerebellum or from the cerebellum back to the motor cortex before the movements are over. These movements are called *ballistic movements*, meaning that the entire movement is preplanned and set into motion to go a specific distance and then to stop. Another important example is the *saccadic movements* of the eyes, in which the eyes jump from one position to the next when reading or when looking at successive points along a road as a person is moving in a car.

Three major changes occur in these ballistic movements when the cerebellum is removed: (1) the movements are slow to develop and do not have the extra onset surge that the cerebellum usually provides; (2) the force developed is weak; and (3) the movements are slow to turn off, usually allowing the movement to go well beyond the intended mark. Therefore, in the absence of the cerebellar circuit, the motor cortex has much more difficulty in turning ballistic movements on and off. Thus, the automatism of ballistic movements is lost.

The circuitry of the cerebellum is beautifully organized to perform this biphasic excitatory and then delayed inhibitory function that is required for preplanned rapid ballistic movements. Also, the built-in timing circuits of the cerebellar cortex are fundamental to this particular ability of the cerebellum.

Cerebrocerebellum—Function of the Large Lateral Zone of the Cerebellar Hemisphere to Plan, Sequence, and Time Complex Movements

In humans the lateral zones of the two cerebellar hemispheres are highly developed and greatly enlarged. This characteristic is consistent with human abilities to plan and perform intricate sequential patterns of movement, especially with the hands and fingers, and to speak. Yet, the large lateral zones of the cerebellar hemispheres have no direct input of information from the peripheral parts of the body. In addition, almost all communication between these lateral cerebellar areas and the cerebral cortex is not with the primary cerebral motor cortex but instead with the *premotor area* and *primary* and *association somatosensory areas*.

Even so, destruction of the lateral zones of the cerebellar hemispheres, along with their deep nuclei, the dentate nuclei, can lead to extreme incoordination of complex purposeful movements of the hands, fingers, and feet and of the speech apparatus. This condition has been difficult to understand because there is no direct communication between this part of the cerebellum and the primary motor cortex. However, experimental studies suggest that these portions of the cerebellum are concerned with two other important but indirect aspects of motor control: (1) planning of sequential movements and (2) "timing" of the sequential movements.

Planning of Sequential Movements. Planning sequential movements requires the lateral zones of the hemispheres to communicate with the premotor and sensory portions of the cerebral cortex, and it requires two-way

communication between these cerebral cortex areas with corresponding areas of the basal ganglia. The "plan" of sequential movements apparently begins in the sensory and premotor areas of the cerebral cortex, and from there the plan is transmitted to the lateral zones of the cerebellar hemispheres. Then, amid much two-way traffic between the cerebellum and the cerebral cortex, appropriate motor signals provide transition from one sequence of movements to the next.

An interesting observation that supports this view is that many neurons in the cerebellar dentate nuclei display the activity pattern for the sequential movement that is yet to come while the present movement is still occurring. Thus, the lateral cerebellar zones appear to be involved not with what movement is happening at a given moment but with *what will be happening during the next sequential movement* a fraction of a second or perhaps even seconds later.

To summarize, one of the most important features of normal motor function is one's ability to progress smoothly from one movement to the next in orderly succession. In the absence of the large lateral zones of the cerebellar hemispheres, this capability is seriously disturbed for rapid movements.

Timing Function for Sequential Movements. Another important function of the lateral zones of the cerebellar hemispheres is to provide appropriate timing for each succeeding movement. In the absence of these cerebellar zones, one loses the subconscious ability to predict how far the different parts of the body will move in a given time. Without this timing capability, the person becomes unable to determine when the next sequential movement needs to begin. As a result, the succeeding movement may begin too early or, more likely, too late. Therefore, lesions in the lateral zones of the cerebellum cause complex movements (e.g., those required for writing, running, or even talking) to become uncoordinated, lacking the ability to progress in orderly sequence from one movement to the next. Such cerebellar lesions are said to cause *failure of smooth progression of movements*.

Extramotor Predictive Functions of the Cerebrocerebellum. The cerebrocerebellum (the large lateral lobes) also helps to "time" events other than movements of the body. For example, the rates of progression of both auditory and visual phenomena can be predicted by the brain, but both of these require cerebellar participation. As an example, a person can predict from the changing visual scene how rapidly they are approaching an object. A striking experiment that demonstrates the importance of the cerebellum in this ability is the effect of removing the large lateral portions of the cerebellum in monkeys. Such a monkey occasionally charges into the wall of a corridor because it is unable to predict when it will reach the wall.

It is quite possible that the cerebellum provides a "time base," perhaps using time-delay circuits, against which signals from other parts of the central nervous system can be compared. It is often stated that the cerebellum is particularly helpful in interpreting *rapidly changing spatiotemporal relations* in sensory information.

Clinical Abnormalities of the Cerebellum

Destruction of small portions of the lateral cerebellar *cortex* seldom causes detectable abnormalities in motor function. In fact, several months after as much as one-half of the lateral cerebellar cortex on one side of the brain has been removed, if the deep cerebellar nuclei are not removed along with the cortex, the motor functions of the animal appear to be almost normal *as long as the animal performs all movements slowly*. Thus, the remaining portions of the motor control system are capable of compensating to a great extent for loss of parts of the cerebellum.

To cause serious and continuing dysfunction of the cerebellum, the cerebellar lesion usually must involve one or more of the deep cerebellar nuclei—the *dentate, interposed*, or *fastigial nuclei.*

Dysmetria and Ataxia

Two of the most important symptoms of cerebellar disease are *dysmetria* and *ataxia*. In the absence of the cerebellum, the subconscious motor control system cannot predict how far movements will go. Therefore, the movements ordinarily overshoot their intended mark; then, the conscious portion of the brain overcompensates in the opposite direction for the succeeding compensatory movement. This effect is called *dysmetria*, which is a form of *ataxia*, or uncoordinated movements that can adversely affect a person's coordination, balance, and speech. Dysmetria and ataxia can also result from *lesions in the spinocerebellar tracts* because feedback information from the moving parts of the body to the cerebellum is essential for cerebellar timing of movement termination.

Past Pointing

Past pointing means that in the absence of the cerebellum, a person ordinarily moves the hand or some other moving part of the body considerably beyond the point of intention. This movement results from the fact that normally the cerebellum initiates most of the motor signal that turns off a movement after it is begun; if the cerebellum is not available to initiate this motor signal, the movement ordinarily goes beyond the intended mark. Therefore, past pointing is actually a manifestation of dysmetria.

Failure of Progression

Dysdiadochokinesia—Inability to Perform Rapid Alternating Movements. When the motor control system fails to predict where the different parts of the body will be at a given time, it "loses" perception of the parts during rapid motor movements. As a result, the succeeding movement may begin too early or too late, so no orderly "progression of movement" can occur. One can demonstrate this effect readily by having a patient with cerebellar damage turn one hand upward and downward at a rapid rate. The patient rapidly "loses" all perception of the instantaneous position of the hand during any portion of the movement. As a result, a series of stalled attempted but jumbled movements occurs

instead of the normal coordinated upward and downward motions. This condition is called *dysdiadochokinesia.*

Dysarthria—Failure of Progression in Talking. Another example in which failure of progression occurs is in talking because the formation of words depends on rapid and orderly succession of individual muscle movements in the larynx, mouth, and respiratory system. Lack of coordination among these structures and the inability to adjust in advance either the intensity of sound or the duration of each successive sound causes jumbled vocalization, with some syllables loud, some weak, some held for long intervals, and some held for short intervals, with resultant speech that is often unintelligible. This condition is called *dysarthria.*

Cerebellar Nystagmus—Tremor of the Eyeballs. *Cerebellar nystagmus* is tremor of the eyeballs that usually occurs when one attempts to fixate the eyes on a scene to one side of the head. This off-center type of fixation results in rapid, tremulous movements of the eyes rather than steady fixation, and it is another manifestation of the failure of damping by the cerebellum. It occurs especially when the flocculonodular lobes of the cerebellum are damaged; in this case, it is also associated with loss of equilibrium because of dysfunction of the pathways through the flocculonodular cerebellum from the semicircular ducts.

Hypotonia—Decreased Tone of the Musculature

Loss of the deep cerebellar nuclei, particularly of the dentate and interposed nuclei, causes decreased tone of the peripheral body musculature on the side of the cerebellar lesion. The hypotonia results from loss of cerebellar facilitation of the motor cortex and brain stem motor nuclei by tonic signals from the deep cerebellar nuclei.

NONMOTOR FUNCTIONS OF THE CEREBELLUM

There is increasing evidence that the cerebellum, in addition to its well-established role in motor control, contributes to a broad range of nonmotor functions, including cognition and social behavior. For example, functional magnetic resonance imaging studies in humans indicate that the cerebellum is activated during tasks involving language, memory, and emotional processing. Also, patients with cerebellums that have been damaged by tumor growth or strokes experience a constellation of cognitive and behavioral impairments, such as diminished abstract reasoning and emotional control, a condition called *cerebellar cognitive affective syndrome* or *Schmahmann syndrome.* Clinical observations have also implicated abnormalities of the cerebellum in neuropsychiatric disorders such as autism and schizophrenia. However, the specific mechanisms that underlie the cerebellum's cognitive and affective functions are still unclear.

THE BASAL GANGLIA AND THEIR MOTOR FUNCTIONS

The basal ganglia, like the cerebellum, constitute another *accessory motor system* that functions usually not by itself but in close association with the cerebral cortex and corticospinal motor control system. In fact, the basal ganglia receive most of their input signals from the cerebral cortex and also return almost all their output signals back to the cortex.

Fig. 57.9 shows the anatomical relationships of the basal ganglia to other structures of the brain. On each side of the brain, these ganglia consist of four major components: (1) the *striatum* (named for its striated appearance), which has two main parts, the *caudate nucleus* and *putamen*, separated by an internal capsule; (2) the *globus pallidus;* (3) the *substantia nigra*; and (4) the *subthalamic nucleus.* These ganglia are located mainly lateral to and surrounding the thalamus, occupying a large portion of the interior regions of both cerebral hemispheres. Almost all motor and sensory nerve fibers connecting the cerebral cortex and spinal cord pass through the space that lies between the major masses of the basal ganglia, the *caudate nucleus* and the *putamen.* This space is called the *internal capsule* of the brain. It is important for our current discussion because of the intimate association between the basal ganglia and the corticospinal system for motor control.

NEURONAL CIRCUITRY OF THE BASAL GANGLIA

The anatomical connections between the basal ganglia and the other brain elements that provide motor control are complex, as shown in **Fig. 57.10**. To the left is shown the motor cortex, thalamus, and associated brain stem and cerebellar circuitry. To the right is the major circuitry of the basal ganglia system, showing the tremendous interconnections among the basal ganglia plus extensive input and output pathways between the other motor regions of the brain and the basal ganglia.

In the next few sections we concentrate especially on two major circuits, the *putamen circuit* and the *caudate circuit.*

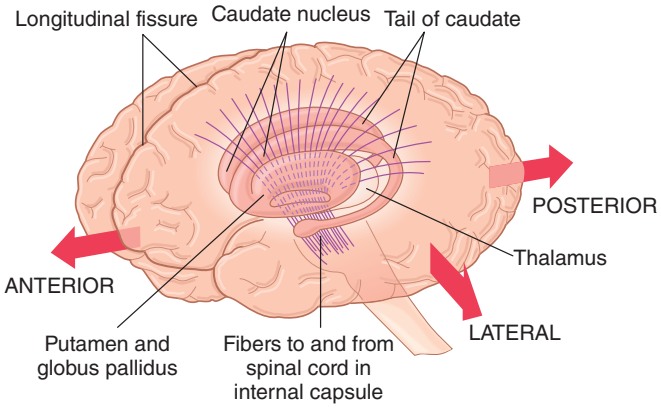

Figure 57.9 Anatomical relations of the basal ganglia to the cerebral cortex and thalamus, shown in three-dimensional view.

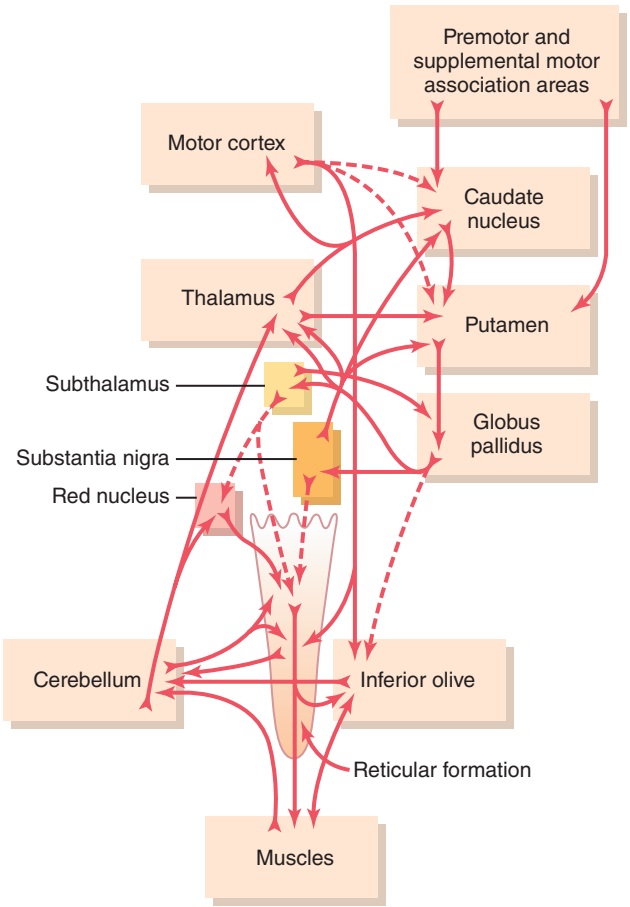

Figure 57.10 Relationship of the basal ganglial circuitry to the corticospinal-cerebellar system for movement control.

FUNCTION OF THE BASAL GANGLIA IN EXECUTING PATTERNS OF MOTOR ACTIVITY—THE PUTAMEN CIRCUIT

One of the principal roles of the basal ganglia in motor control is to function in association with the corticospinal system to control *complex patterns of motor activity*. An example is the writing of letters of the alphabet. When the basal ganglia sustain serious damage, the cortical system of motor control can no longer provide these patterns. Instead, a person's writing becomes crude, as if learning how to write for the first time.

Other patterns that require the basal ganglia are cutting paper with scissors, hammering nails, shooting a basketball through a hoop, passing a football, throwing a baseball, the movements of shoveling dirt, most aspects of vocalization, controlled movements of the eyes, and virtually any other of our skilled movements, most of them performed subconsciously.

Neural Pathways of the Putamen Circuit. Fig. 57.11 shows the principal pathways through the basal ganglia for executing learned patterns of movement. They begin mainly in the premotor and supplementary areas of the motor cortex and in the somatosensory areas of the sensory cortex. Next they pass to the putamen (mainly bypassing the caudate nucleus), then to the internal portion of the globus pallidus, and next to the ventroanterior and ventrolateral relay nuclei of the thalamus, and they finally return to the cerebral primary motor cortex and to portions of the premotor and supplementary cerebral areas closely associated with the primary motor cortex. Thus, *the putamen circuit has its inputs mainly from the parts of the brain adjacent to the primary motor cortex* but not much from the primary motor cortex itself. Then its outputs do go mainly back to the *primary* motor cortex or closely associated *premotor* and *supplementary* cortex. Functioning in close association with this primary putamen circuit are ancillary circuits that pass from the putamen through the external globus pallidus, the subthalamus, and the substantia nigra—finally returning to the motor cortex by way of the thalamus.

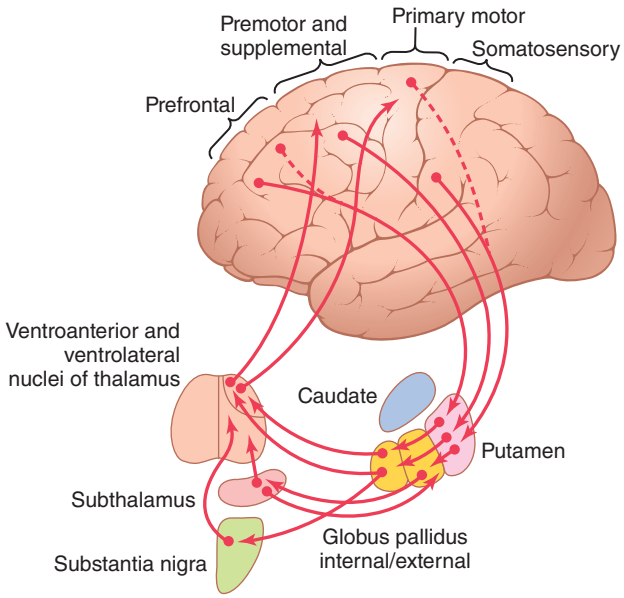

Figure 57.11 Putamen circuit through the basal ganglia for subconscious execution of learned patterns of movement.

Abnormal Function in the Putamen Circuit: Athetosis, Hemiballismus, and Chorea. Although the putamen circuit function helps execute patterns of movement, this function is not well understood. When a portion of the circuit is damaged or blocked, certain patterns of movement become severely abnormal. For example, lesions in the *globus pallidus* frequently lead to spontaneous and often continuous *writhing movements* of a hand, an arm, the neck, or the face. These movements are called *athetosis*.

A lesion in the *subthalamus* often leads to sudden *flailing movements* of an entire limb, a condition called *hemiballismus*.

Multiple small lesions in the *putamen* lead to *flicking movements* in the hands, face, and other parts of the body, called *chorea*.

Lesions of the *substantia nigra* lead to the common and extremely severe disease of *rigidity, akinesia*, and *tremors* known as *Parkinson disease*, which we discuss in more detail later in this chapter.

ROLE OF THE BASAL GANGLIA FOR COGNITIVE CONTROL OF MOTOR PATTERN SEQUENCES—THE CAUDATE CIRCUIT

The term *cognition* means the thinking processes of the brain, using both sensory input to the brain plus information already stored in memory. Most of our motor actions occur as a consequence of thoughts generated in the mind, a process called *cognitive control of motor activity*. The caudate nucleus plays a major role in this cognitive control of motor activity.

The neural connections between the caudate nucleus and the corticospinal motor control system, shown in **Fig. 57.12**, are somewhat different from those of the putamen circuit. Part of the reason for this difference is that the caudate nucleus, as shown in **Fig. 57.9**, extends into all lobes of the cerebrum, beginning anteriorly in the frontal lobes, then passing posteriorly through the parietal and occipital lobes, and finally curving forward again like the letter "C" into the temporal lobes. Furthermore, the caudate nucleus receives large amounts of its input from the *association areas* of the cerebral cortex overlying the caudate nucleus, mainly areas that also integrate the different types of sensory and motor information into usable thought patterns.

After the signals pass from the cerebral cortex to the caudate nucleus, they are transmitted to the internal globus pallidus, then to the relay nuclei of the ventroanterior and ventrolateral thalamus, and finally back to the prefrontal, premotor, and supplementary motor areas of the cerebral cortex, but with almost none of the returning signals passing directly to the primary motor cortex. Instead, the returning signals go to the accessory motor regions in the premotor and supplementary motor areas that are concerned with building sequential patterns of movement lasting 5 seconds or more instead of exciting individual muscle movements.

A good example of this phenomenon would be a person seeing a lion approach and then responding instantaneously and automatically by (1) turning away from the lion, (2) beginning to run, and (3) even attempting to climb a tree. Without the cognitive functions, the person might not have the instinctive knowledge, without thinking for too long a time, to respond quickly and appropriately. Thus, cognitive control of motor activity determines subconsciously, and within seconds, which patterns of movement will be used together to achieve a complex goal that might itself last for many seconds.

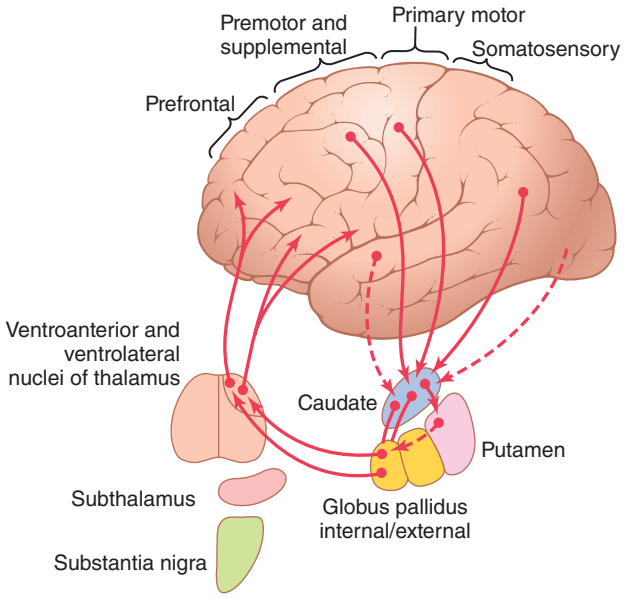

Figure 57.12 Caudate circuit through the basal ganglia for cognitive planning of sequential and parallel motor patterns to achieve specific conscious goals.

FUNCTION OF THE BASAL GANGLIA TO CHANGE THE TIMING AND TO SCALE THE INTENSITY OF MOVEMENTS

Two important capabilities of the brain in controlling movement are (1) to determine how rapidly the movement is to be performed and (2) to control how large the movement will be. For example, a person may write the letter "A" slowly or rapidly. Also, they may write a small "A" on a piece of paper or a large "A" on a chalkboard. Regardless of the choice, the proportional characteristics of the letter remain nearly the same.

In patients with severe lesions of the basal ganglia, these timing and scaling functions are poor, and sometimes nonexistent. Here again, the basal ganglia do not function alone; rather, they function in close association with the cerebral cortex. One especially important cortical area is the posterior parietal cortex, which is the locus of the spatial coordinates for motor control of all parts of the body, as well as for the relationship of the body and its parts to all its surroundings. Damage to this area does not produce simple deficits of sensory perception, such as loss of tactile sensation, blindness, or deafness. Instead, lesions of the posterior parietal cortex produce an inability to perceive objects accurately through normally functioning sensory mechanisms, a condition called *agnosia*.

Fig. 57.13 shows how a person with a lesion in the right posterior parietal cortex might try to copy drawings. In these cases, the patient's ability to copy the left side of the drawings is severely impaired. Also, such a person will always try to avoid using their left arm, left hand, or other portions of the left side of their body for performing tasks; the person may not even wash this side of the body *(personal neglect syndrome)*, almost not knowing that these parts of the body exist.

Because the caudate circuit of the basal ganglial system functions mainly with association areas of the cerebral cortex, such as the posterior parietal cortex, presumably the timing and scaling of movements are functions of this caudate cognitive motor control circuit. However, our understanding of basal ganglia function is still so

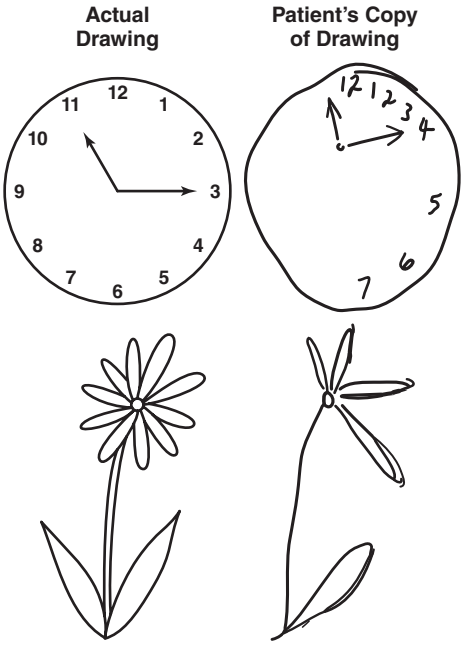

Figure 57.13 Illustration of drawings that might be made by a person who has *neglect syndrome* caused by severe damage in their right posterior parietal cortex, compared with the actual drawings the patient was requested to copy. Note that the person's ability to copy the left side of the drawings is severely impaired.

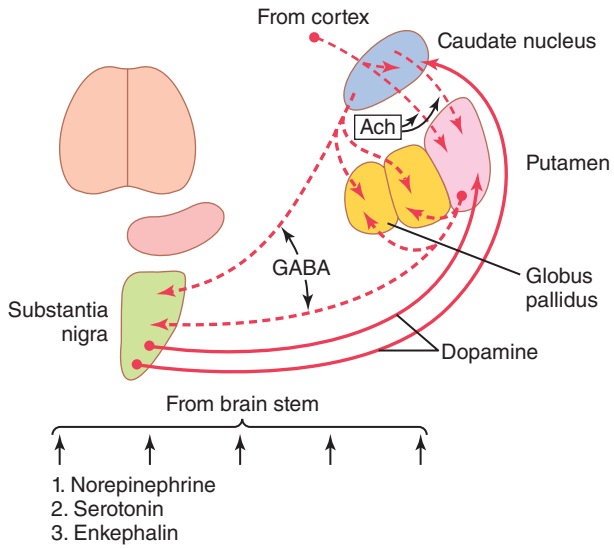

Figure 57.14 Neuronal pathways that secrete different types of neurotransmitter substances in the basal ganglia. *Ach*, Acetylcholine; *GABA*, gamma-aminobutyric acid.

imprecise that much of what is discussed in the last few sections is analytical deduction rather than proven fact.

FUNCTIONS OF SPECIFIC NEUROTRANSMITTER SUBSTANCES IN THE BASAL GANGLIAL SYSTEM

Fig. 57.14 illustrates the interplay of several specific neurotransmitters that are known to function in the basal ganglia: (1) *dopamine* pathways from the substantia nigra to the caudate nucleus and putamen; (2) *gamma-aminobutyric acid* (GABA) pathways from the caudate nucleus and putamen to the globus pallidus and substantia nigra; (3) *acetylcholine* pathways from the cortex to the caudate nucleus and putamen; and (4) multiple pathways from the brain stem that secrete *norepinephrine, serotonin, enkephalin*, and several other neurotransmitters in the basal ganglia, as well as in other parts of the cerebrum.

There are also are *multiple glutamate pathways* that provide most of the excitatory signals (not shown in the figure) that balance out the large numbers of inhibitory signals transmitted especially by the dopamine, GABA, and serotonin inhibitory transmitters. We have more to say about some of these neurotransmitter and hormonal systems in subsequent sections when we discuss diseases of the basal ganglia, as well as in subsequent chapters when we discuss behavior, sleep, wakefulness, and functions of the autonomic nervous system.

For the present, it should be remembered that *GABA functions as an inhibitory neurotransmitter*. Therefore, GABA neurons in the feedback loops from the cortex through the basal ganglia and then back to the cortex make virtually all these loops *negative feedback loops*, rather than positive feedback loops, thus lending stability to the motor control systems. Dopamine also functions as an inhibitory neurotransmitter in most parts of the brain, so it also functions as a stabilizer under some conditions.

Clinical Syndromes Resulting From Damage to the Basal Ganglia

Aside from *athetosis* and *hemiballismus*, which have already been mentioned in relation to lesions in the globus pallidus and subthalamus, two other major diseases result from damage in the basal ganglia. These diseases are *Parkinson disease* and *Huntington disease*.

Parkinson Disease

Parkinson disease, also known as *paralysis agitans*, results from widespread degeneration of the portion of the substantia nigra (the pars compacta) that sends dopamine-secreting nerve fibers to the caudate nucleus and putamen. Although the etiology of Parkinson is uncertain, a combination of genetic and environmental factors, including toxins such as pesticides, is believed to be involved. More than 10 million people worldwide have Parkinson disease, and men are 1.5 times more likely than women to have this disorder.

Parkinson disease is characterized by the following: (1) rigidity of much of the musculature of the body; (2) involuntary tremor at a fixed rate of 3 to 6 cycles/sec of the involved areas, even when the person is resting; (3) serious difficulty in initiating movement, called *akinesia;* (4) postural instability caused by impaired postural reflexes, leading to poor balance and falls; and (5) other motor symptoms, including *dysphagia* (impaired ability to swallow), speech disorders, gait disturbances, and fatigue.

Decreased dopamine secreted in the caudate nucleus and putamen appears to play a key role in the abnormal

motor effects of Parkinson disease. Dopamine is an inhibitory transmitter, and destruction of the dopaminergic neurons in the substantia nigra may allow the caudate nucleus and putamen to become overly active and cause continuous output of excitatory signals to the corticospinal motor control system. These signals could overly excite many of the muscles of the body, thus leading to *rigidity* in patients with Parkinson disease.

Some of the feedback circuits might easily *oscillate* because of high feedback gains after loss of their inhibition, leading to the *tremor* of Parkinson disease. This tremor is quite different from that of cerebellar disease because it occurs during all waking hours and therefore is an *involuntary tremor*, in contradistinction to cerebellar tremor, which occurs only when the person performs intentionally initiated movements.

The *akinesia* that occurs in patients with severe Parkinson disease is often much more distressing than are the symptoms of muscle rigidity and tremor, because the person must exert the highest degree of concentration to perform even the simplest movement. The mental effort, even mental anguish, that is necessary to make the desired movements is often at the limit of the patient's willpower. Then, when the movements do occur, they are usually stiff and staccato in character instead of smooth. The cause of this akinesia is still speculative. However, dopamine secretion in the limbic system, especially in the *nucleus accumbens*, is often decreased, along with its decrease in the basal ganglia. It has been suggested that this decrease might reduce the psychic drive for motor activity and contribute to akinesia.

Nonmotor features of Parkinson disease include sleep disturbances, depression and anxiety, autonomic dysfunction, and cognitive impairment in advanced stages.

Treatment of Parkinson Disease With L-Dopa. Administration of the drug L-*dopa* to patients with Parkinson disease usually ameliorates many of the motor disturbances, especially the rigidity and akinesia, but has little beneficial effect on nonmotor symptoms. The reason for the amelioration of motor disorders is believed to be that L-dopa is converted in the brain into dopamine, and dopamine then restores the normal balance between inhibition and excitation in the caudate nucleus and putamen. Administration of dopamine does not have the same effect because dopamine has a chemical structure that will not allow it to pass through the blood–brain barrier; the slightly different structure of L-dopa allows it to pass through this barrier.

Treatment of Parkinson Disease With Monoamine Oxidase Inhibitors. Another treatment for Parkinson disease includes drugs that inhibit monoamine oxidase, which is responsible for destruction of most of the dopamine after it has been released. Therefore, any dopamine that is released remains in the basal ganglial tissues for a longer time. In addition, for reasons that are not understood, this treatment helps to slow destruction of the dopamine-secreting neurons in the substantia nigra. Therefore, appropriate combinations of L-dopa therapy along with monoamine oxidase inhibitor therapy usually provide much better treatment than use of one of these drugs alone.

Treatment of Parkinson Disease With Transplanted Fetal Dopamine Cells. Transplantation of fetal dopamine-secreting brain cells into the caudate nuclei and putamen has been used with some short-term success to treat Parkinson disease. If persistence of dopamine secretion by these cells could be achieved, perhaps this treatment would become the therapy of the future.

Huntington Disease (Huntington Chorea)

Huntington disease is an autosomal-dominant hereditary disorder that affects men and women equally and usually begins causing symptoms at age 30 to 40 years. It is characterized at first by flicking movements in individual muscles and then progressively severe distortional movements of the entire body. In addition, severe dementia develops along with the motor dysfunctions.

The abnormal movements of Huntington disease are believed to be caused by the loss of cell bodies of the GABA-secreting neurons in the caudate nucleus and putamen and the loss of acetylcholine-secreting neurons in many parts of the brain. The axon terminals of the GABA neurons normally inhibit portions of the globus pallidus and substantia nigra. This loss of inhibition is believed to allow spontaneous outbursts of globus pallidus and substantia nigra activity that cause the distortional movements.

Dementia in persons with Huntington disease probably does not result from the loss of GABA neurons but from the loss of acetylcholine-secreting neurons, perhaps especially in the thinking areas of the cerebral cortex.

The abnormal gene that causes Huntington disease has been found; it has a codon (CAG) that repeats many times and codes for multiple extra *glutamine* amino acids in the molecular structure of an abnormal neuronal cell protein called *huntingtin* that causes the symptoms. How this protein causes the effects of the disease is now a question for major research efforts.

INTEGRATION OF THE MANY PARTS OF THE ENTIRE MOTOR CONTROL SYSTEM

Finally, we will summarize as best we can what is known about overall control of movement. To do this, let us first give a synopsis of the different levels of control.

SPINAL LEVEL

Programmed in the spinal cord are local patterns of movement for all muscle areas of the body—for example, programmed withdrawal reflexes that pull any part of the body away from a source of pain. The spinal cord is the locus also of complex patterns of rhythmic motions, such as to-and-fro movement of the limbs for walking, plus reciprocal motions on opposite sides of the body or of the hindlimbs versus the forelimbs in four-legged animals.

All these programs of the cord can be commanded into action by higher levels of motor control, or they can be inhibited while the higher levels take over control.

HINDBRAIN LEVEL

The hindbrain provides two major functions for general motor control of the body: (1) maintenance of axial tone

of the body for the purpose of standing and (2) continuous modification of the degrees of tone in the different muscles in response to information from the vestibular apparatuses for the purpose of maintaining body equilibrium.

MOTOR CORTEX LEVEL

The motor cortex system provides most of the activating motor signals to the spinal cord. It functions partly by issuing sequential and parallel commands that set into motion various cord patterns of motor action. It can also change the intensities of the different patterns or modify their timing or other characteristics. When needed, the corticospinal system can bypass the cord patterns, replacing them with higher-level patterns from the brain stem or cerebral cortex. The cortical patterns are usually complex; also, they can be "learned," whereas cord patterns are mainly determined by heredity and are said to be "hard wired."

Associated Functions of the Cerebellum. The cerebellum functions with all levels of muscle control. It functions with the spinal cord especially to enhance the stretch reflex, so when a contracting muscle encounters an unexpectedly heavy load, a long stretch reflex signal transmitted all the way through the cerebellum and back again to the cord strongly enhances the load-resisting effect of the basic stretch reflex.

At the brain stem level, the cerebellum functions to make the postural movements of the body, especially the rapid movements required by the equilibrium system, smooth and continuous and without abnormal oscillations.

At the cerebral cortex level, the cerebellum operates in association with the cortex to provide many accessory motor functions, especially to provide extra motor force for turning on muscle contraction rapidly at the start of a movement. Near the end of each movement, the *cerebellum* turns on antagonist muscles at exactly the right time and with proper force to stop the movement at the intended point. Furthermore, almost all aspects of this turn-on/turn-off patterning by the cerebellum can be learned with experience.

The cerebellum functions with the cerebral cortex at still another level of motor control; it helps to program in advance muscle contractions that are required for smooth progression from a present rapid movement in one direction to the next rapid movement in another direction, with all this occurring in a fraction of a second. The neural circuit for this motor control passes from the cerebral cortex to the large lateral zones of the cerebellar hemispheres and then back to the cerebral cortex.

The cerebellum functions mainly when rapid muscle movements are required. Without the cerebellum, slow and calculated movements can still occur, but it is difficult for the corticospinal system to achieve rapid and changing intended movements to execute a particular goal or to progress smoothly from one rapid movement to the next.

Associated Functions of the Basal Ganglia. The basal ganglia are essential to motor control in ways entirely different from those of the cerebellum. Their most important functions are (1) to help the cortex execute subconscious but *learned patterns of movement* and (2) to help plan multiple parallel and sequential patterns of movement that the mind puts together to accomplish a purposeful task.

The types of motor patterns that require the basal ganglia include those for writing all the different letters of the alphabet, for throwing a ball, and for typing. Also, the basal ganglia are required to modify these patterns for writing small or writing very large, thus controlling dimensions of the patterns.

At a still higher level of control is another combined cerebral and basal ganglia circuit, beginning in the thinking processes of the cerebrum to provide overall sequential steps of action for responding to each new situation, such as planning one's immediate motor response to an assailant or one's sequential response to an unexpectedly fond embrace.

WHAT DRIVES US TO ACTION?

What is it that arouses us from inactivity and sets into play our trains of movement? We are beginning to learn about the motivational systems of the brain. Basically, the brain has an older core located beneath, anterior, and lateral to the thalamus—including the hypothalamus, amygdala, hippocampus, septal region anterior to the hypothalamus and thalamus, and even old regions of the thalamus and cerebral cortex. All of these components function together to initiate most motor and other functional activities of the brain. These areas are collectively called the *limbic system* of the brain. We discuss this system in more detail in Chapter 59.

CHAPTER 58

Cerebral Cortex, Intellectual Functions of the Brain, Learning, and Memory

It is ironic that of all the parts of the brain, we are the least certain about the complex functions of the cerebral cortex, even though it is by far the largest and perhaps the most studied portion of the nervous system. However, we do know the effects of damage or stimulation of various portions of the cerebral cortex. In the first part of this chapter, the known cortical functions are discussed, and then basic theories of neuronal mechanisms involved in thought processes, memory, analysis of sensory information, and so forth are presented briefly.

PHYSIOLOGICAL ANATOMY OF THE CEREBRAL CORTEX

The main functional part of the cerebral cortex is a thin layer of neurons covering the surface of all the convolutions of the cerebrum. This layer is only 2 to 5 millimeters thick, with a total area of about 25% of a square meter. The total cerebral cortex has been estimated to contain over 80 *billion* neurons.

Fig. 58.1 shows the typical histological structure of the neuronal surface of the cerebral cortex, with its successive layers of different types of neurons. Most of the neurons are of three types: (1) *granular* (also called *stellate*); (2) *fusiform;* and (3) *pyramidal*, the latter named for their characteristic pyramidal shape.

The *granular* neurons generally have short axons and, therefore, function mainly as interneurons that transmit neural signals only short distances in the cortex. Some are excitatory, releasing mainly the neurotransmitter *glutamate*, whereas others are inhibitory and release mainly the neurotransmitter *gamma-aminobutyric acid* (GABA). The sensory areas of the cortex, as well as the association areas between sensory and motor areas, have large concentrations of these granule cells, suggesting a high degree of intracortical processing of incoming sensory signals within the sensory areas and association areas.

The *pyramidal* and *fusiform cells* give rise to almost all the output fibers from the cortex. The pyramidal cells, which are larger and more numerous than the fusiform cells, are the source of the long, large nerve fibers that go all the way to the spinal cord. The pyramidal cells also give rise to most of the large subcortical association fiber bundles that pass from one major part of the brain to another.

To the right in **Fig. 58.1** is shown the typical organization of nerve fibers within the different layers of the cerebral cortex. Note particularly the large number of *horizontal fibers* that extend between adjacent areas of the cortex, but note also the *vertical fibers* that extend to and from the cortex to lower areas of the brain and some all the way to the spinal cord or to distant regions of the cerebral cortex through long association bundles.

The functions of the specific layers of the cerebral cortex are discussed in Chapters 48 and 52. By way of review, let us recall that most incoming sensory signals from the body terminate in cortical layer IV. Most of the output signals leave the cortex through neurons located in layers V and

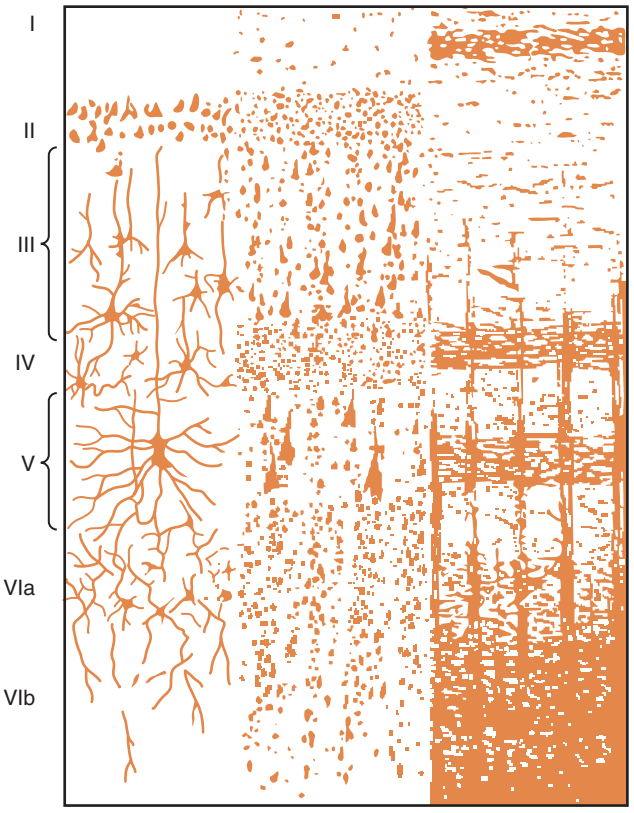

Figure 58.1 Structure of the cerebral cortex, showing the following layers: I, molecular layer; II, external granular layer; III, layer of pyramidal cells; IV, internal granular layer; V, large pyramidal cell layer; and VI, layer of fusiform or polymorphic cells. *(Modified from Ranson SW, Clark SL.* Anatomy of the Nervous System. *Philadelphia: WB Saunders; 1959.)*

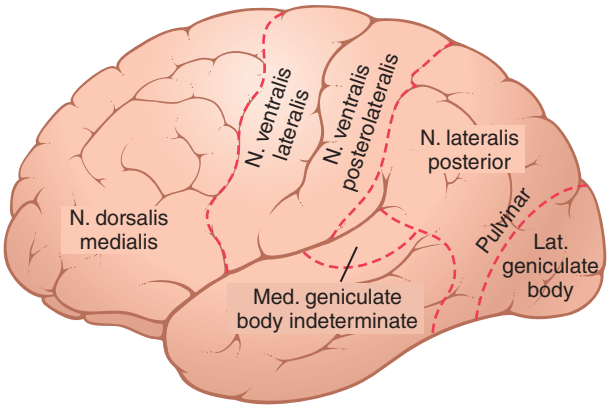

Figure 58.2 Areas of the cerebral cortex that connect with specific portions of the thalamus. *N.*, Nerve.

VI. The very large fibers to the brain stem and cord arise generally in layer V, and the tremendous numbers of fibers to the thalamus arise in layer VI. Layers I, II, and III perform most of the intracortical association functions, with especially large numbers of neurons in layers II and III making short horizontal connections with adjacent cortical areas.

ANATOMICAL AND FUNCTIONAL RELATIONS OF THE CEREBRAL CORTEX TO THE THALAMUS AND OTHER LOWER CENTERS

All areas of the cerebral cortex have extensive to-and-fro efferent and afferent connections with deeper structures of the brain. It is important to emphasize the relation between the cerebral cortex and the thalamus. When the thalamus is damaged along with the cortex, the loss of cerebral function is far greater than when the cortex alone is damaged, because thalamic excitation of the cortex is necessary for almost all cortical activity.

Fig. 58.2 shows the areas of the cerebral cortex that connect with specific parts of the thalamus. These connections act in *two* directions—from the thalamus to the cortex and then from the cortex back to essentially the same area of the thalamus. Furthermore, when the thalamic connections are cut, the functions of the corresponding cortical area become almost entirely lost. Therefore, the cortex operates in close association with the thalamus and can almost be considered both anatomically and functionally a unit with the thalamus; for this reason, the thalamus and the cortex together are sometimes called the *thalamocortical system*. Almost all pathways from the sensory receptors and sensory organs to the cortex pass through the thalamus, with the principal exception of some sensory pathways of olfaction.

FUNCTIONS OF SPECIFIC CORTICAL AREAS

Fig. 58.3 is a map of some of the functions of different cerebral cortical areas as determined from electrical

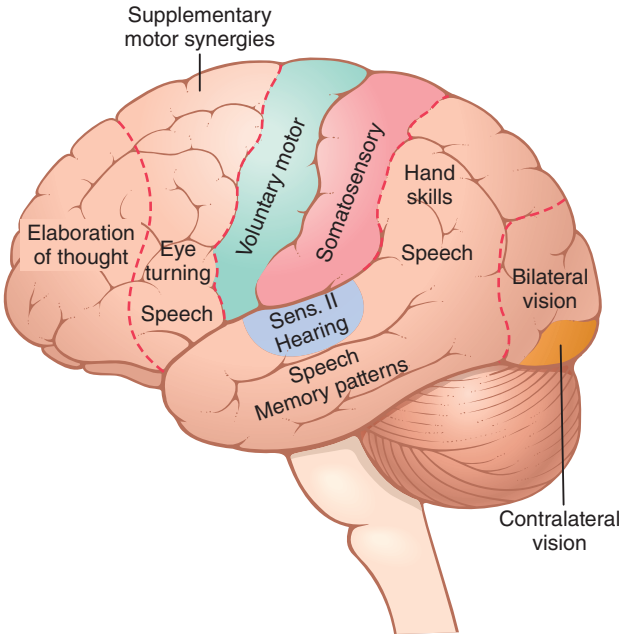

Figure 58.3 Functional areas of the human cerebral cortex as determined by electrical stimulation of the cortex during neurosurgical operations and by neurological examinations of patients with destroyed cortical regions. *(Modified from Penfield W, Rasmussen T.* The Cerebral Cortex of Man: A Clinical Study of Localization of Function. *New York: Hafner; 1968.)*

stimulation of the cortex in awake patients or during neurological examination of patients after portions of their cortex were removed. The electrically stimulated patients told their thoughts evoked by the stimulation, and sometimes they experienced movements. Occasionally they spontaneously emitted a sound or even a word or gave some other evidence of the stimulation.

Putting large amounts of information together from many different sources gives a more general map, as shown in **Fig. 58.4**. This figure shows the major primary and secondary premotor and supplementary motor areas of the cortex, as well as the major primary and secondary sensory areas for somatic sensation, vision, and hearing, all of which are discussed in earlier chapters. The primary motor areas have direct connections with specific muscles for causing discrete muscle movements. The primary sensory areas detect specific sensations—visual, auditory, or somatic—transmitted to the brain from peripheral sensory organs.

The secondary areas make sense out of the signals in the primary areas. For example, the supplementary and premotor areas function along with the primary motor cortex and basal ganglia to provide "patterns" of motor activity. On the sensory side, the secondary sensory areas, located within a few centimeters of the primary areas, begin to analyze the meanings of the specific sensory signals, such as the following: (1) interpretation of the shape or texture of an object in one's hand; (2) interpretation of color, light intensity, directions of lines and angles, and other aspects of vision; and (3) interpretations of the meanings of sound tones and the sequence of tones in auditory signals.

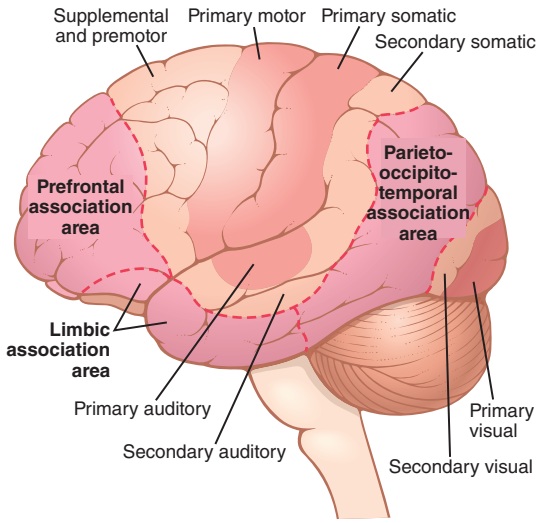

Figure 58.4 Locations of major association areas of the cerebral cortex, as well as primary and secondary motor and sensory areas.

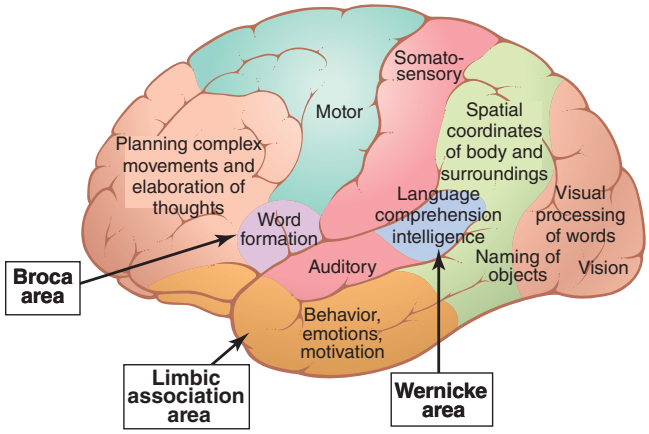

Figure 58.5 Map of specific functional areas in the cerebral cortex, showing especially Wernicke and Broca areas for language comprehension and speech production, which in 95% of all people are located in the left hemisphere.

ASSOCIATION AREAS

Fig. 58.4 also shows several large areas of the cerebral cortex that do not fit into the rigid categories of primary and secondary motor and sensory areas. These areas are called *association areas* because they receive and analyze signals simultaneously from multiple regions of both the motor and sensory cortices, as well as from subcortical structures. Yet, even the association areas have their specializations. Major association areas include (1) the *parieto-occipitotemporal association area*, (2) the *prefrontal association area*, and (3) the *limbic association area*.

Parieto-Occipitotemporal Association Area

The parieto-occipitotemporal association area lies in the large parietal and occipital cortical space bounded by the somatosensory cortex anteriorly, the visual cortex posteriorly, and the auditory cortex laterally. Although it provides a high level of interpretative meaning for signals from all the surrounding sensory areas, the parieto-occipitotemporal association area has its own functional subareas, which are shown in **Fig. 58.5**.

Analysis of the Spatial Coordinates of the Body. An area beginning in the *posterior parietal cortex* and extending into the *superior occipital cortex* provides continuous analysis of the spatial coordinates of all parts of the body, as well as of the surroundings of the body. This area receives visual sensory information from the posterior occipital cortex and simultaneous somatosensory information from the anterior parietal cortex. From all this information, it computes the coordinates of the visual, auditory, and body surroundings.

Wernicke Area Is Important for Language Comprehension. The major area for language comprehension, called the *Wernicke area*, lies behind *the primary auditory cortex in the posterior part of the superior gyrus of the temporal lobe.* It is one of the most important regions of the entire brain for higher intellectual function because most of these intellectual functions are language based; we will discuss this area more fully later.

The Angular Gyrus Area Is Needed for Initial Processing of Visual Language (Reading). Posterior to the language comprehension area, lying mainly in the anterolateral region of the occipital lobe, is a visual association area that feeds visual information conveyed by words read from a book into Wernicke area, the language comprehension area. This *angular gyrus area* is needed to make meaning out of the visually perceived words. In its absence, a person can still have excellent language comprehension through hearing but not through reading; injury to the angular gyrus can result in *agraphia* (inability to write) with *alexia* (inability to read), a condition in which a person cannot read, write, or spell words.

Area for Naming Objects. *In the most lateral portions of the anterior occipital lobe and posterior temporal lobe is an area for naming objects.* The names are learned mainly through auditory input, whereas the physical natures of the objects are learned mainly through visual input. In turn, the names are essential for both auditory and visual language comprehension (*functions performed in the Wernicke area*, located immediately superior to the auditory "names" region and anterior to the visual word processing area).

Prefrontal Association Area

As discussed in Chapter 57, the prefrontal association area functions in close association with the motor cortex to plan complex patterns and sequences of motor movements. To aid in this function, it receives strong input through a massive subcortical bundle of nerve fibers connecting the parieto-occipitotemporal association area with the prefrontal association area. Through this bundle, the prefrontal cortex receives much preanalyzed sensory information, especially information on the spatial coordinates of the body that is necessary for planning effective movements. Much of the output from the prefrontal area into the motor control system passes through the caudate portion of the basal ganglia–thalamic feedback circuit for motor planning, which provides many of the sequential and parallel components of movement stimulation.

The *prefrontal association area* is also *essential to carrying out "thought" processes*. This characteristic presumably results from some of the same capabilities of the prefrontal cortex that allow it to plan motor activities. It seems to be capable of processing nonmotor and motor information from widespread areas of the brain and therefore to achieve nonmotor types of thinking, as well as motor types. In fact, the prefrontal association area is frequently described as important for *elaboration of thoughts*, and it is said to store on a short-term basis "working memories" that are used to combine new thoughts while they are entering the brain.

Broca Area Provides the Neural Circuitry for Word Formation. The *Broca area*, shown in **Fig. 58.5**, is located partly in the posterior lateral prefrontal cortex and partly in the premotor area. It is here that plans and motor patterns for expressing individual words or even short phrases are initiated and executed. This area also works in close association with the Wernicke language comprehension center in the temporal association cortex, as we discuss more fully later in the chapter.

An especially interesting discovery is that when a person has already learned one language and then learns a new language, the area in the brain where the new language is stored is slightly removed from the storage area for the first language. However, if both languages are learned simultaneously, they are stored together in the same area of the brain.

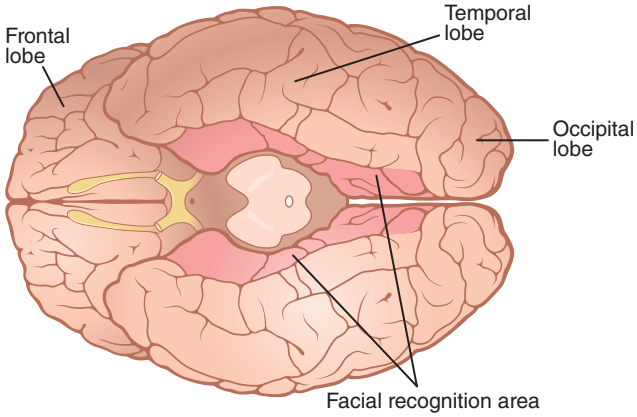

Figure 58.6 Facial recognition areas located on the underside of the brain in the medial occipital and temporal lobes. *(Modified from Geschwind N. Specializations of the human brain.* Sci Am. *1979;241:180.)*

Limbic Association Area

Figs. 58.4 and **58.5** show another association area called the *limbic association area*. This area is found in the anterior pole of the temporal lobe, in the ventral portion of the frontal lobe, and in the cingulate gyrus lying deep in the longitudinal fissure on the midsurface of each cerebral hemisphere. It is concerned primarily with *behavior, emotions*, and *motivation*. We discuss in Chapter 59 that the limbic cortex is part of a much more extensive system, the *limbic system*, that includes a complex set of neuronal structures in the midbasal regions of the brain. This limbic system provides most of the emotional drives for activating other areas of the brain and even provides motivational drive for the process of learning itself.

Area for Recognition of Faces

An interesting type of brain abnormality called *prosopagnosia* is the inability to recognize faces. This condition occurs in people who have extensive damage on the medial undersides of both occipital lobes and along the medioventral surfaces of the temporal lobes, as shown in **Fig. 58.6**. Loss of these face recognition areas, strangely enough, results in little other abnormality of brain function.

One may wonder why so much of the cerebral cortex should be reserved for the simple task of face recognition. However, most of our daily tasks involve associations with other people, and thus one can see the importance of this intellectual function.

The occipital portion of this facial recognition area is contiguous with the visual cortex, and the temporal portion is closely associated with the limbic system, which has to do with emotions, brain activation, and control of one's behavioral response to the environment, as we discuss in Chapter 59.

COMPREHENSIVE INTERPRETATIVE FUNCTION OF THE POSTERIOR SUPERIOR TEMPORAL LOBE—WERNICKE AREA

The somatic, visual, and auditory association areas all meet one another in the posterior part of the superior temporal lobe, shown in **Fig. 58.7**, where the temporal, parietal, and occipital lobes all come together. This area of confluence of the different sensory interpretative areas is especially highly developed in the *dominant* side of the brain—the *left side* in almost all right-handed people—and it plays the greatest single role of any part of the cerebral cortex for the higher comprehension levels of brain function that we call *intelligence*. Therefore, this region has been called by different names suggestive of an area that has almost global importance: the *general interpretative area*, the *gnostic area*, the *knowing*

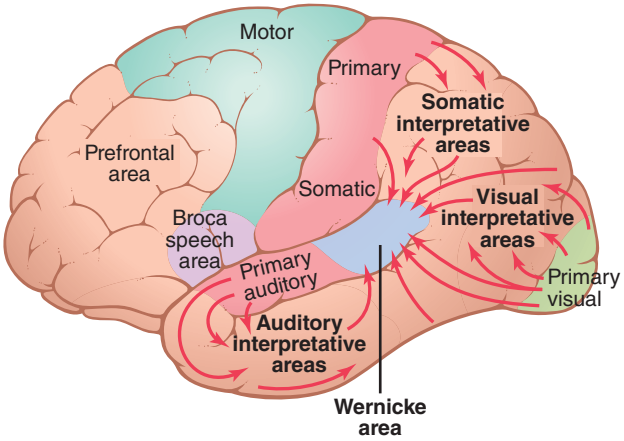

Figure 58.7 Organization of the somatic auditory and visual association areas into a general mechanism for interpretation of sensory experience. All of these also feed into the *Wernicke area*, located in the posterosuperior portion of the temporal lobe. Note also the prefrontal area and *Broca speech area* in the frontal lobe.

area, the *tertiary association area*, and so forth. It is best known as the *Wernicke area*, in honor of the neurologist who first described its special significance in intellectual processes.

After severe damage in the Wernicke area, a person might hear perfectly well and even recognize different words but still be unable to arrange these words into a coherent thought. Likewise, the person may be able to read words from the printed page but be unable to recognize the thought that is conveyed.

Electrical stimulation of the Wernicke area in a conscious person occasionally causes a highly complex thought, particularly when the stimulation electrode is passed deep enough into the brain to approach the corresponding connecting areas of the thalamus. The types of thoughts that might be experienced include complicated visual scenes remembered from childhood, auditory hallucinations such as a specific musical piece, or even a statement made by a specific person. For this reason, it is believed that activation of the Wernicke area can call forth complicated memory patterns that involve more than one sensory modality even though most of the individual memories may be stored elsewhere. This belief is in accord with the importance of the Wernicke area in interpreting the complicated meanings of different patterns of sensory experiences.

The Angular Gyrus Is Important for Interpreting Visual Information. The *angular gyrus* is the most inferior portion of the posterior parietal lobe, lying immediately behind the Wernicke area and fusing posteriorly into the visual areas of the occipital lobe as well. If this region is destroyed while the Wernicke area in the temporal lobe is still intact, the person can still interpret auditory experiences as usual, but the stream of visual experiences passing into the Wernicke area from the visual cortex is mainly blocked. Therefore, the person may be able to see words and even know that they are words but may not be able to interpret their meanings. This condition is called *alexia*, or *word blindness*. The term *"dyslexia"* is used to describe *difficulty* in learning about written language, not complete word blindness.

Concept of the Dominant Hemisphere

The general interpretative functions of the Wernicke area and the angular gyrus, as well as the functions of the speech and motor control areas, are usually much more highly developed in one cerebral hemisphere than in the other. Therefore, this hemisphere is called the *dominant hemisphere*. In about 95% of all people, the left hemisphere is the dominant one.

Even at birth, the area of the cortex that will eventually become the Wernicke area is as much as 50% larger in the left hemisphere than in the right in more than one-half of neonates. Therefore, it is easy to understand why the left side of the brain might become dominant over the right side. However, if for some reason this left side area is damaged or removed in very early childhood, the opposite side of the brain will usually develop dominant characteristics.

The following theory can explain the capability of one hemisphere to dominate the other hemisphere. The attention of the "mind" seems to be directed to one principal thought at a time. Presumably, because the left posterior temporal lobe at birth is usually slightly larger than the right lobe, the left side normally begins to be used to a greater extent than is the right side. Thereafter, because of the tendency to direct one's attention to the better developed region, the rate of learning in the cerebral hemisphere that gains the first start increases rapidly, whereas in the opposite, less-used side, learning remains less well developed. Therefore, the left side normally becomes dominant over the right side.

In about 95% of all people, the left temporal lobe and angular gyrus become dominant, and in the remaining 5%, either both sides develop simultaneously to have dual function or, more rarely, the right side alone becomes highly developed, with full dominance.

As discussed later in this chapter, the premotor speech area (Broca area), located far laterally in the intermediate frontal lobe, is also almost always dominant on the left side of the brain. This speech area is responsible for formation of words by exciting simultaneously the laryngeal muscles, respiratory muscles, and muscles of the mouth.

The motor areas for controlling hands are also dominant in the left side of the brain in about 90% of persons, thus causing right-handedness in most people.

Although the interpretative areas of the temporal lobe and angular gyrus, as well as many of the motor areas, are usually highly developed in only the left hemisphere, these

areas receive sensory information from both hemispheres and are also capable of controlling motor activities in both hemispheres. For this purpose, they use mainly fiber pathways in the *corpus callosum* for communication between the two hemispheres. This unitary, cross-feeding organization prevents interference between the two sides of the brain; such interference could create havoc with both mental thoughts and motor responses.

Role of Language in the Wernicke Area Function and in Intellectual Functions

A major share of our sensory experience is converted into its language equivalent before being stored in the memory areas of the brain and before being processed for other intellectual purposes. For example, when we read a book, we do not store the visual images of the printed words but instead store the words themselves or their conveyed thoughts, often in language form.

The sensory area of the dominant hemisphere for interpretation of language is the Wernicke area, and this area is closely associated with both the primary and secondary hearing areas of the temporal lobe. This close relation probably results from the fact that the first introduction to language is by way of hearing. Later in life, when visual perception of language through the medium of reading develops, the visual information conveyed by written words is then presumably channeled through the angular gyrus, a visual association area, into the already developed Wernicke language interpretative area of the dominant temporal lobe.

FUNCTIONS OF THE PARIETO-OCCIPITOTEMPORAL CORTEX IN THE NONDOMINANT HEMISPHERE

When the Wernicke area in the dominant hemisphere of an adult person is destroyed, the person normally loses almost all intellectual functions associated with language or verbal symbolism, such as the ability to read, the ability to perform mathematical operations, and even the ability to think through logical problems. Many other types of interpretative capabilities, some of which use the temporal lobe and angular gyrus regions of the opposite hemisphere, are retained.

Psychological studies in patients with damage to the nondominant hemisphere have suggested that this hemisphere may be especially important for understanding and interpreting music, nonverbal visual experiences (especially visual patterns), spatial relations between the person and their surroundings, the significance of "body language" and intonations of people's voices, and probably many somatic experiences related to use of the limbs and hands. Thus, even though we speak of the "dominant" hemisphere, this dominance is primarily for language-based intellectual functions; the so-called nondominant hemisphere might actually be dominant for some other types of intelligence.

HIGHER INTELLECTUAL ("EXECUTIVE") FUNCTIONS OF THE PREFRONTAL ASSOCIATION AREAS

For years, it has been taught that the prefrontal cortex is the locus of "higher intellect" in the human being, principally because the main difference between the brains of monkeys and of human beings is the great prominence of the human prefrontal areas. Yet efforts to show that the prefrontal cortex is more important in higher intellectual functions than other portions of the brain have not been successful. Indeed, destruction of the language comprehension area in the posterior superior temporal lobe (Wernicke area) and the adjacent angular gyrus region in the dominant hemisphere causes much more harm to the intellect than does destruction of the prefrontal areas.

The prefrontal areas do, however, have less definable but important intellectual functions. Patients with damage to the prefrontal cortex may have normal motor functions and may even perform normally on some intelligence tests. However, they are unable to function effectively in normal daily life. These functions can be explained by describing what happens to patients in whom the prefrontal areas have become damaged, as follows.

Several decades ago, before the advent of modern drugs for treating psychiatric conditions, it was discovered that some patients could receive significant relief from severe psychotic depression by severing the neuronal connections between the prefrontal areas of the brain and the remainder of the brain by a procedure called *prefrontal lobotomy*. This procedure was performed by inserting a blunt, thin-bladed knife through a small opening in the lateral frontal skull on each side of the head and slicing the brain at the back edge of the prefrontal lobes from top to bottom. Subsequent studies in these patients showed the following mental changes:

1. The patients lost their ability to solve complex problems.
2. They became unable to string together sequential tasks to reach complex goals.
3. They became unable to learn to do several parallel tasks at the same time.
4. Their level of aggressiveness decreased, sometimes markedly, and they often lost ambition.
5. Their social responses were often inappropriate for the occasion, sometimes including loss of morals and little reticence in relation to sexual activity and excretion.
6. The patients could still talk and comprehend language, but they were unable to carry through any long trains of thought, and their moods changed rapidly from sweetness to rage to exhilaration to madness.
7. The patients could also still perform most of the usual patterns of motor function that they had performed throughout life, but often without purpose.

From this information, let us try to piece together a coherent understanding of the function of the prefrontal association areas.

Decreases in Aggressiveness and Inappropriate Social Responses. Decreases in aggressiveness and inappropriate social responses after prefrontal lobotomy probably result from loss of the ventral parts of the frontal lobes on the underside of the brain. As explained earlier and as shown in **Figs. 58.4** and **58.5**, this area is part of the limbic association cortex rather than of the prefrontal association cortex. This limbic area helps to control behavior, which is discussed in detail in Chapter 59.

Inability to Progress Toward Goals or to Carry Through Sequential Thoughts. We learned earlier in this chapter that the prefrontal association areas are capable of calling forth information from widespread areas of the brain and using this information to achieve deeper thought patterns for attaining goals.

Although people without prefrontal cortices can still think, they show little concerted thinking in logical sequence for longer than a few seconds or a minute or so at most. Thus, people without prefrontal cortices are *easily distracted from their central theme of thought*, whereas people with functioning prefrontal cortices can drive themselves to completion of their thought goals, even with distractions.

Elaboration of Thought, Prognostication, and Performance of Higher Intellectual Functions By the Prefrontal Areas—Concept of a "Working Memory." Another function that has been ascribed to the prefrontal areas is *elaboration of thought*, which means simply an increase in depth and abstractness of the different thoughts put together from multiple sources of information. Psychological tests have shown that prefrontal lobectomized lower animals presented with successive bits of sensory information fail to keep track of these bits even in temporary memory, probably because they are distracted so easily that they cannot hold thoughts long enough for memory storage to take place.

This ability of the prefrontal areas to keep track of many bits of information simultaneously and to cause recall of this information instantaneously as it is needed for subsequent thoughts is called the "brain's working memory," which may explain the many functions of the brain that we associate with higher intelligence. In fact, studies have shown that different prefrontal areas store different types of temporary memory, such as one area for storing shape and form of an object or a part of the body and another for storing movement.

By combining all these temporary bits of working memory, we have extraordinary abilities, including the following: (1) prognostication; (2) planning for the future; (3) delaying action in response to incoming sensory signals so that the sensory information can be weighed until the best course of response is decided; (4) considering the consequences of motor actions before they are performed; (5) solving complicated mathematical, legal, or philosophical problems; (6) correlating all avenues of information in diagnosing rare diseases; and (7) controlling our activities in accord with moral laws.

Function of the Brain in Communication—Language Input and Language Output

Because neurological tests can easily assess the ability of a person to communicate with others, we know more about the sensory and motor systems related to communication than about any other segment of brain cortex function. Therefore, with the help of anatomical maps of neural pathways in **Fig. 58.8**, we will review the function of the cortex in communication. From this examination, one will see immediately how the principles of sensory analysis and motor control apply to this art.

Language communication has two major aspects—the *sensory* (language input), involving the ears and eyes, and the *motor* (language output), involving vocalization and its control.

Sensory Aspects of Communication. We noted earlier in the chapter that destruction of portions of the *auditory* or *visual association areas* of the cortex can result in the inability to understand the spoken or written word. These effects are called, respectively, *auditory receptive aphasia* and *visual receptive aphasia* or, more commonly, *word deafness* and *word blindness* (also called *alexia*).

Wernicke Aphasia and Global Aphasia. Some people are capable of understanding either the spoken word or the written word but are *unable to interpret the thought* that is expressed. This condition results most frequently when *the Wernicke area* in the *posterior superior temporal gyrus in the dominant hemisphere* is damaged or destroyed. Therefore, this type of aphasia is called *Wernicke aphasia*.

When the lesion in the Wernicke area is widespread and extends (1) backward into the angular gyrus region, (2) inferiorly into the lower areas of the temporal lobe, and (3) superiorly into the superior border of the sylvian fissure, the person is likely to be almost totally demented for language understanding or communication and therefore is said to have *global aphasia*.

Motor Aspects of Communication

The process of speech involves two principal stages of mentation: (1) formation in the mind of thoughts to be expressed, as well as choice of words to be used; and then (2) motor control of vocalization and the actual act of vocalization itself.

The formation of thoughts and even most choices of words are the function of sensory association areas of the brain. Again, it is the Wernicke area in the posterior part of the superior temporal gyrus that is most important for this ability. Therefore, a person with either Wernicke aphasia

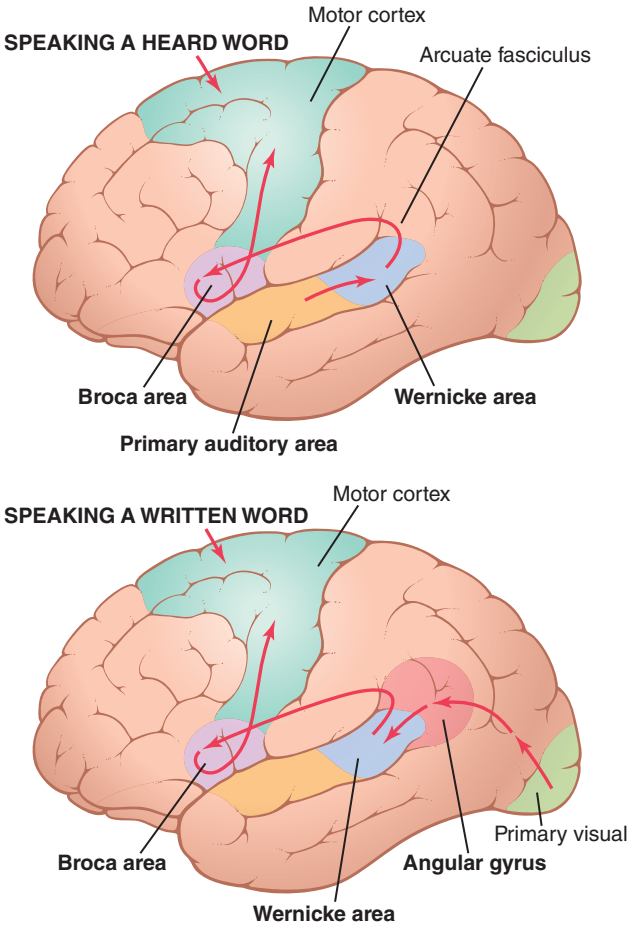

Figure 58.8 Brain pathways for (*top*) perceiving a heard word and then speaking the same word and (*bottom*) perceiving a written word and then speaking the same word. *(Modified from Geschwind N. Specializations of the human brain.* Sci Am. *1979;241:180.)*

or global aphasia is unable to formulate the thoughts that are to be communicated. Or, if the lesion is less severe, the person may be able to formulate the thoughts but unable to put together appropriate sequences of words to express the thought. The person sometimes is even fluent with words, but the words are jumbled.

Loss of the Broca Area Causes Motor Aphasia. Sometimes a person is capable of deciding what they want to say but cannot make the vocal system emit words instead of noises. This effect, called *motor aphasia*, results from damage to the *Broca speech area*, which lies in the *prefrontal* and *premotor* facial regions of the cerebral cortex—about 95% of the time in the left hemisphere, as shown in **Figs. 58.5** and **58.8**. The *skilled motor patterns* for control of the larynx, lips, mouth, respiratory system, and other accessory muscles of speech are all initiated from this area.

Articulation. Finally, we have the act of articulation, which means the muscular movements of the mouth, tongue, larynx, vocal cords, and so forth that are responsible for the intonations, timing, and rapid changes in intensities of the sequential sounds. The *facial and laryngeal regions of the motor cortex* activate these muscles, and the *cerebellum, basal ganglia,* and *sensory cortex* all help to control the sequences and intensities of muscle contractions, making liberal use of basal ganglial and cerebellar feedback mechanisms described in Chapters 56 and 57. Destruction of any of these regions can cause either total or partial inability to speak distinctly.

Summary

Fig. 58.8 shows two principal pathways for communication. The upper half of the figure shows the pathway involved in hearing and speaking. This sequence is as follows: (1) reception in the primary auditory area of the sound signals that encode the words; (2) interpretation of the words in the Wernicke area; (3) determination, also in the Wernicke area, of thoughts and words to be spoken; (4) transmission of signals from the Wernicke area to the Broca area by way of the *arcuate fasciculus;* (5) activation of skilled motor programs in the Broca area for control of word formation; and (6) transmission of appropriate signals into the motor cortex to control the speech muscles.

The lower part of the figure illustrates the comparable steps in reading and then speaking in response. The initial receptive area for the words is in the primary visual area rather than in the primary auditory area. The information then passes through early stages of interpretation in the *angular gyrus region* and finally reaches its full level of recognition in the Wernicke area. From here, the sequence is the same as for speaking in response to the spoken word.

THE CORPUS CALLOSUM AND ANTERIOR COMMISSURE TRANSFER THOUGHTS, MEMORIES, TRAINING, AND OTHER INFORMATION BETWEEN THE TWO CEREBRAL HEMISPHERES

Fibers in the *corpus callosum* provide abundant bidirectional neural connections between most of the cortical areas of the two cerebral hemispheres, except for the anterior portions of the temporal lobes; these temporal areas, including especially the *amygdala*, are interconnected by fibers that pass through the *anterior commissure*.

One of the functions of the corpus callosum and the anterior commissure is to make information stored in the cortex of one hemisphere available to corresponding cortical areas of the opposite hemisphere. The following important examples illustrate such cooperation between the two hemispheres.

1. Cutting the corpus callosum blocks transfer of information from the Wernicke area of the dominant hemisphere to the motor cortex on the opposite side of the brain. Therefore, the intellectual functions of the Wernicke area, located in the left hemisphere, lose control over the right motor cortex that initiates voluntary motor functions of the left hand and arm, even though the usual subconscious movements of the left hand and arm are normal.
2. Cutting the corpus callosum prevents transfer of somatic and visual information from the right hemisphere into the Wernicke area in the left dominant

hemisphere. Therefore, somatic and visual information from the left side of the body frequently fails to reach this general interpretative area of the brain and thus cannot be used for decision making.

3. Finally, people whose corpus callosum is completely sectioned have two separate conscious portions of the brain. For example, in a teenage boy with a sectioned corpus callosum, only the left half of his brain could understand both the written word and the spoken word because the left side was the dominant hemisphere. Conversely, the right side of the brain could understand the written word but not the spoken word. Furthermore, the right cortex could elicit a motor action response to the written word without the left cortex ever knowing why the response was performed. The effect was quite different when an emotional response was evoked in the right side of the brain: in this case, a subconscious emotional response occurred in the left side of the brain as well. This response undoubtedly occurred because the areas of the two sides of the brain for emotions, the anterior temporal cortices and adjacent areas, were still communicating with each other through the anterior commissure that was not sectioned. For example, when the command "kiss" was written for the right half of his brain to see, the boy immediately and with full emotion said, "No way!" This response required function of the Wernicke area and the motor areas for speech in the left hemisphere because these left-sided areas were necessary to speak the words "No way!" When asked why he said this, however, the boy could not explain it.

Thus, the two halves of the brain have independent capabilities for consciousness, memory storage, communication, and control of motor activities. The corpus callosum is required for the two sides to operate cooperatively at the superficial subconscious level, and the anterior commissure plays an important additional role in unifying the emotional responses of the two sides of the brain.

THOUGHTS, CONSCIOUSNESS, AND MEMORY

Our most difficult problem in discussing consciousness, thoughts, memory, and learning is that we do not understand the neural mechanisms involved. We know that destruction of large portions of the cerebral cortex does not prevent a person from having thoughts, but it does reduce the *depth* of the thoughts and also the *degree* of awareness of the surroundings.

Each Thought Involves Simultaneous Signals in Many Portions of the Brain. Our thoughts involve concurrent signals from multiple parts of the brain, including the cerebral cortex, thalamus, limbic system, and reticular formation of the brain stem. Some basic thoughts probably depend almost entirely on lower centers; the thought of pain is probably a good example because electrical stimulation of the human cortex seldom elicits anything more than mild pain, whereas stimulation of certain areas of the hypothalamus, amygdala, and mesencephalon can cause excruciating pain. Conversely, a type of thought pattern that requires large involvement of the cerebral cortex is that of vision, because loss of the visual cortex causes complete inability to perceive visual form or color.

We might formulate a provisional definition of a thought in terms of neural activity as follows. A thought results from a "pattern" of stimulation of many parts of the nervous system at the same time, probably involving most importantly the cerebral cortex, thalamus, limbic system, and upper reticular formation of the brain stem. This theory is called the *holistic theory* of thoughts and, in simplistic terms, means that the whole is greater than the sum of its parts. The stimulated areas of the limbic system, thalamus, and reticular formation are believed to determine the general nature of the thought, giving it such qualities as pleasure, displeasure, pain, comfort, crude modalities of sensation, localization to gross areas of the body, and other general characteristics. However, specific stimulated areas of the cerebral cortex determine discrete characteristics of the thought, such as (1) specific localization of sensations on the surface of the body and of objects in the fields of vision, (2) the feeling of the texture of silk, (3) visual recognition of the rectangular pattern of a concrete block wall, and (4) other individual characteristics that enter into one's overall awareness of a particular instant.

Consciousness Is a State of Self-Awareness. *Consciousness* can perhaps be described as our continuing stream of awareness of either our surroundings or our sequential thoughts. Although multiple theories of consciousness have been proposed, it has been challenging to define objective markers and neural correlates of consciousness. Conscious experiences are fundamentally subjective and have properties that differ from other mental functions. Each of us experiences sensations, moods, and ideas that feel unique. Multiple areas of the cerebral cortex contribute to consciousness while the midbrain reticular formation and thalamus provide gating and other key functions of the cortex. However, despite increasingly refined clinical and experimental studies, an understanding of the relationship between consciousness and its cortex-thalamus neural correlates has remained elusive. Many questions about consciousness have fascinated scientists, as well as philosophers, for centuries. For example, it is still uncertain why consciousness fades during deep sleep while the cerebral cortex remains active.

MEMORY—ROLES OF SYNAPTIC FACILITATION AND SYNAPTIC INHIBITION

Memories are stored in the brain by changing the basic sensitivity of synaptic transmission between neurons as

a result of previous neural activity. The new or facilitated pathways are called *memory traces*. They are important because once the traces are established, they can be selectively activated by the thinking mind to reproduce the memories.

Experiments in lower animals have demonstrated that memory traces can occur at all levels of the nervous system. Even spinal cord reflexes can change at least slightly in response to repetitive cord activation, and these reflex changes are part of the memory process. Also, long-term memories result from changed synaptic conduction in lower brain centers. However, most memory that we associate with intellectual processes is based on memory traces in the cerebral cortex.

Positive and Negative Memory—"Sensitization" or "Habituation" of Synaptic Transmission. Although we often think of memories as being *positive* recollections of previous thoughts or experiences, probably the greater share of our memories is *negative*, not positive. Our brains are inundated with sensory information from all our senses. Fortunately, the brain has the capability to ignore information that is of no consequence. This capability results from *inhibition* of the synaptic pathways for this type of information; the resulting effect is called *habituation*, which is a type of *negative* memory.

Conversely, for incoming information that causes important consequences such as pain or pleasure, the brain has a different automatic capability of enhancing and storing the memory traces, which is *positive* memory. It results from *facilitation* of the synaptic pathways, and the process is called *memory sensitization*. As we discuss later, special areas in the basal limbic regions of the brain determine whether information is important or unimportant and make the subconscious decision about whether to store the thought as a *sensitized* memory trace or to suppress it.

Classification of Memories. Some memories last for only a few seconds, whereas others last for hours, days, months, or years. For the purpose of discussing these types of memories, we can use a common classification that divides memories into the following: (1) *short-term memory*, which includes memories that last for seconds or at most minutes unless they are converted into longer-term memories; (2) *intermediate long-term memories*, which last for days to weeks but then fade away; and (3) *long-term memory*, which, once stored, can be recalled up to years later, or even a lifetime.

In addition to this general classification of memories, we also discussed earlier (in connection with the prefrontal lobes) another type of memory, called "working memory," which includes mainly short-term memory that is used during the course of intellectual reasoning but is terminated as each stage of the problem is resolved.

Memories are frequently classified according to the type of information that is stored. One of these classifications divides memory into *declarative memory* and *skill memory*, as follows:

1. *Declarative memory* basically means memory of the various details of an integrated thought, such as memory of an important experience that includes memory of the following: (1) the surroundings; (2) time relationships; (3) causes of the experience; (4) meaning of the experience; and (5) the deductions that were left in the person's mind.
2. *Skill memory* is frequently associated with motor activities of the person's body, such as all the skills developed for hitting a tennis ball, including automatic memories to (1) sight the ball, (2) calculate the relationship and speed of the ball to the racquet, and (3) deduce rapidly the motions of the body, the arms, and the racquet required to hit the ball as desired—with all of these skills activated instantly based on previous learning of the game—and then moving on to the next stroke of the game while forgetting the details of the previous stroke.

SHORT-TERM MEMORY

Short-term memory is typified by one's memory of 7 to 10 numerals in a telephone number (or 7 to 10 other discrete facts) for a few seconds to a few minutes at a time but lasting only as long as the person continues to think about the numbers or facts.

Many physiologists have suggested that this short-term memory is caused by continual neural activity resulting from nerve signals that travel around and around a temporary memory trace in a *circuit of reverberating neurons*, although this hypothesis has not been proved. Another possible explanation of short-term memory is *presynaptic facilitation or inhibition*, which occurs at synapses that lie on terminal nerve fibrils immediately before these fibrils synapse with a subsequent neuron. The neurotransmitter chemicals secreted at such terminals frequently cause facilitation or inhibition lasting for seconds up to several minutes. Circuits of this type could lead to short-term memory.

INTERMEDIATE LONG-TERM MEMORY

Intermediate long-term memories may last for many minutes or even weeks. They will eventually be lost unless the memory traces are activated enough to become more permanent; then they are classified as *long-term memories*. Experiments in animals have demonstrated that memories of the intermediate long-term type can result from temporary chemical or physical changes, or both, in either the synapse presynaptic terminals or the synapse postsynaptic membrane, changes that can persist for a few minutes up to several weeks. These mechanisms are so important that they deserve special description.

Memory Based on Chemical Changes in Presynaptic Terminals or Postsynaptic Neuronal Membranes

Fig. 58.9 shows a mechanism of memory studied especially by Eric Kandel and his colleagues that can cause memories lasting from a few minutes up to 3 weeks in the large snail *Aplysia*. In this figure, there are two synaptic terminals. One terminal, which is from a sensory input neuron, terminates directly on the surface of the neuron that is to be stimulated and is called the *sensory terminal*. The other terminal, a *presynaptic ending* that lies on the surface of the sensory terminal, is called the *facilitator terminal*. When the sensory terminal is stimulated repeatedly but without stimulation of the facilitator terminal, signal transmission at first is great, but it becomes less and less intense with repeated stimulation until transmission almost ceases. This phenomenon is *habituation*, as was explained previously. It is a type of *negative* memory that causes the neuronal circuit to lose its response to repeated events that are insignificant.

Conversely, if a noxious stimulus excites the facilitator terminal at the same time that the sensory terminal is stimulated, instead of the transmitted signal into the postsynaptic neuron becoming progressively weaker, the ease of transmission becomes stronger and stronger. It will remain strong for minutes, hours, days, or, with more intense training, up to about 3 weeks even without further stimulation of the facilitator terminal. Thus, the noxious stimulus causes the memory pathway through the sensory terminal to become *facilitated* for days or weeks thereafter. Even after habituation has occurred, this pathway can be converted back to a facilitated pathway with only a few noxious stimuli.

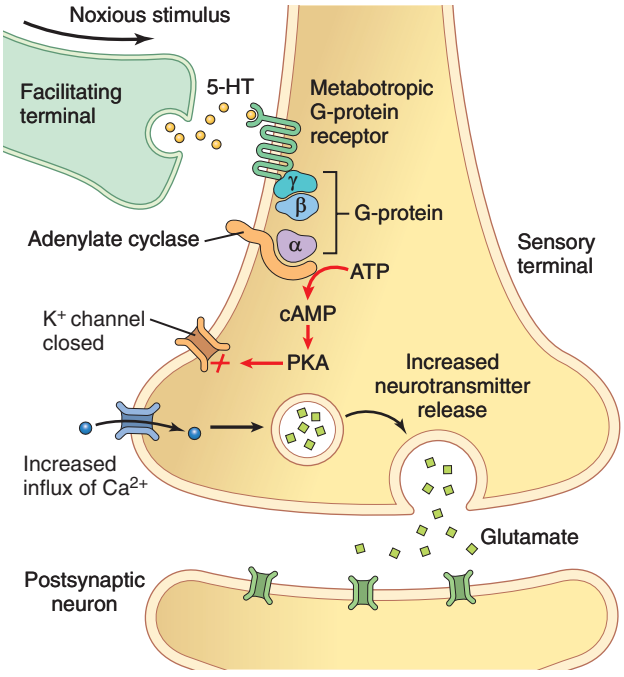

Figure 58.9 Short-term memory system that has been discovered in the snail *Aplysia*. The facilitating terminal releases 5-HT, which acts on sensory terminal metabotropic receptors, engaging the G-protein and increasing adenylate cyclase activity, which converts ATP to cAMP. The cAMP activates PKA, which closes the K^+ channels, prolonging the action potential and increasing the influx of Ca^{2+}. The increase in Ca^{2+} enhances the release of neurotransmitter (glutamate), which activates the postsynaptic receptors. *5-HT*, Serotonin; *ATP*, adenosine triphosphate; *cAMP*, cyclic adenosine monophosphate; *PKA*, protein kinase activity.

Molecular Mechanism of Intermediate Memory

Mechanism for Habituation. At the molecular level, the habituation effect in the sensory terminal results from progressive closure of calcium channels through the terminal membrane, although the cause of this calcium channel closure is not fully known. Nevertheless, much smaller than normal amounts of calcium ions can diffuse into the habituated terminal, and much less sensory terminal transmitter is therefore released because calcium entry is the principal stimulus for transmitter release (as was discussed in Chapter 46).

Mechanism for Facilitation. In the case of facilitation, at least part of the molecular mechanism is believed to be the following:

1. Stimulation of the facilitator presynaptic terminal at the same time that the sensory terminal is stimulated causes *serotonin* release at the facilitator synapse on the surface of the sensory terminal.
2. The serotonin acts on *serotonin receptors* in the sensory terminal membrane, and these receptors activate the enzyme *adenylate cyclase* inside the membrane. The adenylate cyclase then causes formation of *cyclic adenosine monophosphate* (cAMP), also inside the sensory presynaptic terminal.
3. The cAMP activates a *protein kinase* that causes phosphorylation of a protein that is part of the potassium channels in the sensory synaptic terminal membrane; this in turn blocks the channels for potassium conductance. The blockage can last for minutes up to several weeks.
4. Lack of potassium conductance causes a greatly prolonged action potential in the synaptic terminal because flow of potassium ions out of the terminal is necessary for rapid recovery from the action potential.
5. The prolonged action potential causes prolonged activation of the calcium channels, allowing tremendous quantities of calcium ions to enter the sensory synaptic terminal. These calcium ions cause greatly increased transmitter release by the synapse, thereby markedly facilitating synaptic transmission to the subsequent neuron.

Thus, in a very indirect way, the associative effect of stimulating the facilitator terminal at the same time that the sensory terminal is stimulated causes prolonged increase in excitatory sensitivity of the sensory terminal, which establishes the memory trace.

Additional studies in the snail *Aplysia* have suggested still another mechanism of synaptic memory. These studies have shown that stimuli from separate sources acting on a single neuron, under appropriate conditions, can cause long-term changes in *membrane properties of the postsynaptic neuron* instead of in the presynaptic neuronal membrane, but leading to essentially the same memory effects.

LONG-TERM MEMORY

No obvious demarcation exists between the more prolonged types of intermediate long-term memory and true long-term memory. The distinction is one of degree. However, long-term memory is generally believed to result from actual *structural changes*, in addition to chemical changes, at the synapses, and these changes enhance or suppress signal conduction. Experiments in primitive animals (where the nervous systems are much easier to study) have aided immensely in understanding possible mechanisms of long-term memory.

Structural Changes Occur in Synapses During Development of Long-Term Memory

Electron microscopic pictures taken from invertebrate animals have demonstrated multiple physical structural changes in many synapses during development of long-term memory traces. The structural changes will not occur if a drug is given that blocks protein synthesis in the presynaptic neuron, nor will the permanent memory trace develop. Therefore, it appears that development of true long-term memory depends on physically restructuring the synapses in a way that changes their sensitivity for transmitting nervous signals.

The following important structural changes occur:

1. An increase in vesicle release sites for secretion of transmitter substance
2. An increase in the number of transmitter vesicles released
3. An increase in the number of presynaptic terminals
4. Changes in structures of the dendritic spines that permit transmission of stronger signals

Thus, in several different ways, the structural capability of synapses to transmit signals appears to increase during establishment of true long-term memory traces.

Number of Neurons and Their Connectivities Often Change Significantly During Learning

During the first few weeks, months, and perhaps even a year or more of life, various parts of the brain produce many new neurons that send out numerous axon branches to make connections with other neurons. If the new axons fail to connect with appropriate neurons, muscle cells, or gland cells, the new axons will degenerate within a few weeks. Thus, the number of neuronal connections is determined by specific *nerve growth factors* released retrogradely from the stimulated cells. Furthermore, when insufficient connectivity occurs, the entire neuron that is sending out the axon branches might eventually disappear.

Therefore, soon after birth, the principle of "use it or lose it" governs the final number of neurons and their connectivities in respective parts of the human nervous system. This is a type of learning. For example, if one eye of a newborn animal is covered for many weeks after birth, neurons in alternate stripes of the cerebral visual cortex—neurons normally connected to the covered eye—will degenerate, and the covered eye will remain either partially or totally blind for the remainder of life. It was previously believed that very little "learning" is achieved in adult human beings and animals by modification of numbers of neurons in the memory circuits; however, considerable research now suggests that even adults use this mechanism at least to some extent.

CONSOLIDATION OF MEMORY

For short-term memory to be converted into long-term memory that can be recalled weeks or years later, it must become "consolidated." That is, the short-term memory, if activated repeatedly, will initiate chemical, physical, and anatomical changes in the synapses that are responsible for the long-term type of memory. This process requires 5 to 10 minutes for minimal consolidation and 1 hour or more for strong consolidation, which requires synthesis of messenger RNA and proteins in the neurons. For example, if a strong sensory impression is made on the brain but is then followed within a minute or so by an electrically induced brain convulsion, the sensory experience will not be remembered. Likewise, brain concussion, sudden application of deep general anesthesia, or any other effect that temporarily blocks the dynamic function of the brain can prevent consolidation.

Consolidation and the time required for it to occur can probably be explained by the phenomenon of rehearsal of the short-term memory, as described in the following section.

Rehearsal Enhances the Transference of Short-Term Memory Into Long-Term Memory. Studies have shown that rehearsal of the same information again and again in the mind accelerates and potentiates the degree of transfer of short-term memory into long-term memory and therefore accelerates and enhances consolidation. The brain has a natural tendency to rehearse newfound information, especially newfound information that catches the mind's attention. Therefore, over a period of time, the important features of sensory experiences become progressively more and more fixed in the memory stores. This phenomenon explains why a person can remember small amounts of information studied in depth far better than large amounts of information studied only superficially. It

also explains why a person who is wide awake can consolidate memories far better than a person who is in a state of mental fatigue.

New Memories Are Codified During Consolidation. One of the most important features of consolidation is that new memories are *codified* into different classes of information. During this process, similar types of information are pulled from the memory storage bins and used to help process the new information. The new and old are compared for similarities and differences, and part of the storage process is to store the information about these similarities and differences, rather than to store the new information unprocessed. Thus, during consolidation, the new memories are not stored randomly in the brain but are stored in direct association with other memories of the same type. This process is necessary for one to be able to "search" the memory store at a later date to find the required information.

Role of the Hippocampus and Other Brain Regions in Memory

Anterograde Amnesia—Inability to Create New Declarative Long-Term Memories After Hippocampal Lesions. The hippocampus is the most medial portion of the temporal lobe cortex, where it folds first medially underneath the brain and then upward into the lower, inside surface of the lateral ventricle. The two hippocampi have been removed for the treatment of epilepsy in a few patients. This procedure does not seriously affect the person's memory for information stored in the brain before removal of the hippocampi. However, after removal, these people have virtually no capability thereafter for storing *verbal and symbolic types* of memories (declarative types of memory) in long-term memory or even in intermediate memory lasting longer than a few minutes. Therefore, these people are unable to create new long-term memories of those types of information that are the basis of intelligence. This condition is called *anterograde amnesia*.

But why are the hippocampi so important in helping the brain to store new memories? The probable answer is that the hippocampi are among the most important output pathways from the "reward" and "punishment" areas of the limbic system, as explained in Chapter 59. Sensory stimuli or thoughts that cause pain or aversion excite the limbic *punishment centers*, and stimuli that cause pleasure, happiness, or sense of reward excite the limbic *reward centers*. All these together provide the background mood and motivations of the person. Among these motivations is the drive in the brain to remember those experiences and thoughts that are either pleasant or unpleasant. The hippocampi especially and, to a lesser degree, the dorsal medial nuclei of the thalamus, another limbic structure, have proved especially important in making the decision about which of our thoughts are important enough on a basis of reward or punishment to be worthy of memory.

Retrograde Amnesia—Inability to Recall Memories From the Past After Hippocampal or Thalmic Lesions. When retrograde amnesia occurs, there is a loss of memory access to events and information learned prior to an injury or disease that caused the amnesia.

In some people who have hippocampal lesions, some degree of retrograde amnesia occurs along with anterograde amnesia, which suggests that these two types of amnesia are at least partially related and that hippocampal lesions can cause both. However, damage in some thalamic areas may lead specifically to retrograde amnesia without causing significant anterograde amnesia. A possible explanation of this is that the thalamus may play a role in helping the person "search" the memory storehouses and thus "read out" the memories. That is, the memory process not only requires the storing of memories but also an ability to search and find the memory at a later date. The possible function of the thalamus in this process is discussed further in Chapter 59.

Hippocampi Are Not Important in Reflexive Learning. People with hippocampal lesions usually do not have difficulty in learning physical skills that do not involve verbalization or symbolic types of intelligence. For example, these people can still learn the rapid hand and physical skills required in many types of sports. This type of learning is called *skill learning* or *reflexive learning;* it depends on physically repeating the required tasks over and over again, rather than on symbolic rehearsing in the mind.

CHAPTER 59

The Limbic System and the Hypothalamus—Behavioral and Motivational Mechanisms of the Brain

Control of behavior is a function of the entire nervous system. Even the wakefulness and sleep cycle discussed in Chapter 60 is one of our most important behavioral patterns.

In this chapter, we deal first with the mechanisms that control activity levels in different parts of the brain. Then we discuss the causes of motivational drives, especially motivational control of the learning process and feelings of pleasure and punishment. These functions of the nervous system are performed mainly by the basal regions of the brain, which together are loosely called the *limbic system*, meaning the "border" system.

ACTIVATING–DRIVING SYSTEMS OF THE BRAIN

Without continuous transmission of nerve signals from the lower brain into the cerebrum, the cerebrum becomes useless. In fact, severe compression of the brain stem at the juncture between the mesencephalon and cerebrum, as sometimes results from a pineal tumor, often causes the person to enter into unremitting coma lasting for the remainder of their life.

Nerve signals in the brain stem activate the cerebrum in two ways: (1) by directly stimulating a background level of neuronal activity in wide areas of the brain and (2) by activating neurohormonal systems that release specific facilitatory or inhibitory hormone-like neurotransmitters into selected areas of the brain.

Reticular Excitatory Area of the Brain Stem—a Driver of Brain Activity

Fig. 59.1 shows a general system for controlling the activity level of the brain. The central driving component of this system is an excitatory area located in the *reticular substance of the pons and mesencephalon*. This area is also called the *bulboreticular facilitatory area*. We also discuss this area in Chapter 56 because it is the same brain stem reticular area that transmits facilitatory signals *downward to the spinal cord* to maintain tone in the antigravity muscles and to control levels of activity of the spinal cord reflexes. In addition to these downward signals, this area also sends a profusion of signals in the upward direction. Most of these signals go first to the thalamus, where they excite a different set of neurons that transmit nerve signals to all regions of the cerebral cortex, as well as to multiple subcortical areas.

The signals passing through the thalamus are of two types. One type is rapidly transmitted action potentials that excite the cerebrum for only a few milliseconds. These signals originate from large neuronal cell bodies that lie throughout the brain stem reticular area. Their nerve endings release the neurotransmitter *acetylcholine*, which serves as an excitatory agent that lasts for only a few milliseconds before it is destroyed by the enzyme acetylcholinesterase.

The second type of excitatory signal originates from large numbers of small neurons spread throughout the brain stem reticular excitatory area. Again, most of these signals pass to the thalamus, but through small, slowly conducting fibers that synapse mainly in the intralaminar nuclei of the thalamus and in the reticular nuclei over the surface of the thalamus. From here, additional small fibers are distributed throughout the cerebral cortex. The excitatory effect caused by this system of fibers can build up progressively for many seconds to a minute or more, which suggests that its signals are especially important for controlling the longer-term background excitability level of the brain.

Excitation of the Reticular Excitatory Area By Peripheral Sensory Signals. The level of activity of the reticular excitatory area in the brain stem, and therefore the level of activity of the entire brain, is determined to a great extent by the number and type of sensory signals that enter the brain from the periphery. Pain signals in particular increase activity in this excitatory area and therefore strongly excite the brain to attention.

The importance of sensory signals in activating the excitatory area is demonstrated by the effect of cutting the brain stem above the point where the fifth cerebral nerves enter the pons. These nerves are the highest nerves entering the brain that transmit significant numbers of somatosensory signals into the brain. When all these input sensory signals are gone, the level of activity in the brain excitatory area diminishes abruptly, and the brain proceeds rapidly to a state of greatly reduced activity, approaching a permanent state of coma. However, when the brain stem is transected *below* the fifth nerves, which

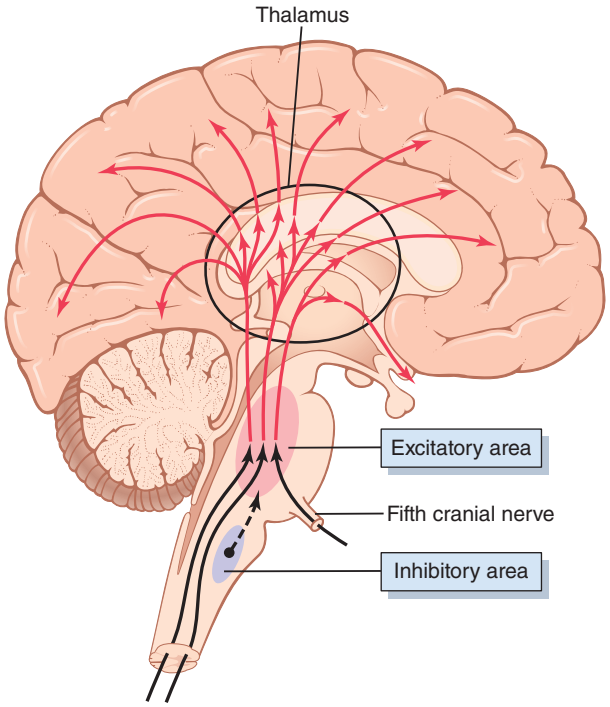

Figure 59.1 The *excitatory-activating system* of the brain. Also shown is an *inhibitory area* in the medulla that can inhibit or depress the activating system.

leaves much input of sensory signals from the facial and oral regions, coma is averted.

Increased Activity of the Excitatory Area Caused By Feedback Signals Returning From the Cerebral Cortex. Not only do excitatory signals pass to the cerebral cortex from the bulboreticular excitatory area of the brain stem, but feedback signals also return from the cerebral cortex back to this same area. Therefore, any time the cerebral cortex becomes activated by brain thought processes or by motor processes, signals are sent from the cortex to the brain stem excitatory area, which in turn sends still more excitatory signals to the cortex. This process helps to maintain the level of excitation of the cerebral cortex or even to enhance it. This is a *positive feedback* mechanism that allows any beginning activity in the cerebral cortex to support still more activity, thus leading to an "awake" mind.

The Thalamus Is a Distribution Center That Controls Activity in Specific Regions of the Cortex. As pointed out in Chapter 58, almost every area of the cerebral cortex connects with its own highly specific area in the thalamus. Therefore, electrical stimulation of a specific point in the thalamus generally activates its own specific small region of the cortex. Furthermore, signals regularly reverberate back and forth between the thalamus and the cerebral cortex, with the thalamus exciting the cortex and the cortex then reexciting the thalamus via return fibers. Activation of these back-and-forth reverberation signals has been suggested to establish long-term memories.

Whether the thalamus also functions to call forth specific memories from the cortex or to activate specific thought processes is still unclear, but the thalamus does have appropriate neuronal circuitry for these purposes.

A Reticular Inhibitory Area Is Located in the Lower Brain Stem

Fig. 59.1 shows another area that is important in controlling brain activity—the reticular *inhibitory area*, located medially and ventrally in the medulla. In Chapter 56, we learned that this area can inhibit the reticular facilitatory area of the upper brain stem and thereby decrease activity in the superior portions of the brain. One of the mechanisms for this activity is to excite *serotonergic neurons*, which in turn secrete the inhibitory neurohormone *serotonin* at crucial points in the brain; we discuss this concept in more detail later.

NEUROHORMONAL CONTROL OF BRAIN ACTIVITY

Aside from direct control of brain activity by specific transmission of nerve signals from the lower brain areas to the cortical regions of the brain, still another physiological mechanism is often used to control brain activity. This mechanism is to secrete *excitatory* or *inhibitory neurotransmitter hormonal agents* into the substance of the brain. These neurohormones often persist for minutes or hours and thereby provide long periods of control, rather than just instantaneous activation or inhibition.

Fig. 59.2 shows three neurohormonal systems that have been studied in detail in the rat brain: (1) a *norepinephrine system*, (2) a *dopamine system*, and (3) a *serotonin system*. Norepinephrine usually functions as an excitatory hormone, whereas serotonin is usually inhibitory and dopamine is excitatory in some areas but inhibitory in others. As would be expected, these three systems have different effects on levels of excitability in different parts of the brain. The norepinephrine system spreads to virtually every area of the brain, whereas the serotonin and dopamine systems are directed much more to specific brain regions—the dopamine system mainly into the basal ganglial regions and the serotonin system more into the midline structures.

Neurohormonal and Neurotransmitter Systems in the Human Brain. **Fig. 59.3** shows the brain stem areas in the human brain for activating four neurohormonal systems, the same three discussed for the rat and one other, the *acetylcholine system*. Some of the specific functions of these systems are as follows.

1. *The locus ceruleus and the norepinephrine system.* The locus ceruleus is a small area located bilaterally and posteriorly at the juncture between the pons and mesencephalon. Nerve fibers from this area spread throughout the brain, the same as shown for the rat in the top frame of **Fig. 59.2**, and they secrete *norepinephrine*. The norepinephrine generally

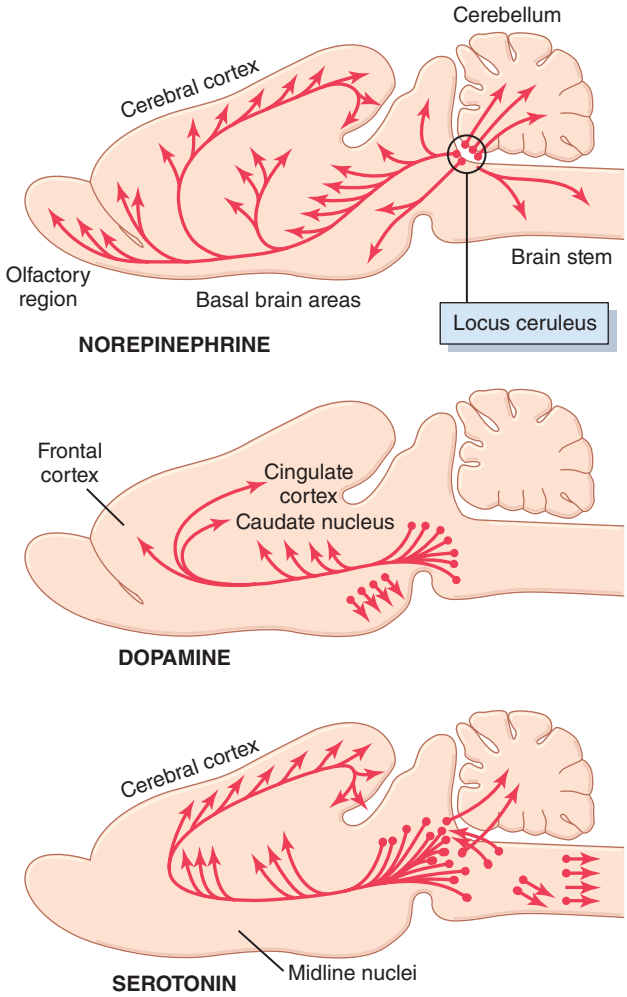

Figure 59.2 Three neurohormonal systems that have been mapped in the rat brain—a *norepinephrine system*, a *dopamine system*, and a *serotonin system*. *(Modified from Kandel ER, Schwartz JH, eds.* Principles of Neural Science. *2nd ed. New York: Elsevier; 1985.)*

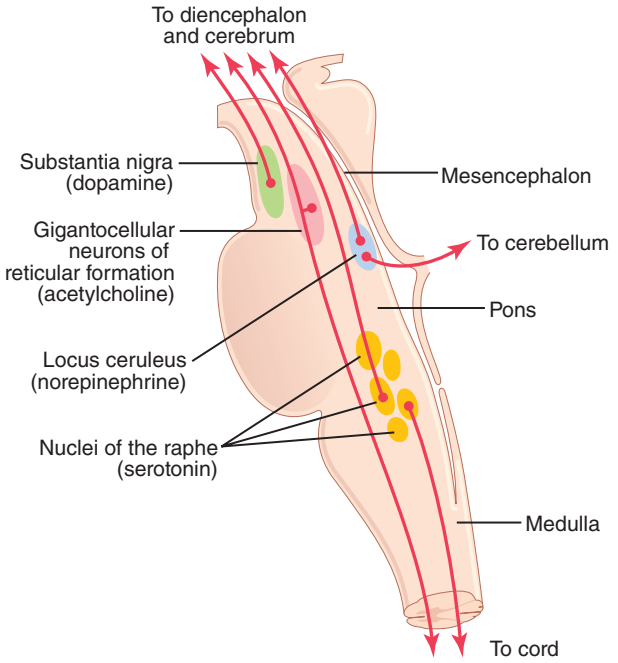

Figure 59.3 Multiple centers in the human brain stem. These neurons secrete different transmitter substances (specified in parentheses). The neurons send control signals upward into the diencephalon and cerebrum and downward into the spinal cord.

excites the brain to increased activity. However, it has inhibitory effects in a few brain areas because of inhibitory receptors at certain neuronal synapses. Chapter 60 describes how this system probably plays an important role in causing dreaming, thus leading to a type of sleep called rapid eye movement (REM) sleep.

2. *The substantia nigra and the dopamine system.* The substantia nigra is discussed in Chapter 57 in relation to the basal ganglia. It lies anteriorly in the superior mesencephalon, and its neurons send nerve endings mainly to the caudate nucleus and putamen of the cerebrum, where they secrete *dopamine*. Other neurons located in adjacent regions also secrete dopamine, but they send their endings into more ventral areas of the brain, especially to the hypothalamus and the limbic system. The dopamine is believed to act as an inhibitory transmitter in the basal ganglia, but in some other areas of the brain it is possibly excitatory. Also, remember from Chapter 57 that destruction of the dopaminergic neurons in the substantia nigra is the basic cause of *Parkinson disease*.
3. *The raphe nuclei and the serotonin system.* In the midline of the pons and medulla are several thin nuclei called the *raphe nuclei*. Many of the neurons in these nuclei secrete *serotonin*. They send fibers into the diencephalon and a few fibers to the cerebral cortex; additional fibers descend to the spinal cord. The serotonin secreted at the cord fiber endings has the ability to suppress pain, as discussed in Chapter 49. The serotonin released in the diencephalon and cerebrum almost certainly plays an essential inhibitory role to help cause normal sleep, as we discuss in Chapter 60.
4. *The gigantocellular neurons of the reticular excitatory area and the acetylcholine system.* We previously discussed the gigantocellular neurons *(giant cells)* in the reticular excitatory area of the pons and mesencephalon. The fibers from these large cells divide immediately into two branches, one passing upward to the higher levels of the brain and the other passing downward through the reticulospinal tracts into the spinal cord. The neurohormone secreted at their terminals is *acetylcholine*. In most places, the acetylcholine functions as an excitatory neurotransmitter. Activation of these acetylcholine neurons leads to an acutely awake and excited nervous system.

Other Neurotransmitters and Neurohormonal Substances Secreted in the Brain. Without describing their function, the following is a partial list of additional

neurohormonal substances that function either at specific synapses or by release into the fluids of the brain: enkephalins, gamma-aminobutyric acid, glutamate, vasopressin, adrenocorticotropic hormone, α-melanocyte stimulating hormone (α-MSH), neuropeptide-Y (NPY), epinephrine, histamine, endorphins, angiotensin II, and neurotensin. Thus, there are multiple neurohormonal systems in the brain, and activation of each one plays its own role in controlling a different quality of brain function.

LIMBIC SYSTEM

The word "limbic" means "border." Originally, the term "limbic" was used to describe the border structures around the basal regions of the cerebrum, but as we have learned more about the functions of the limbic system, the term *limbic system* has been expanded to mean the entire neuronal circuitry that controls emotional behavior and motivational drives.

A major part of the limbic system is the *hypothalamus*, with its related structures. In addition to their roles in behavioral control, these areas control many internal conditions of the body, such as body temperature, osmolality of the body fluids, the drives to eat and drink, and control of energy balance and body weight. These internal functions are collectively called *vegetative functions* of the brain, and their control is closely related to behavior.

FUNCTIONAL ANATOMY OF THE LIMBIC SYSTEM—KEY POSITION OF THE HYPOTHALAMUS

Fig. 59.4 shows the anatomical structures of the limbic system, demonstrating that they are an interconnected complex of basal brain elements. Located in the middle of all these structures is the small *hypothalamus*, which from a physiological point of view is one of the central elements of the limbic system. **Fig. 59.5** illustrates schematically this key position of the hypothalamus in the

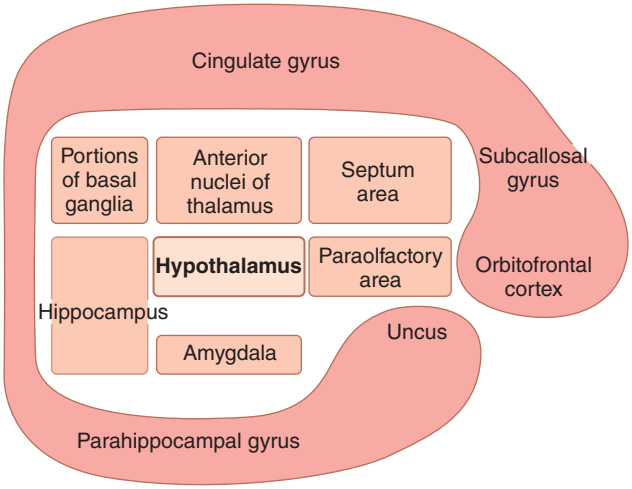

Figure 59.5 The limbic system, showing the key position of the hypothalamus.

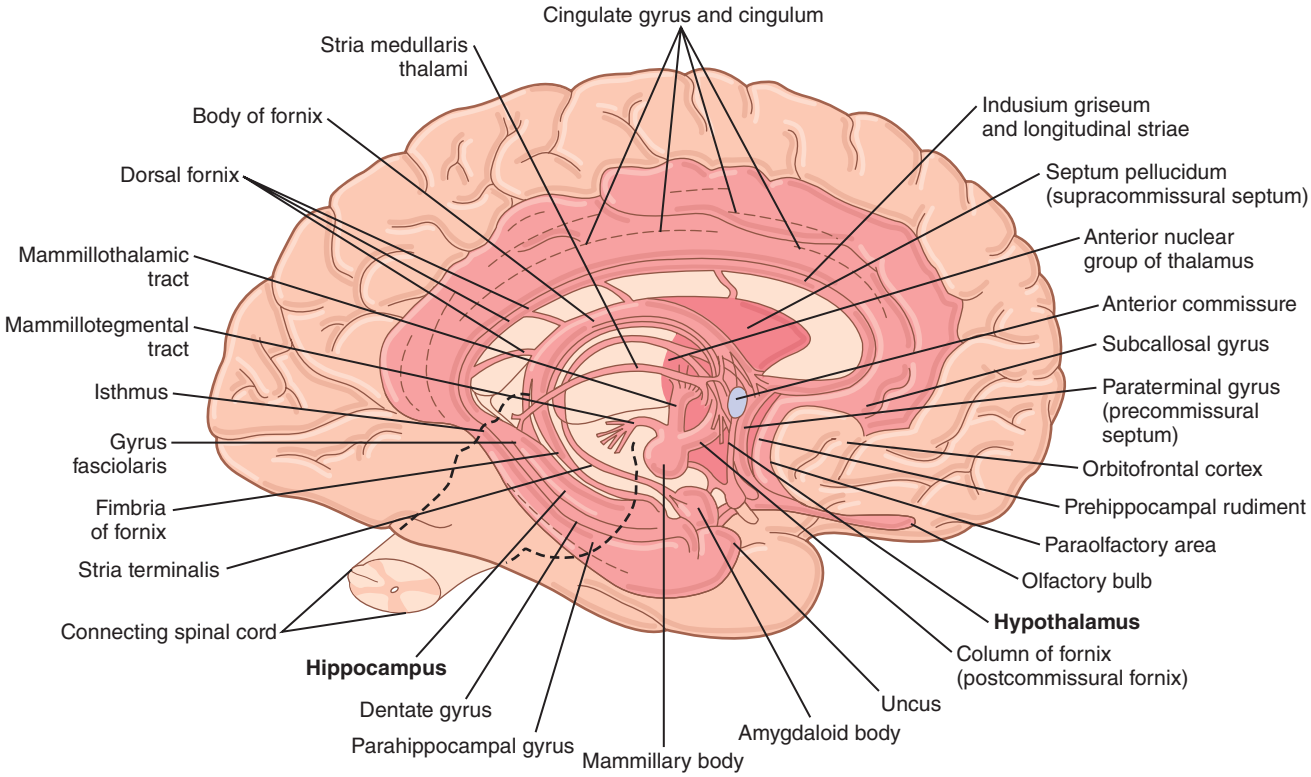

Figure 59.4 Anatomy of the limbic system, shown in the dark pink area. *(Modified from Warwick R, Williams PL.* Gray's Anatomy. *35th ed. London: Longman Group Ltd.; 1973.)*

limbic system and shows other subcortical structures of the limbic system surrounding it, including the *septum, paraolfactory area, anterior nucleus of the thalamus, portions of the basal ganglia, hippocampus*, and *amygdala*.

Surrounding the subcortical limbic areas is the *limbic cortex*, composed of a ring of cerebral cortex on each side of the brain—(1) beginning in the *orbitofrontal area* on the ventral surface of the frontal lobes, (2) extending upward into the *subcallosal gyrus*, (3) then over the top of the corpus callosum onto the medial aspect of the cerebral hemisphere in the *cingulate gyrus*, and finally (4) passing behind the corpus callosum and downward onto the ventromedial surface of the temporal lobe to the *parahippocampal gyrus* and *uncus*.

Thus, on the medial and ventral surfaces of each cerebral hemisphere is a ring of mostly *paleocortex* that surrounds a group of deep structures intimately associated with overall behavior and emotions. In turn, this ring of limbic cortex functions as a two-way communication and association linkage between the *neocortex* and the lower limbic structures.

Many of the behavioral functions elicited from the hypothalamus and other limbic structures are also mediated through the reticular nuclei in the brain stem and their associated nuclei. We pointed out in Chapter 56, as well as earlier in this chapter, that stimulation of the excitatory portion of this reticular formation can cause high degrees of cerebral excitability while also increasing the excitability of much of the spinal cord synapses. In Chapter 61, we see that most of the hypothalamic signals for controlling the autonomic nervous system are also transmitted through synaptic nuclei located in the brain stem.

An important route of communication between the limbic system and the brain stem is the *medial forebrain bundle*, which extends from the septal and orbitofrontal regions of the cerebral cortex downward through the middle of the hypothalamus to the brain stem reticular formation. This bundle carries fibers in both directions, forming a trunk line communication system. A second route of communication is through short pathways among the reticular formation of the brain stem, thalamus, hypothalamus, and most other contiguous areas of the basal brain.

THE HYPOTHALAMUS, A MAJOR CONTROL HEADQUARTERS FOR THE LIMBIC SYSTEM

The hypothalamus, despite its small size of only a few cubic centimeters (weighing only about 4 grams), has two-way communicating pathways with all levels of the limbic system. In turn, the hypothalamus and its closely allied structures send output signals in three directions: (1) backward and downward to the brain stem, mainly into the reticular areas of the mesencephalon, pons, and medulla, and from these areas into the peripheral nerves of the autonomic nervous system; (2) upward toward many higher areas of the diencephalon and cerebrum, especially to the anterior thalamus and limbic portions of the cerebral cortex; and (3) into the hypothalamic infundibulum to control or partially control most of the secretory functions of both the posterior and the anterior pituitary glands.

Thus, the hypothalamus, which represents less than 1% of the brain mass, is one of the most important control pathways of the limbic system. It controls most of the vegetative and endocrine functions of the body and many aspects of emotional behavior.

VEGETATIVE AND ENDOCRINE CONTROL FUNCTIONS OF THE HYPOTHALAMUS

The different hypothalamic mechanisms for controlling multiple functions of the body are so important that they are discussed in multiple chapters throughout this text. For example, the role of the hypothalamus to help regulate arterial pressure is discussed in Chapter 18, thirst and water conservation in Chapter 30, appetite and energy expenditure in Chapter 72, temperature regulation in Chapter 74, and endocrine control in Chapter 76. To illustrate the organization of the hypothalamus as a functional unit, we summarize a few of its vegetative and endocrine functions here as well.

Figs. 59.6 and 59.7 show enlarged sagittal and coronal views of the hypothalamus, which represents only a small area in **Fig. 59.4**. Especially note in **Fig. 59.6** the multiple activities that are excited or inhibited when respective hypothalamic nuclei are stimulated. In addition to these centers, a large *lateral hypothalamic* area (shown in **Fig. 59.7**) is present on each side of the hypothalamus. The lateral areas are especially important in controlling thirst, hunger, and many of the emotional drives.

A word of caution must be issued when studying these diagrams because the areas that cause specific activities are not nearly as accurately localized as suggested in the figures. Also, it is not known whether the effects noted in the figures result from stimulation of specific control nuclei or merely from activation of fiber tracts leading from or to control nuclei located elsewhere. With this caution in mind, we can give the following general description of the vegetative and control functions of the hypothalamus.

Cardiovascular Regulation. Stimulation of different areas throughout the hypothalamus can cause many neurogenic effects on the cardiovascular system, including changes in arterial pressure and heart rate. In general, stimulation in the *posterior* and *lateral hypothalamus* increases the arterial pressure and heart rate, whereas stimulation in the *preoptic area* often has opposite effects, causing a decrease in both heart rate and arterial pressure. These effects are transmitted mainly through specific cardiovascular control centers in the reticular regions of the pons and medulla.

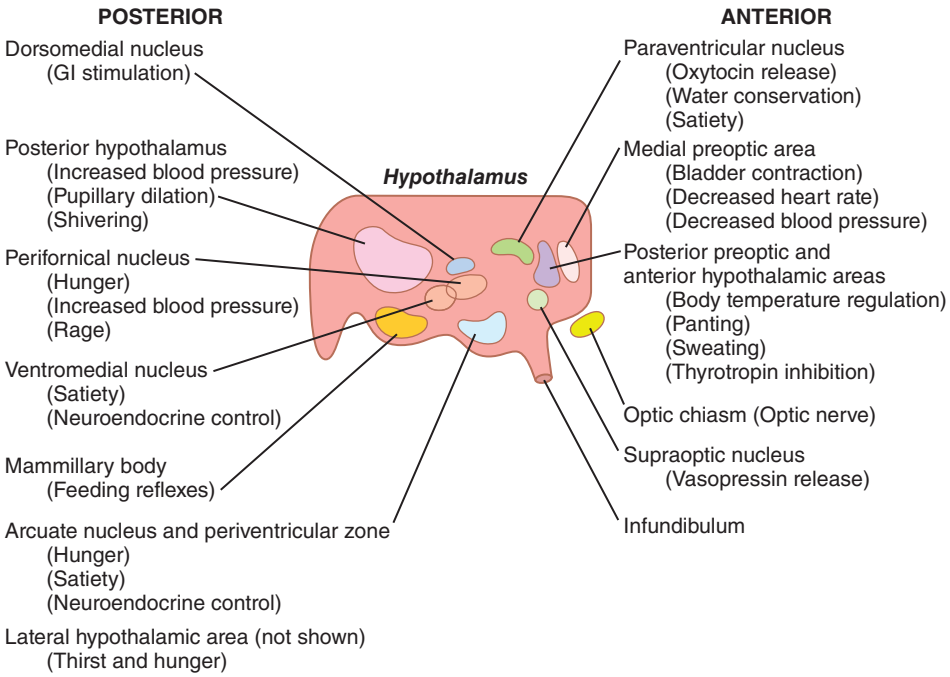

Figure 59.6 Control centers of the hypothalamus (sagittal view). *GI*, Gastrointestinal.

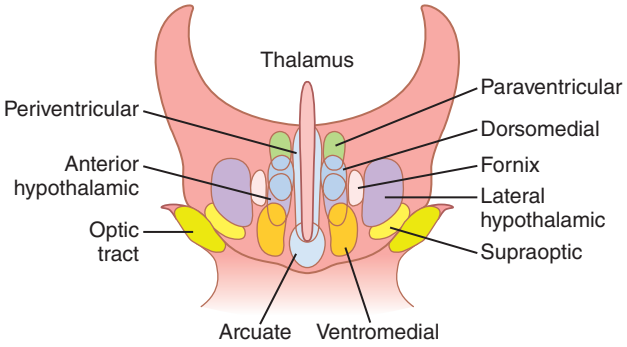

Figure 59.7 Coronal view of the hypothalamus, showing the mediolateral positions of the respective hypothalamic nuclei.

Body Temperature Regulation. The anterior portion of the hypothalamus, especially the *preoptic area*, is concerned with regulation of body temperature. An increase in temperature of the blood flowing through this area increases activity of temperature-sensitive neurons, whereas a decrease in temperature decreases their activity. In turn, these neurons control mechanisms for increasing or decreasing body temperature, as discussed in Chapter 74.

Body Water Regulation. The hypothalamus regulates body water in two ways: (1) by creating the sensation of thirst, which drives the animal or person to drink water, and (2) by controlling the excretion of water into the urine. An area called the *thirst center* is located in the lateral hypothalamus. When the fluid electrolytes in either this center or closely allied areas become too concentrated, the animal develops an intense desire to drink water; it will search out the nearest source of water and drink enough to return the electrolyte concentration of the thirst center to normal.

Control of renal excretion of water, independently of electrolytes, is vested mainly in the *supraoptic* nuclei. When the body fluids become too concentrated, the neurons of these areas become stimulated. Nerve fibers from these neurons project downward through the infundibulum of the hypothalamus into the posterior pituitary gland, where the nerve endings secrete the hormone *antidiuretic hormone* (also called *vasopressin*). This hormone is then absorbed into the blood and transported to the kidneys, where it acts on the collecting tubules and collecting ducts of the kidneys to cause increased reabsorption of water. This action decreases loss of water into the urine but allows continuing excretion of electrolytes, thus decreasing the concentration of the body fluids back toward normal. These functions are presented in Chapter 29.

Regulation of Uterine Contractility and Milk Ejection From the Breasts. Stimulation of the *paraventricular nuclei* causes their neuronal cells to secrete the hormone *oxytocin*. This hormone, in turn, increases contractility of the uterus, as well as contracting the myoepithelial cells surrounding the alveoli of the breasts, which then causes the alveoli to empty their milk through the nipples.

At the end of pregnancy, especially large quantities of oxytocin are secreted, promoting labor contractions that expel the baby. Then, whenever the baby suckles the mother's breast, a reflex signal from the nipple to the posterior hypothalamus also stimulates oxytocin release, and the oxytocin now performs the necessary function of contracting the ductules of the breast, thereby expelling milk through the nipples so that the baby can nourish itself. These functions are discussed in Chapter 83.

Gastrointestinal and Feeding Regulation. Stimulation of several areas of the hypothalamus causes an animal

to experience extreme hunger, a voracious appetite, and an intense desire to search for food. One area associated with hunger is the *lateral hypothalamic area*. Conversely, damage to this area on both sides of the hypothalamus causes the animal to lose desire for food, sometimes causing lethal starvation, as discussed in Chapter 72.

A center that opposes the desire for food, called the *satiety center*, is located in the *ventromedial nuclei*. When this center is stimulated electrically, an animal that is eating food suddenly stops eating and shows complete indifference to food. However, if this area is destroyed bilaterally, the animal cannot be satiated; instead, its hypothalamic hunger centers become overactive, so it has a voracious appetite, resulting eventually in tremendous obesity. The *arcuate nucleus* of the hypothalamus contains at least two different types of neurons that, when stimulated, lead either to increased or decreased appetite. Another area of the hypothalamus that participates in overall control of gastrointestinal activity is the *mammillary bodies*, which control at least partially the patterns of many feeding reflexes, such as licking the lips and swallowing.

Hypothalamic Control of Endocrine Hormone Secretion By the Anterior Pituitary Gland. Stimulation of certain areas of the hypothalamus also causes the *anterior* pituitary gland to secrete its endocrine hormones. This subject is discussed in detail in Chapter 75 in relation to neural control of the endocrine glands. Briefly, the basic mechanisms are as follows. The anterior pituitary gland receives its blood supply mainly from blood that flows first through the lower part of the hypothalamus and then through the anterior pituitary vascular sinuses. As the blood courses through the hypothalamus before reaching the anterior pituitary, specific *releasing* and *inhibitory hormones* are secreted into the blood by various hypothalamic nuclei. These hormones are then transported via the blood to the anterior pituitary gland, where they act on the glandular cells to control release of specific anterior pituitary hormones.

Hypothalamic Control of Circadian Rhythms—The Suprachiasmatic Nucleus. The suprachiasmatic nucleus (SCN) of the hypothalamus contains about 20,000 neurons and is located above the optic chiasm where the optic nerves cross underneath the hypothalamus, as discussed in Chapter 52. The neurons of the SCN serve as a "master clock," with a pacemaker firing frequency that follows a circadian rhythm (**Fig. 59.8**). This pacemaker function is critical for organizing sleep into a recurring 24-hour circadian pattern of sleeping and waking. Lesions of the SCN cause many physiological and behavioral disturbances, including loss of the circadian sleep-wake rhythms. Thus, the SCN directs daily cycles of our physiology and behavior that set the tempo of our lives.

The importance of these daily cycles to human health has led to increasing interest in the field of *chronobiology*, the study of these circadian rhythms. In 2017, the Nobel Prize in Physiology or Medicine was awarded to Jeffrey C. Hall, Michael Rosbash, and Michael W. Young for their discoveries of molecular mechanisms controlling the circadian rhythm in fruit flies.

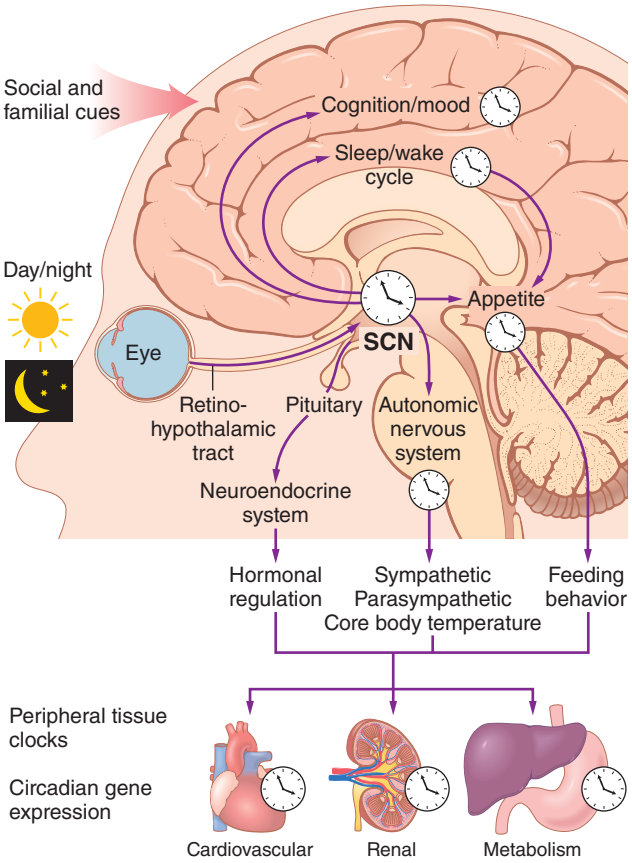

Figure 59.8 The suprachiasmatic nucleus (SCN) of the hypothalamus serves as a "master clock" for many physiological, mental, and behavioral activities. The SCN receives direct innervation from the retina via the retinohypothalamic tract (RHT) to entrain its activity to day–night cycles. SCN neurons project to various brain centers, which contain local circadian clocks that direct feeding–fasting, sleep–wakefulness, and autonomic and neuroendocrine circadian rhythms. These systemic cues synchronize local molecular clocks in peripheral tissues, and these local clocks then direct circadian gene expression that regulates physiological rhythms, including those related to mental alertness and cognition, cardiovascular regulation, metabolism, and renal function.

The SCN is organized into specific functional groups that control the rhythmic patterns of biological clocks in other parts of the body. These biological clocks are comprised of a complex set of gene transcription factors, proteins/enzymes, and other regulator factors that operate to establish circadian rhythms in most living organisms, including mammals, microbes, and even plants. These biological clocks are found in nearly every tissue and organ of the body and are capable of maintaining their own circadian rhythms, although their circadian rhythms are usually maintained for only a few days in the absence of signals from the SCN.

Key components of the clock mechanisms in the SCN, and in other tissues, are two feedback loops that rely

on the transcriptional activators, *CLOCK* and *BMAL1*, which bind to each other and, following translocation to the nucleus, initiate transcription of "*clock genes*" (*PER1*, *PER2*, and *PER3*) and "*cryptochrome genes*" (*CRY1* and *CRY2*). These genes turn on synthesis of PER and CRY proteins; as the proteins accumulate, they inhibit CLOCK and BMAL1, thereby repressing PER and CRY transcription. This feedback sequence of on-off PER and CRY protein synthesis normally occurs in a 24-hour circadian pattern.

Once the SCN clock has established its circadian rhythm, this information is transmitted to other brain regions through action potentials and to various organs and tissues via nervous and hormonal signals. Axons from the SCN project to other regions of the hypothalamus that are especially important for circadian variations in body temperature, the sleep-wake cycle, and various hormonal changes.

Although the circadian rhythms of the SCN are endogenous and self-sustained, they are altered ("entrained") by environmental cues such as temperature and timing of the light-dark cycle. The SCN receives neural input from specialized *intrinsically photosensitive retinal ganglion cells* that contain the photopigment *melanopsin* and transmit signals through the *retinohypothalamic tract*. The importance of this pathway in altering the timing of circadian rhythms is illustrated by the observation that a person who travels across several time zones may experience "*jet lag*" but their circadian clock is eventually synchronized with local day-night time.

BEHAVIORAL FUNCTIONS OF THE HYPOTHALAMUS AND ASSOCIATED LIMBIC STRUCTURES

Behavioral Effects Caused By Stimulation of the Hypothalamus. In addition to the vegetative and endocrine functions of the hypothalamus, stimulation of or lesions in the hypothalamus often have profound effects on emotional behavior of animals and human beings. Some of the behavioral effects of stimulation are the following:

1. Stimulation in the *lateral hypothalamus* not only causes thirst and eating, as discussed earlier, but also increases the general level of activity of the animal, sometimes leading to overt rage and fighting, discussed subsequently.
2. Stimulation in the *ventromedial nucleus* and surrounding areas mainly causes effects opposite to those caused by lateral hypothalamic stimulation—that is, a sense of *satiety, decreased eating*, and *tranquility*.
3. Stimulation of a *thin zone of periventricular nuclei*, located immediately adjacent to the third ventricle (or also stimulation of the central gray area of the mesencephalon that is continuous with this portion of the hypothalamus), usually leads to *fear* and *punishment reactions*.
4. *Sexual drive* can be stimulated from several areas of the hypothalamus, especially the most anterior and most posterior portions.

Behavioral Effects Caused By Hypothalamic Lesions. Lesions in the hypothalamus, in general, cause effects opposite to those caused by stimulation, such as the following:

1. Bilateral lesions in the lateral hypothalamus will decrease drinking and eating almost to zero, often leading to lethal starvation. These lesions cause extreme *passivity* of the animal as well, with loss of most of its overt drives.
2. Bilateral lesions of the ventromedial areas of the hypothalamus cause effects that are mainly opposite to those caused by lesions of the lateral hypothalamus: excessive drinking and eating, as well as hyperactivity and often frequent bouts of extreme rage on the slightest provocation.

Stimulation or lesions in other regions of the limbic system, especially in the amygdala, the septal area, and areas in the mesencephalon, often cause effects similar to those elicited from the hypothalamus. We discuss some of these effects in more detail later.

"REWARD" AND "PUNISHMENT" FUNCTION OF THE LIMBIC SYSTEM

From the discussion thus far, it is already clear that several limbic structures are particularly concerned with the *affective* nature of sensory sensations—that is, whether the sensations are *pleasant* or *unpleasant*. These affective qualities are also called *reward* or *punishment*, or *satisfaction* or *aversion*. Electrical stimulation of certain limbic areas pleases or satisfies the animal, whereas electrical stimulation of other regions causes terror, pain, fear, defense, escape reactions, and all the other elements of punishment. The degrees of stimulation of these two oppositely responding systems greatly affect the behavior of the animal.

Reward Centers

Through experimental studies using electrical stimulators to map out the reward and punishment centers of the brain, the major reward centers have been found to be located *along the course of the medial forebrain bundle*, especially in the *lateral* and *ventromedial nuclei of the hypothalamus*. It is interesting that the lateral nucleus is included among the reward areas because strong stimuli in this area can actually cause rage. However, this phenomenon occurs in many areas, with weaker stimuli giving a sense of reward and stronger ones a sense of punishment. Less potent reward centers, which are perhaps secondary to the major ones in the hypothalamus, are found in the septum, the amygdala, certain areas of the thalamus and basal ganglia, and extending downward into the basal tegmentum of the mesencephalon.

Punishment Centers

The most potent areas for punishment and escape tendencies have been found in the central gray area surrounding the aqueduct of Sylvius in the mesencephalon and extending upward into the periventricular zones of the hypothalamus and thalamus. Less potent punishment areas are found in some locations in the amygdala and hippocampus. It is particularly interesting that stimulation in the punishment centers can frequently inhibit the reward and pleasure centers completely, demonstrating that *punishment and fear can take precedence over pleasure and reward*.

Association of Rage With Punishment Centers. An emotional pattern that involves the punishment centers of the hypothalamus and other limbic structures and that has also been well characterized is the *rage pattern*. This is described as follows.

Strong stimulation of the punishment centers of the brain, especially in the *periventricular zone of the hypothalamus* and in the *lateral hypothalamus*, causes the animal to (1) develop a defense posture; (2) extend its claws; (3) lift its tail; (4) hiss; (5) spit; (6) growl; and (7) develop piloerection, wide-open eyes, and dilated pupils. Furthermore, even the slightest provocation causes an immediate savage attack. This behavior is approximately the behavior that one would expect from an animal being severely punished, and it is a pattern of behavior called *rage*.

Fortunately, in the normal animal, the rage phenomenon is held in check mainly by inhibitory signals from the ventromedial nuclei of the hypothalamus. In addition, portions of the hippocampi and anterior limbic cortex, especially in the anterior cingulate gyri and subcallosal gyri, help suppress the rage phenomenon.

Placidity and Tameness. Exactly the opposite emotional behavior patterns occur when the reward centers are stimulated—placidity and tameness.

Importance of Reward or Punishment on Behavior

Almost everything that we do is related in some way to reward and punishment. If we are doing something that is rewarding, we continue to do it; if it is punishing, we cease to do it. Therefore, the reward and punishment centers undoubtedly constitute one of the most important of all the controllers of our bodily activities, our drives, our aversions, and our motivations.

Effect of Tranquilizers on the Reward or Punishment Centers. Administration of a tranquilizer, such as chlorpromazine, usually inhibits both the reward and the punishment centers, thereby decreasing the affective reactivity of the animal. Therefore, it is presumed that tranquilizers function in psychotic states by suppressing many of the important behavioral areas of the hypothalamus and its associated regions of the limbic brain.

Role of Reward or Punishment in Learning and Memory—Habituation Versus Reinforcement

Animal experiments have shown that a sensory experience that causes neither reward nor punishment is hardly remembered at all. Electrical recordings from the brain show that a newly experienced sensory stimulus almost always excites multiple areas in the cerebral cortex. However, if the sensory experience does not elicit a sense of either reward or punishment, repetition of the stimulus over and over leads to almost complete extinction of the cerebral cortical response—that is, the animal becomes *habituated* to that specific sensory stimulus and thereafter ignores it.

If the stimulus *does* cause reward or punishment rather than indifference, the cerebral cortical response becomes progressively more and more intense during repeated stimulation instead of fading away, and the response is said to be *reinforced*. An animal builds up strong memory traces for sensations that are either rewarding or punishing but, conversely, develops complete habituation to indifferent sensory stimuli.

It is evident that the reward and punishment centers of the limbic system have much to do with selecting the information that we learn, usually throwing away more than 99% of it and selecting less than 1% for retention.

SPECIFIC FUNCTIONS OF OTHER PARTS OF THE LIMBIC SYSTEM

FUNCTIONS OF THE HIPPOCAMPUS

The hippocampus is the elongated portion of the cerebral cortex that folds inward to form the ventral surface of much of the inside of the lateral ventricle. One end of the hippocampus abuts the amygdaloid nuclei, and along its lateral border it fuses with the parahippocampal gyrus, which is the cerebral cortex on the ventromedial outside surface of the temporal lobe.

The hippocampus (and its adjacent temporal and parietal lobe structures, all together called the *hippocampal formation*) has numerous but mainly indirect connections with many portions of the cerebral cortex, as well as with the basal structures of the limbic system—the amygdala, hypothalamus, septum, and mammillary bodies. Almost any type of sensory experience causes activation of at least some part of the hippocampus, and the hippocampus in turn distributes many outgoing signals to the anterior thalamus, hypothalamus, and other parts of the limbic system, especially through the *fornix*, a major communicating pathway. Thus, the hippocampus is an additional channel through which incoming sensory signals can initiate behavioral reactions for different purposes. As in other limbic structures, stimulation of different areas in the hippocampus can cause almost any of the different behavioral patterns, such as pleasure, rage, passivity, or excess sex drive.

Another feature of the hippocampus is that it can become hyperexcitable. For example, weak electrical stimuli can cause focal epileptic seizures in small areas of the hippocampi. These seizures often persist for many seconds after the stimulation is over, suggesting that the hippocampi can perhaps give off prolonged output signals, even under normal functioning conditions. During hippocampal seizures, the person experiences various psychomotor effects, including olfactory, visual, auditory, tactile, and other types of hallucinations that cannot be suppressed as long as the seizure persists, even though the person has not lost consciousness and knows these hallucinations to be unreal. Probably one of the reasons for this hyperexcitability of the hippocampi is that they have a different type of cortex from that elsewhere in the cerebrum, with only three nerve cell layers in some of its areas instead of the six layers found elsewhere.

Role of the Hippocampus in Learning

Anterograde Amnesia After Bilateral Removal of the Hippocampi. Portions of the hippocampi have been surgically removed bilaterally in a few human beings for treatment of epilepsy. These people can recall most previously learned memories satisfactorily. However, they often can learn essentially no new information that is based on verbal symbolism—they often cannot even learn the names of people with whom they come in contact every day. Yet they can remember for a moment or so what transpires during the course of their activities. Thus, they are capable of short-term memory for seconds up to a minute or two, although their ability to establish memories lasting longer than a few minutes is either completely or almost completely abolished. This phenomenon, called *anterograde amnesia*, was discussed in Chapter 58.

Theoretical Function of the Hippocampus in Learning. The hippocampus originated as part of the olfactory cortex. In many lower animals, this cortex plays essential roles in determining whether the animal will eat a particular food, whether the smell of a particular object suggests danger, or whether the odor is sexually inviting, thus making decisions that are of life-or-death importance. Very early in evolutionary development of the brain, the hippocampus presumably became a critical decision-making neuronal mechanism, determining the importance of the incoming sensory signals. Once this critical decision-making capability had been established, presumably the remainder of the brain also began to call on the hippocampus for decision making. Therefore, if the hippocampus signals that a neuronal input is important, the information is likely to be committed to memory.

Thus, a person rapidly becomes habituated to indifferent stimuli but learns assiduously any sensory experience that causes either pleasure or pain. But what is the mechanism by which this occurs? It has been suggested that the hippocampus provides the drive that causes translation of short-term memory into long-term memory—that is, the hippocampus transmits signals that seem to make the mind *rehearse over and over* the new information until permanent storage takes place. Whatever the mechanism, without the hippocampi, *consolidation* of long-term memories of the verbal or symbolic thinking type is poor or does not take place.

Functions of the Amygdala

The amygdala is a complex of multiple small nuclei located immediately beneath the cerebral cortex of the medial anterior pole of each temporal lobe. It has abundant bidirectional connections with the hypothalamus, as well as with other areas of the limbic system.

In lower animals, the amygdala is concerned to a great extent with olfactory stimuli and their interrelations with the limbic brain. It was noted in Chapter 54 that one of the major divisions of the olfactory tract terminates in a portion of the amygdala called the *corticomedial nuclei*, which lies immediately beneath the cerebral cortex in the olfactory pyriform area of the temporal lobe. In humans, another portion of the amygdala, the *basolateral nuclei*, has become much more highly developed than the olfactory portion and plays important roles in many behavioral activities not generally associated with olfactory stimuli.

The amygdala receives neuronal signals from all portions of the limbic cortex, as well as from the neocortex of the temporal, parietal, and occipital lobes—especially from the auditory and visual association areas. Because of these multiple connections, the amygdala has been called the "window" through which the limbic system sees the place of the person in the world. In turn, the amygdala transmits signals (1) back into these same cortical areas, (2) into the hippocampus, (3) into the septum, (4) into the thalamus, and (5) especially into the hypothalamus.

Effects of Stimulating the Amygdala. In general, stimulation in the amygdala can cause many of the same effects as those elicited by direct stimulation of the hypothalamus, plus other effects. Effects initiated from the amygdala and then sent through the hypothalamus include the following: (1) increases or decreases in arterial pressure and heart rate; (2) increases or decreases in gastrointestinal motility and secretion; (3) defecation or micturition; (4) pupillary dilation or, rarely, constriction; (5) piloerection; and (6) secretion of various anterior pituitary hormones, especially the gonadotropins and adrenocorticotropic hormone.

Aside from these effects mediated through the hypothalamus, amygdala stimulation can also cause several types of involuntary movement, including the following: (1) tonic movements, such as raising the head or bending the body; (2) circling movements; (3) occasionally clonic, rhythmical movements; and (4) different types of movements associated with olfaction and eating, such as licking, chewing, and swallowing.

Stimulation of certain amygdaloid nuclei can also cause a pattern of rage, escape, punishment, severe pain, and fear similar to the rage pattern elicited from the hypothalamus, as described earlier. Stimulation of other amygdaloid nuclei can give reactions of reward and pleasure.

Finally, excitation of other portions of the amygdala can cause sexual activities that include erection, copulatory

movements, ejaculation, ovulation, uterine activity, and premature labor.

Effects of Bilateral Ablation of the Amygdala—The Klüver-Bucy Syndrome. When the anterior parts of both temporal lobes are destroyed in a monkey, this procedure removes not only portions of temporal cortex but also of the amygdalas that lie inside these parts of the temporal lobes. This removal causes changes in behavior called the *Klüver-Bucy syndrome*, which is demonstrated by an animal that (1) is not afraid of anything, (2) has extreme curiosity about everything, (3) forgets rapidly, (4) has a tendency to place everything in its mouth and sometimes even tries to eat solid objects, and (5) often has a sex drive so strong that it attempts to copulate with immature animals, animals of the same sex, or even animals of a different species. Although similar lesions in human beings are rare, afflicted people respond in a manner not too different from that of the monkey.

Overall Function of the Amygdalas. The amygdalas seem to be behavioral awareness areas that operate at a semiconscious level. They also seem to project into the limbic system one's current status in relation to both surroundings and thoughts. On the basis of this information, the amygdala is believed to play a role in making the person's behavioral response appropriate for the occasion.

Function of the Limbic Cortex

The least understood portion of the limbic system is the ring of cerebral cortex called the *limbic cortex* that surrounds the subcortical limbic structures. This cortex functions as a transitional zone through which signals are transmitted from the remainder of the brain cortex into the limbic system and in the opposite direction. Therefore, the limbic cortex in effect functions as a *cerebral association area for control of behavior*.

Stimulation of the different regions of the limbic cortex has failed to give any clear idea of their functions. However, many behavioral patterns can be elicited by stimulation of specific portions of the limbic cortex. Likewise, ablation of some limbic cortical areas can cause persistent changes in an animal's behavior, as follows.

Ablation of the Anterior Temporal Cortex. When the anterior temporal cortex is ablated bilaterally, the amygdalas are almost invariably damaged as well and, as discussed earlier, the Klüver-Bucy syndrome occurs. The animal especially develops consummatory behavior: it investigates any and all objects, has intense sex drives, and loses all fear—and thus develops tameness as well.

Ablation of the Posterior Orbital Frontal Cortex. Bilateral removal of the posterior portion of the orbital frontal cortex often causes an animal to develop insomnia associated with intense motor restlessness; the animal becomes unable to sit still and moves about continuously.

Ablation of the Anterior Cingulate Gyri and Subcallosal Gyri. The anterior cingulate gyri and the subcallosal gyri are the portions of the limbic cortex that communicate between the prefrontal cerebral cortex and the subcortical limbic structures. Destruction of these gyri bilaterally releases the rage centers of the septum and hypothalamus from prefrontal inhibitory influence. Therefore, the animal can become vicious and much more subject to fits of rage than normally.

Summary. Until further information is available, it is perhaps best to state that the cortical regions of the limbic system occupy intermediate associative positions between the functions of the specific areas of the cerebral cortex and functions of the subcortical limbic structures for control of behavioral patterns. Thus, in the anterior temporal cortex, one especially finds gustatory and olfactory behavioral associations. In the parahippocampal gyri, there is a tendency for complex auditory associations and complex thought associations derived from the Wernicke area of the posterior temporal lobe. In the middle and posterior cingulate cortex, there is evidence that sensorimotor behavioral associations occur.

CHAPTER 60

States of Brain Activity—Sleep, Brain Waves, Epilepsy, Psychoses, and Dementia

All of us are aware of the many different states of brain activity, including sleep, wakefulness, extreme excitement, and even different levels of mood, such as exhilaration, depression, and fear. All these states can result from different activating or inhibiting forces generated within the brain. In Chapter 59, we began a partial discussion of this subject when we described different systems that are capable of activating large portions of the brain. In this chapter, we present brief surveys of specific states of brain activity, beginning with sleep.

SLEEP

Sleep is a state of unconsciousness from which a person can be aroused by sensory or other stimuli. It is to be distinguished from *coma*, which is unconsciousness from which a person cannot be aroused. There are multiple stages of sleep, from very light sleep to very deep sleep. Sleep researchers also divide sleep into two major types of sleep that have different qualities, as described in the following section.

TWO TYPES OF ALTERNATING SLEEP—SLOW-WAVE SLEEP AND RAPID EYE MOVEMENT SLEEP

Each night, a person generally goes through stages of two major types of sleep that alternate with each other (**Fig. 60.1**). These types are called (1) *rapid eye movement sleep* (REM sleep), in which the eyes undergo rapid movements even though the person is still asleep, and (2) *slow-wave sleep* or *non-REM* (NREM) *sleep*, in which the brain waves are strong and of low frequency, as we discuss later.

REM sleep occurs in episodes that occupy about 25% of the sleep time in young adults; each episode normally recurs about every 90 minutes. This type of sleep is not so restful, and it is often associated with vivid dreaming. Most sleep during each night is of the NREM variety, which is the deep, restful sleep that the person experiences during the first hour of sleep after having been awake for many hours.

REM (Paradoxical, Desynchronized) Sleep

In a normal night of sleep, bouts of REM sleep lasting 5 to 30 minutes usually appear on average every 90 minutes in young adults. When a person is extremely sleepy, each bout of REM sleep is short and may even be absent. As the person becomes more rested through the night, the durations of the REM bouts increase.

REM sleep has several important characteristics:

1. It is an active form of sleep usually associated with dreaming and active bodily muscle movements.
2. The person is even more difficult to arouse by sensory stimuli than during deep NREM sleep, and yet people usually awaken spontaneously in the morning during an episode of REM sleep.
3. Muscle tone throughout the body is exceedingly depressed, indicating strong inhibition of the spinal muscle control areas.
4. Heart rate and respiratory rate usually become irregular, which is characteristic of the dream state.
5. Despite the extreme inhibition of the peripheral muscles, irregular muscle movements do occur in addition to the rapid eye movements.
6. The brain is highly active in REM sleep, and overall brain metabolism may be increased as much as 20%. An electroencephalogram (EEG) shows a pattern of brain waves similar to those that occur during wakefulness. This type of sleep is also called *paradoxical* sleep because it is a paradox that a person can still be asleep despite the presence of marked activity in the brain.

In summary, REM sleep is a type of sleep in which the brain is quite active. However, the person is not fully aware of their surroundings and therefore is truly asleep.

Non-REM Slow-Wave Sleep

The characteristics of deep NREM sleep can be understood by remembering the last time we were kept awake for more than 24 hours and the deep sleep that occurred during the first hour after going to sleep. This sleep is exceedingly restful and is associated with decreases in peripheral vascular tone and many other vegetative functions of the body. For example, 10% to 30% decreases occur in blood pressure, respiratory rate, and basal metabolic rate.

Although slow-wave NREM sleep is frequently called "dreamless sleep," dreams and sometimes even nightmares do occur during NREM sleep. The difference between the

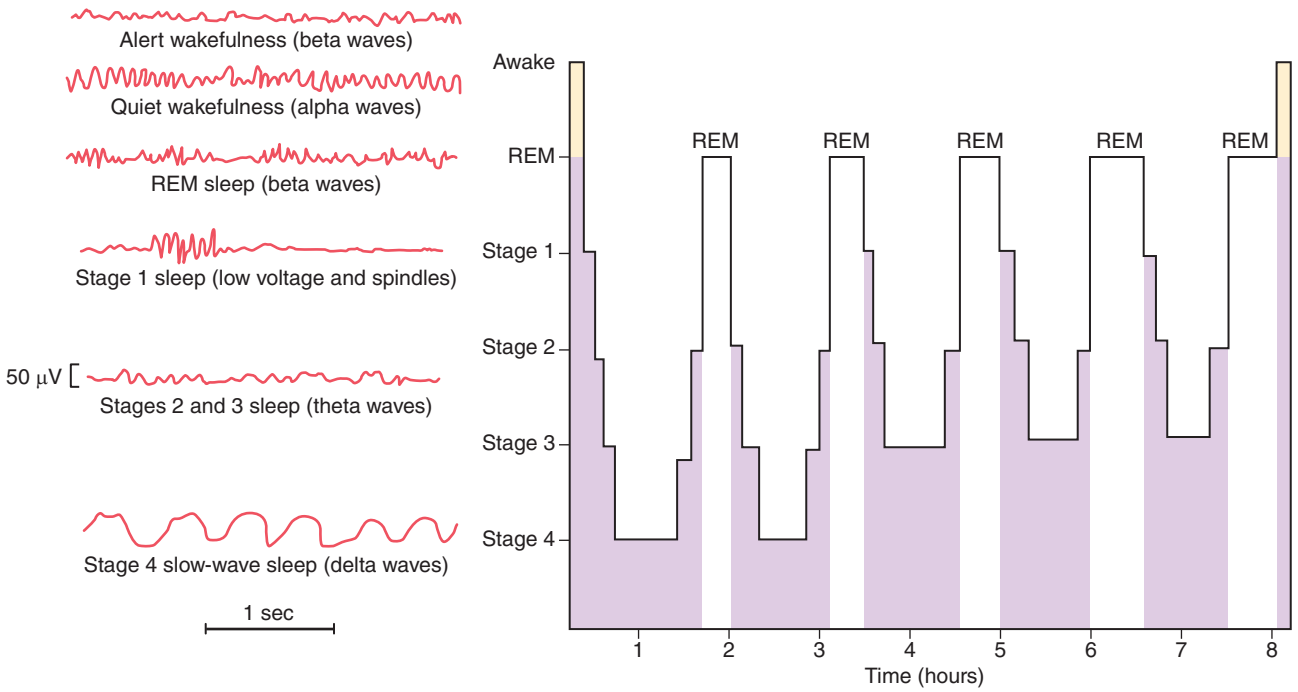

Figure 60.1 Progressive change in the characteristics of the brain waves during alert wakefulness, rapid eye movement (REM) sleep, and stages one through four of sleep.

dreams that occur in NREM sleep and those that occur in REM sleep is that those of REM sleep are associated with more bodily muscle activity. Also, the dreams of NREM sleep are usually not remembered because consolidation of the dreams in memory does not occur.

BASIC THEORIES OF SLEEP

Sleep Is Caused By an Active Inhibitory Process. An earlier theory of sleep was that the excitatory areas of the upper brain stem, the *reticular activating system*, simply became fatigued during the waking day and became inactive as a result. An important experiment changed this thinking to the current view that *sleep is caused by an active inhibitory process*, because it was discovered that transecting the brain stem at the level of the midpons creates a brain cortex that never goes to sleep. In other words, a center located below the midpontile level of the brain stem appears to be required to cause sleep by inhibiting other parts of the brain.

Neuronal Centers, Neurohumoral Substances, and Mechanisms That Can Cause Sleep—Possible Role for Serotonin

Stimulation of several specific areas of the brain can produce sleep with characteristics near those of natural sleep. Some of these areas are the following:

1. The *raphe nuclei in the lower half of the pons and in the medulla* are the most conspicuous stimulation area for causing almost natural sleep. These nuclei comprise a thin sheet of special neurons located in the midline. Nerve fibers from these nuclei spread locally in the brain stem reticular formation and upward into the thalamus, hypothalamus, most areas of the limbic system, and even the neocortex of the cerebrum. In addition, fibers extend downward into the spinal cord, terminating in the posterior horns, where they can inhibit incoming sensory signals, including pain, as discussed in Chapter 49. Many nerve endings of fibers from these raphe neurons secrete *serotonin*. When a drug that blocks the formation of serotonin is administered to an animal, the animal often cannot sleep for the next several days. Therefore, it has been assumed that serotonin is a transmitter substance associated with production of sleep.
2. Stimulation of some areas in the *nucleus of the tractus solitarius* can also cause sleep. This nucleus is the termination in the medulla and pons for visceral sensory signals entering by way of the vagus and glossopharyngeal nerves.
3. Sleep can be promoted by stimulation of *several regions in the diencephalon*, including (1) the rostral part of the hypothalamus, mainly in the suprachiasmal area, and (2) an occasional area in the diffuse nuclei of the thalamus.

Lesions in Sleep-Promoting Centers Can Cause Intense Wakefulness. Discrete lesions in the *raphe nuclei* lead to a high state of wakefulness. This phenomenon is also true of bilateral lesions in the *medial rostral suprachiasmal area in the anterior hypothalamus*. In both cases, the excitatory reticular nuclei of the mesencephalon and upper pons seem to become released from inhibition, thus causing intense wakefulness. Indeed,

sometimes lesions of the anterior hypothalamus can cause such intense wakefulness that complete (and even deadly) exhaustion may occur.

Other Possible Transmitter Substances Related to Sleep. Experiments have shown that the cerebrospinal fluid and the blood or urine of animals that have been kept awake for several days contain a substance or substances that will cause sleep when injected into the brain ventricular system of another animal. One likely substance has been identified as *muramyl peptide*, a low-molecular-weight substance that accumulates in the cerebrospinal fluid and urine in animals kept awake for several days. When only micrograms of this sleep-producing substance are injected into the third ventricle, almost natural sleep occurs within a few minutes, and the animal may stay asleep for several hours.

Another substance that has similar effects in causing sleep is *delta sleep–inducing peptide*, a nonapeptide found in the cerebrospinal fluid after electrical stimulation of the thalamus to induce sleep. Several other potential sleep factors, mostly peptides, have been isolated from the cerebrospinal fluid or neuronal tissues of the brain stem of animals kept awake for days. It is possible that prolonged wakefulness causes progressive accumulation of a sleep factor or factors in the brain stem or cerebrospinal fluid that lead to sleep.

Possible Cause of REM Sleep. It is not clear why NREM sleep is broken periodically by REM sleep. However, drugs that mimic the action of acetylcholine increase the occurrence of REM sleep. Therefore, it has been postulated that the large acetylcholine-secreting neurons in the upper brain stem reticular formation might, through their extensive efferent fibers, activate many portions of the brain. This mechanism theoretically could cause the increased activity that occurs in certain brain regions in REM sleep, even though the signals are not channeled appropriately in the brain to cause normal conscious awareness that is characteristic of wakefulness.

Cycle Between Sleep and Wakefulness

The preceding discussions have merely identified neuronal areas, transmitters, and mechanisms that are related to sleep; they have not explained the cyclical, reciprocal operation of the sleep-wakefulness cycle. Although there is as yet no definitive explanation, the following is a possible mechanism for causing the sleep-wakefulness cycle.

When the sleep centers are *not* activated, the mesencephalic and upper pontile reticular activating nuclei are released from inhibition, which allows the reticular activating nuclei to become spontaneously active. This spontaneous activity in turn excites both the cerebral cortex and the peripheral nervous system, both of which send numerous *positive feedback* signals back to the same reticular activating nuclei to activate them still further. Therefore, once wakefulness begins, it has a natural tendency to sustain itself because of all this positive feedback activity.

Then, after the brain remains activated for many hours, even the neurons in the activating system presumably become fatigued. Consequently, the positive feedback cycle between the mesencephalic reticular nuclei and the cerebral cortex fades and the sleep-promoting effects of the sleep centers take over, leading to rapid transition from wakefulness back to sleep.

This overall theory could explain the rapid transitions from sleep to wakefulness and from wakefulness to sleep. It could also explain arousal—that is, the insomnia that occurs when a person's mind becomes preoccupied with a thought—and the wakefulness that is produced by bodily physical activity.

Role of Orexin Neurons in Arousal and Wakefulness. *Orexin* (also called *hypocretin)* is produced by neurons in the hypothalamus that provide excitatory input to many other areas of the brain where there are orexin receptors. Orexin neurons are most active during waking and almost stop firing during slow wave and REM sleep. Loss of orexin signaling as a result of defective orexin receptors or destruction of orexin-producing neurons causes *narcolepsy*, a sleep disorder characterized by overwhelming daytime drowsiness and sudden attacks of sleep that can occur even when a person is talking or working. Patients with narcolepsy may also experience a sudden loss of muscle tone *(cataplexy)* that can be partial or even severe enough to cause paralysis during the attack. These observations point to an important role for orexin neurons in maintaining wakefulness, but their contribution to the normal daily cycle between sleep and wakefulness is unclear.

Sleep Follows Circadian and Ultradian Rhythms

Although the drive to sleep (sleepiness) depends on multiple factors, two of the most important are (1) the "sleep deficit" that builds slowly between periods of restful sleep and then dissipates with sleep, and (2) a *circadian rhythm* of sleep and waking. As we discussed in Chapter 59, neurons of the suprachiasmatic nucleus (SCN) serve as a "master clock" pacemaker, with a firing frequency that follows a 24-hour circadian rhythm and is critical for the normal cyclical patterns of sleeping and waking. The circadian activity of these neurons is entrained by various environmental stimuli, including the light-dark cycle. A small number of retinal ganglion cells respond directly to light and project to the SCN via the retinohypothalamic tract.

The SCN has multiple efferent projections that can influence sleep, including those that innervate the *pineal gland*, which produces *melatonin* during the night for induction of sleep. Several nuclei of the hypothalamus also receive input from the SCN. For example, axons from the SCN terminate in the dorsal and ventral and dorsal subparaventricular regions of the hypothalamus. The dorsal subparaventricular zone, in turn, sends projections to neurons that contribute to circadian regulation of

temperature, whereas the ventral subparaventricular zone and the downstream dorsomedial nucleus of the hypothalamus are important in the sleep-wake cycle.

Although the SCN is critical for synchronization of circadian rhythms, it is not the generator of wakefulness or the much shorter *ultradian rhythms* of REM and NREM sleep that normally occur at about 90-minute intervals during sleep. Instead, the cyclicity of arousal and REM and NREM sleep may result, at least partly, from antagonistic interactions of *brain stem neurons* called *REM-OFF* (serotonin and norepinephrine transmitter) and *REM-ON* (acetylcholine transmitter) neurons. The firing rate of REM-OFF neurons increases during the waking state and then decreases just ahead of REM sleep; during REM sleep these neurons become nearly silent and then increase their firing rate prior to the start of non-REM sleep (**Fig. 60.2**). The REM-ON neurons discharge just prior to and during REM sleep. The discharge on these REM-ON neurons is thought to be responsible for activation of the forebrain and the rapid eye movements during REM sleep.

Although neurons in the brain stem's pons and medulla appear to be critical for the control of arousal, as well as other components of REM sleep, it is also becoming clear that REM sleep and NREM sleep originate from multiple neural networks distributed across the brain.

SLEEP IS ESSENTIAL FOR HOMEOSTASIS

There is little doubt that sleep has essential physiological functions. It exists in all mammals, and after total deprivation there is usually a period of "catch-up" or "rebound" sleep; after selective deprivation of REM or NREM sleep, there is also a selective rebound of these specific stages of sleep. Even mild sleep restriction over a few days degrades cognitive and physical performance, overall productivity, and the health of a person. The essential role of sleep in homeostasis is perhaps most vividly demonstrated by the fact that rats deprived of sleep for 2 to 3 weeks may actually die. Despite the obvious importance of sleep, our understanding of why sleep is an essential part of life is still limited.

Sleep causes two major types of physiological effects: (1) effects on the nervous system, and (2) effects on other functional systems of the body. Mammals, and even invertebrate animals, sleep more in the setting of infectious or noninfectious illnesses. Sickness-induced sleep has been suggested to be a beneficial response that diverts the organism's energy resources from neural and motor demands to fighting off infectious or injurious insults.

Sleep deprivation certainly affects the functions of the central nervous system. Prolonged wakefulness is often associated with progressive malfunction of the thought processes and sometimes even causes abnormal behavioral activities. Increased sluggishness of thought occurs toward the end of a prolonged wakeful period, and a person can become irritable or even psychotic after forced wakefulness. Therefore, we can assume that sleep in multiple ways restores both normal levels of brain activity and normal "balance" among the different functions of the central nervous system.

Sleep has been postulated to serve many functions, including the following: (1) neural maturation; (2) facilitation of learning or memory; (3) targeted erasure of synapses to "forget" unimportant information that might clutter the synaptic network; (4) cognition; (5) clearance of metabolic waste products generated by neural activity in the awake brain; and (6) conservation of metabolic energy. There is some evidence for each of these functions, but evidence supporting these ideas has been challenged. We might postulate that *the principal value of sleep is to restore natural balances among the neuronal centers*, which is necessary for overall health. The specific physiological functions of sleep, however, remain a mystery and are the subject of much research.

Brain Waves

Electrical recordings from the surface of the brain or even from the outer surface of the head demonstrate that there is continuous electrical activity in the brain. Both the intensity and the patterns of this electrical activity are determined by the level of excitation of different parts of the brain resulting from *sleep, wakefulness*, or brain disorders such as *epilepsy* or even *psychoses*. The undulations in the recorded

A limit cycle mathematical model of the REM sleep oscillator system.* Am J Physiol. *1986;R1011-1029.)*

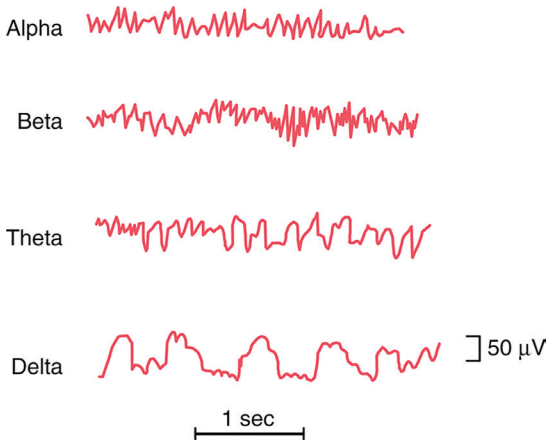

Figure 60.3 Different types of brain waves in the normal electroencephalogram.

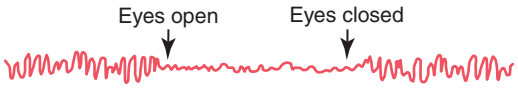

Figure 60.4 Replacement of the alpha rhythm by an asynchronous, low-voltage beta rhythm when the eyes are open.

electrical potentials, shown in **Fig. 60.3**, are called *brain waves*, and the entire record is called an *electroencephalogram* (EEG).

The intensities of brain waves recorded from the surface of the scalp range from 0 to 200 microvolts, and their frequencies range from once every few seconds to 50 or more per second. The character of the waves is dependent on the activity in respective parts of the cerebral cortex, and the waves change markedly between the states of wakefulness and sleep and coma.

Much of the time, the brain waves are irregular and no specific pattern can be discerned in the EEG. At other times, distinct patterns appear, some of which are characteristic of specific abnormalities of the brain, such as epilepsy, which is discussed later.

In healthy people, most waves in the EEG can be classified as *alpha, beta, theta*, and *delta waves*, which are shown in **Fig. 60.3**.

Alpha waves are rhythmical waves that occur at frequencies between 8 and 13 cycles/sec and are found in the EEGs of almost all healthy adults when they are awake and in a quiet, resting state of cerebration. These waves occur most intensely in the occipital region but can also be recorded from the parietal and frontal regions of the scalp. Their voltage is usually about 50 microvolts. During deep sleep, the alpha waves disappear.

When the awake person's attention is directed to some specific type of mental activity, the alpha waves are replaced by asynchronous, higher-frequency but lower-voltage *beta waves*. **Fig. 60.4** shows the effect on the alpha waves of simply opening the eyes in bright light and then closing the eyes. Note that the visual sensations cause immediate cessation of the alpha waves and that these waves are replaced by low-voltage, asynchronous beta waves.

Beta waves occur at frequencies greater than 14 cycles/sec and as high as 80 cycles/sec. They are recorded mainly from the parietal and frontal regions during specific activation of these parts of the brain.

Theta waves have frequencies between 4 and 7 cycles/sec. They occur normally in the parietal and temporal regions in children, but they also occur during emotional stress in some adults, particularly during disappointment and frustration. Theta waves also occur in many brain disorders, often in degenerative brain states.

Delta waves include all the waves of the EEG with frequencies less than 3.5 cycles/sec, and they often have voltages two to four times greater than most other types of brain waves. They occur in very deep sleep, in infancy, and in persons with serious organic brain disease. They also occur in the cortex of animals that have had subcortical transections in which the cerebral cortex is separated from the thalamus. Therefore, delta waves can occur strictly in the cortex independent of activities in lower regions of the brain.

Origin of Brain Waves

The discharge of a single neuron or single nerve fiber in the brain can never be recorded from the surface of the head. Instead, many thousands or even millions of neurons or fibers *must fire synchronously* for the potentials from the individual neurons or fibers to summate enough to be recorded through the skull. Thus, the intensity of the brain waves from the scalp is determined mainly by the numbers of neurons and fibers that fire *in synchrony* with one another, not by the total level of electrical activity in the brain. In fact, strong *nonsynchronous* nerve signals often nullify one another in the recorded brain waves because of opposing polarities. This phenomenon is demonstrated in **Fig. 60.4**, which shows, when the eyes were closed, synchronous discharge of many neurons in the cerebral cortex at a frequency of about 12/sec, thus causing *alpha waves*. Then, when the eyes were opened, the activity of the brain increased greatly, but synchronization of the signals became so little that the brain waves mainly nullified one another. The resultant effect was low-voltage waves of generally high but irregular frequency, the *beta waves*.

Origin of Alpha Waves. Alpha waves will *not* occur in the cerebral cortex without cortical connections with the thalamus. Conversely, stimulation in the nonspecific layer of *reticular nuclei* that surround the thalamus or in "diffuse" nuclei deep inside the thalamus often sets up electrical waves in the thalamocortical system at a frequency between 8 and 13/sec, which is the natural frequency of the alpha waves. Therefore, alpha waves are thought to result from spontaneous feedback oscillation in this diffuse thalamocortical system, possibly including the reticular activating system in the brain stem as well. This oscillation presumably causes the periodicity of the alpha waves and the synchronous activation of literally millions of cortical neurons during each wave.

Origin of Delta Waves. Transection of the fiber tracts from the thalamus to the cerebral cortex, which blocks thalamic activation of the cortex and thereby eliminates the alpha waves, nevertheless does not block delta waves in the cortex. This indicates that some synchronizing mechanism can occur in the cortical neuronal system by itself—mainly

independent of lower structures in the brain—to cause the delta waves.

Delta waves also occur during deep NREM sleep, which suggests that the cortex then is released from the activating influences of the thalamus and other lower centers.

Effect of Varying Levels of Cerebral Activity on the Frequency of the EEG

There is a general correlation between level of cerebral activity and average frequency of the EEG rhythm, with the average frequency increasing progressively with higher degrees of activity. This is demonstrated in **Fig. 60.5**, which shows the existence of delta waves in surgical anesthesia and deep sleep, theta waves in psychomotor states, alpha waves during relaxed states, and beta waves during periods of intense mental activity or fright. *During periods of mental activity, the waves usually become asynchronous rather than synchronous, so the voltage falls considerably despite markedly increased cortical activity*, as shown when the eyes are closed in **Fig. 60.4.**

Changes in the EEG at Different Stages of Wakefulness and Sleep

Fig. 60.1 shows typical EEG patterns in different stages of wakefulness and sleep. Alert wakefulness is characterized by high-frequency *beta waves*, whereas quiet wakefulness is usually associated with *alpha waves*, as demonstrated by the first two EEGs of the figure.

NREM sleep is divided into four stages. In the first stage, a stage of light sleep, the voltage of the EEG waves becomes low. This stage is broken by "*sleep spindles*" (i.e., short spindle-shaped bursts of alpha waves that occur periodically). In stages 2, 3, and 4 of NREM sleep, the frequency of the EEG becomes progressively slower until it reaches a frequency of only one to three waves per second in stage 4; these waves are *delta waves*.

Fig. 60.1 also shows the EEG during REM sleep. It is often difficult to tell the difference between this brain wave pattern and that of an awake, active person. The waves are irregular and of high frequency, which are normally suggestive of desynchronized nervous activity as found in the awake state. Therefore, REM sleep is frequently called *desynchronized sleep* because there is lack of synchrony in the firing of the neurons despite significant brain activity.

Seizures and Epilepsy

Seizures are temporary disruptions of brain function caused by uncontrolled excessive neuronal activity. Depending on the distribution of neuronal discharges, seizure manifestations can range from experiential phenomena that are barely noticeable to dramatic convulsions. These temporary *symptomatic* seizures usually do not persist if the underlying disorder is corrected. They can be caused by multiple neurological or medical conditions, such as acute electrolyte disorders, hypoglycemia, drugs (e.g., cocaine), eclampsia, kidney failure, hypertensive encephalopathy, meningitis, and so forth. Approximately 5% to 10% of the population will have at least one seizure in their lifetime.

In contrast to symptomatic seizures, *epilepsy* is a chronic condition of *recurrent seizures* that can also vary from brief and nearly undetectable symptoms to periods of vigorous shaking and convulsions. Epilepsy is not a single disease. Its clinical symptoms are heterogeneous and reflect multiple underlying pathophysiological mechanisms that cause cerebral dysfunction and injury, such as trauma, stroke, tumors, infection, or degenerative changes. Hereditary factors appear to be important, although a specific cause cannot be identified in many patients and several factors may coexist, reflecting an acquired brain pathology and genetic predisposition. Epilepsy is estimated to affect approximately 1% of the population, or 65 million people worldwide. The incidence of epilepsy in men is slightly greater than in women.

At a basic level an epileptic seizure is caused by a disruption of the normal balance between inhibitory and excitatory currents or transmission in one or more regions of the brain. Drugs or pathological factors that increase neuronal excitation or impair inhibition tend to be *epileptogenic* (i.e., predisposing a person to epilepsy), whereas effective antiepileptic drugs attenuate excitation and facilitate inhibition. In cases in which a person has brain injury due to trauma, stroke, or infection, there may be a delay of several months or years after the injury before the seizures begin.

Epileptic seizures can be classified into two major types: (1) *focal seizures* (also called *partial seizures*) that are limited to a focal area of one cerebral hemisphere, and (2) *generalized seizures* that diffusely involve both hemispheres of the cerebral cortex. However, partial seizures may sometimes evolve into generalized seizures.

Focal (Partial) Epileptic Seizures

Focal epileptic seizures begin in a small localized region of the cerebral cortex or deeper structures of the cerebrum and brain stem and have clinical manifestations that reflect the function of the affected brain area. Most often, focal epilepsy results from some localized organic lesion or functional abnormality, such as (1) scar tissue in the brain that pulls on the adjacent neuronal tissue, (2) a tumor that compresses an area of the brain, (3) a destroyed area of brain tissue, or (4) congenitally deranged local circuitry.

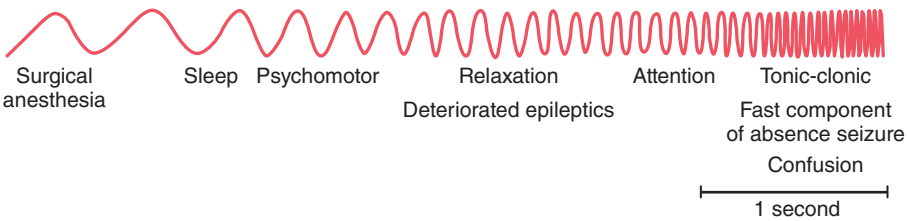

Figure 60.5 Effect of varying degrees of cerebral activity on the basic rhythm of the electroencephalogram.

These lesions can promote extremely rapid discharges in the local neurons; when the discharge rate rises above several hundred per second, synchronous waves begin to spread over adjacent cortical regions. These waves presumably result from *localized reverberating circuits* that may gradually recruit adjacent areas of the cortex into the epileptic discharge zone. The process spreads to adjacent areas at a rate as slow as a few millimeters per minute to as fast as several centimeters per second.

Focal seizures can spread locally from a focus or more remotely to the contralateral cortex and subcortical areas of the brain through projections to the thalamus, which has widespread connections to both hemispheres (**Fig. 60.6**). When such a wave of excitation spreads over the motor cortex, it causes a progressive "march" of muscle contractions throughout the opposite side of the body, beginning most characteristically in the mouth region and marching progressively downward to the legs but at other times marching in the opposite direction. This phenomenon is called *Jacksonian march*.

Focal seizures are often classified as *simple partial seizures* when there is no major change in consciousness or as *complex partial seizures* when consciousness is impaired. Simple partial seizures may be preceded by an *aura*, with sensations such as fear, followed by motor signs, such as rhythmic jerking or tonic stiffening movements of a body part. A focal epileptic attack may remain confined to a single area of the brain, often the temporal lobe, but in some cases strong signals spread from the focal region, and the person may lose consciousness. Complex partial seizures may also begin with an aura followed by impaired consciousness and strange repetitive movements *(automatisms)*, such as chewing or lip smacking. After recovery from the seizure the person may have no memory of the attack, except for the aura. The time after the seizure, prior to the return of normal neurological function, is called the *postictal period*.

Psychomotor, temporal lobe, and *limbic seizures* are terms that have been used in the past to describe many of the behaviors that are now classified as complex partial seizures. However, these terms are not synonymous. Complex partial seizures can arise from regions other than the temporal lobe and do not always involve the limbic system. Also, automatisms (the "psychomotor" element) are not always present in complex partial seizures. Attacks of this type frequently involve part of the limbic portion of the brain, such as the hippocampus, the amygdala, the septum, and/or portions of the temporal cortex.

The lowest tracing of **Fig. 60.7** demonstrates a typical EEG during a psychomotor seizure, showing a low-frequency rectangular wave with a frequency between 2 and 4/sec and with occasional superimposed 14/sec waves.

Generalized Seizures

Generalized epileptic seizures are characterized by diffuse, excessive, and uncontrolled neuronal discharges that at the outset spread rapidly and simultaneously to both cerebral hemispheres through interconnections between the thalamus and cortex (**Fig. 60.6**). However, it is sometimes difficult clinically to distinguish between a primary generalized seizure and a focal seizure that spreads rapidly. Generalized seizures are subdivided primarily on the basis of the ictal motor manifestations, which, in turn, depend on the extent to which subcortical and brain stem regions participate in the seizure.

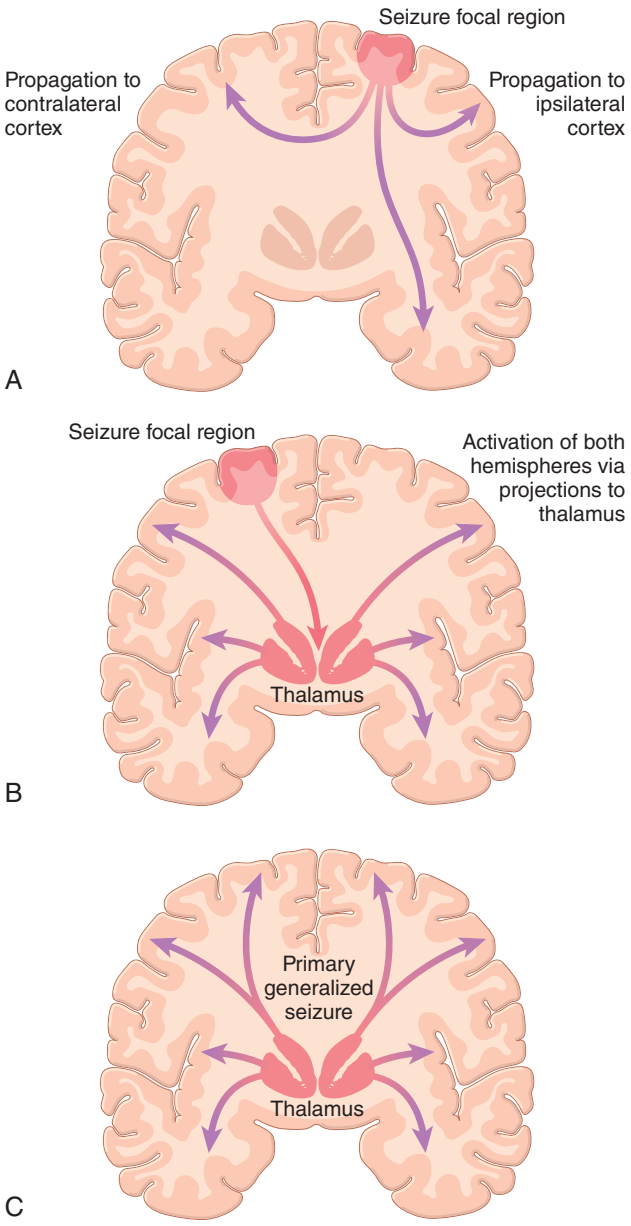

Figure 60.6 (A) Propagation of seizures from focal regions of the cortex can occur through fibers in the same cerebral hemisphere or fibers that connect to the contralateral cortex. (B) Secondary generalization of a focal seizure can sometimes occur by spread to subcortical areas through projections to the thalamus, resulting in activation of both hemispheres. (C) Primary generalized seizure spreads rapidly and simultaneously to both cerebral hemispheres through interconnections between the thalamus and cortex.

Generalized Tonic-Clonic (Grand Mal) Seizures

Generalized tonic-clonic seizures, previously called *grand mal seizures*, are characterized by an abrupt loss of consciousness and extreme neuronal discharges in all areas of the brain—the cerebral cortex, the deeper parts of the

cerebrum, and even the brain stem. Also, discharges transmitted all the way into the spinal cord sometimes cause generalized *tonic seizures* of the entire body, followed toward the end of the attack by alternating tonic and spasmodic muscle contractions called *tonic-clonic seizures*. Often the person bites or "swallows" their tongue and may have difficulty breathing, sometimes to the extent that cyanosis occurs. Also, signals transmitted from the brain to the viscera frequently cause urination and defecation.

The usual generalized tonic-clonic seizure lasts from a few seconds to 3 to 4 minutes. It is also characterized by *postseizure depression* of the entire nervous system; the person remains in stupor for 1 minute to many minutes after the seizure attack is over and then often remains severely fatigued and asleep for hours thereafter.

The top recording of **Fig. 60.7** shows a typical EEG from almost any region of the cortex during the tonic phase of generalized tonic-clonic seizure. This demonstrates that high-voltage, high-frequency discharges occur over the entire cortex. Furthermore, the same type of discharge occurs on both sides of the brain at the same time, demonstrating that the abnormal neuronal circuitry responsible for the attack strongly involves the basal regions of the brain that drive the two halves of the cerebrum simultaneously.

Electrical recordings from the thalamus, as well as from the reticular formation of the brain stem during the generalized tonic-clonic seizure, show typical high-voltage activity in both of these areas similar to that recorded from the cerebral cortex. Therefore, a generalized tonic-clonic seizure presumably involves not only abnormal activation of the thalamus and cerebral cortex but also abnormal activation in the subthalamic brain stem portions of the brain-activating system.

What Initiates a Generalized Tonic-Clonic Seizure? The majority of generalized seizures are *idiopathic*, which means that the cause is unknown. Many people who have generalized tonic-clonic attacks have a hereditary predisposition to epilepsy, a predisposition that occurs in about 1 of every 100 persons. In these people, factors that can increase the excitability of the abnormal "epileptogenic" circuitry enough to precipitate attacks include (1) strong emotional stimuli, (2) alkalosis caused by overbreathing, (3) drugs, (4) fever, and (5) loud noises or flashing lights.

Even in people who are not genetically predisposed, certain types of traumatic lesions in almost any part of the brain can cause excess excitability of local brain areas, as we discuss shortly. These local brain areas also sometimes transmit signals into the activating systems of the brain to elicit tonic-clonic seizures.

What Stops the Generalized Tonic-Clonic Attack? The extreme neuronal overactivity during a tonic-clonic attack is presumed to be caused by massive simultaneous activation of many reverberating neuronal pathways throughout the brain. Although the factors that terminate the attack are not well understood, it is likely that *active inhibition* occurs by inhibitory neurons that have been activated by the attack.

Absence Seizures (Petit Mal Seizures)

Absence seizures, formerly called *petit mal seizures*, usually begin in childhood or early adolescence and account for 15% to 20% of epilepsy cases in children. Absence seizures

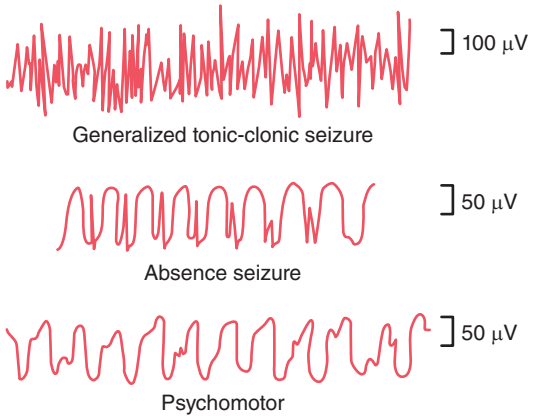

Figure 60.7 Electroencephalograms in different types of epilepsy.

almost certainly involve the thalamocortical brain activating system. They are usually characterized by 3 to 30 seconds of unconsciousness or diminished consciousness, during which time the person often stares and has twitch-like contractions of muscles, usually in the head region and especially blinking of the eyes; this phase is followed by a rapid return of consciousness and resumption of previous activities. The total sequence is called the *absence syndrome* or *absence epilepsy*.

The patient may have one such attack in many months or, in rare cases, may have a rapid series of attacks, one after the other. The usual course is for the absence seizures to appear first during childhood or adolescence and then to disappear by the age of 30 years. On occasion, an absence seizure will initiate a generalized tonic-clonic (grand mal) attack.

The brain wave pattern in a person with absence seizure epilepsy is demonstrated by the middle recording of **Fig. 60.7**, which is typified by a *spike and dome pattern*. The spike and dome can be recorded over most or all of the cerebral cortex, showing that the seizure involves much or most of the thalamocortical activating system of the brain. In fact, animal studies suggest that it results from oscillation of (1) inhibitory thalamic reticular neurons (which are *inhibitory* gamma-aminobutyric acid [GABA]-producing neurons) and (2) *excitatory* thalamocortical and cortico-thalamic neurons.

Treatment of Epilepsy

Most of the currently available drugs used to treat epilepsy appear to block the initiation or spread of seizures, although the precise mode of action for some drugs is unknown or may involve multiple actions. Some of the major effects of various antiepileptic drugs include the following: (1) blockade of voltage-dependent sodium channels (e.g., carbamazepine and phenytoin); (2) altered calcium currents (e.g., ethosuximide); (3) an increase in GABA activity (e.g., phenobarbital and benzodiazepines); (4) inhibition of receptors for glutamate, the most prevalent excitatory neurotransmitter (e.g., perampanel); and (5) multiple mechanisms of action (e.g., valproate and topiramate, which block voltage-dependent sodium channels and increase GABA levels in the brain). The choice of antiepileptic drug recommended by current guidelines depends on the type of seizure, the age of the patient, and other factors, but correction of the

underlying cause of the seizures is the best option when possible.

Epilepsy can usually be controlled with appropriate medications. However, when the epilepsy is medically intractable and does not respond to treatments, the EEG can sometimes be used to localize abnormal spiking waves originating in areas of organic brain disease that predispose to focal epileptic attacks. Once such a focal point is found, surgical excision of the focus frequently prevents future attacks.

Roles of Specific Neurotransmitter Systems in Brain Disorders

Clinical studies of patients with different psychoses or different types of dementia have suggested that many of these conditions result from diminished function of neurons that secrete a specific neurotransmitter. Use of appropriate drugs to counteract loss of the respective neurotransmitter has been successful in treating some patients.

In Chapter 57, we discussed the cause of *Parkinson disease*, which results from loss of neurons in the substantia nigra, whose nerve endings secrete *dopamine* in the caudate nucleus and putamen. We pointed out in Chapter 57 that in *Huntington disease* loss of GABA-secreting neurons and acetylcholine-secreting neurons is associated with *specific abnormal motor patterns* plus *dementia* occurring in the same patient.

Depression and Manic-Depressive Psychoses—Decreased Activity of the Norepinephrine and Serotonin Neurotransmitter Systems

Evidence has accumulated suggesting that *mental depression psychosis*, which occurs in more than 8 million people in the United States, might be caused by *diminished formation in the brain of norepinephrine or serotonin, or both*. New evidence has also implicated other neurotransmitters. Patients with depression experience symptoms of grief, unhappiness, despair, and misery. In addition, they often lose their appetite and sex drive and have severe insomnia. Often associated with these symptoms is a state of psychomotor agitation despite the depression.

Moderate numbers of *norepinephrine-secreting neurons* are located in the brain stem, especially in the *locus ceruleus*. These neurons send fibers upward to most parts of the brain limbic system, thalamus, and cerebral cortex. Also, many *serotonin-producing neurons* located in the *midline raphe nuclei* of the lower pons and medulla send fibers to many areas of the limbic system and to some other areas of the brain.

A principal reason for believing that depression might be caused by diminished activity of norepinephrine- and serotonin-secreting neurons is that drugs that block secretion of norepinephrine and serotonin, such as reserpine, frequently cause depression. Also, about 70% of patients with depression can be treated effectively with drugs that increase the excitatory effects of norepinephrine and serotonin at the nerve endings, for example, as follows: (1) *monoamine oxidase inhibitors*, which block destruction of norepinephrine and serotonin once they are formed, and (2) *tricyclic antidepressants*, such as *imipramine* and *amitriptyline*, which block reuptake of norepinephrine and serotonin by nerve endings so that these transmitters remain active for longer periods after secretion.

Some patients with mental depression alternate between depression and mania, which is called either *bipolar disorder* or *manic-depressive psychosis*, and fewer patients exhibit only mania without the depressive episodes. Drugs that diminish the formation or action of norepinephrine and serotonin, such as lithium compounds, can be effective in treating the manic phase of the condition.

It is presumed that the norepinephrine and serotonin systems normally provide drive to the limbic areas of the brain to increase a person's sense of well-being and to create happiness, contentment, good appetite, appropriate sex drive, and psychomotor balance—although too much of a good thing can cause mania. In support of this concept is the fact that pleasure and reward centers of the hypothalamus and surrounding areas receive large numbers of nerve endings from the norepinephrine and serotonin systems.

Schizophrenia—Possible Exaggerated Function of Part of the Dopamine System

Schizophrenia comes in many varieties. One of the most common types is seen in the person who hears voices and has delusions, intense fear, or other types of feelings that are unreal. Many people with schizophrenia are highly paranoid, with a sense of persecution from outside sources. They may develop incoherent speech, dissociation of ideas, and abnormal sequences of thought, and they are often withdrawn, sometimes with abnormal posture and even rigidity.

There are reasons to believe that schizophrenia results from one or more of three possibilities: (1) multiple areas in the cerebral cortex *prefrontal lobes* in which neural signals have become blocked or where processing of the signals becomes dysfunctional because many synapses normally excited by the neurotransmitter *glutamate* lose their responsiveness to this transmitter; (2) excessive excitement of a group of neurons that secrete *dopamine* in the behavioral centers of the brain, including in the frontal lobes; and/or (3) abnormal function of a crucial part of the brain's *limbic behavioral control system centered around the hippocampus*.

A reason for believing that the prefrontal lobes are involved in schizophrenia is that a schizophrenic-like pattern of mental activity can be induced in monkeys by making multiple minute lesions in widespread areas of the prefrontal lobes.

Dopamine has been implicated in schizophrenia because schizophrenic-like symptoms develop in many patients with Parkinson disease when they are treated with the drug called L-*dopa*. This drug releases dopamine in the brain, which is advantageous for treating Parkinson disease, but at the same time it depresses various portions of the prefrontal lobes and other related areas.

It has been suggested that in persons with schizophrenia, excess dopamine is secreted by a group of dopamine-secreting neurons whose cell bodies lie in the ventral tegmentum of the mesencephalon, medial and superior to the substantia nigra. These neurons give rise to the so-called *mesolimbic dopaminergic system* that projects nerve fibers and dopamine secretion into the medial and anterior

portions of the limbic system, especially into the hippocampus, amygdala, anterior caudate nucleus, and portions of the prefrontal lobes. All these areas are powerful behavioral control centers.

An even more compelling reason for believing that schizophrenia might be caused by excess production of dopamine is that many drugs that are effective in treating schizophrenia, such as chlorpromazine, haloperidol, and thiothixene, all either decrease secretion of dopamine at dopaminergic nerve endings or decrease the effect of dopamine on neurons.

Finally, possible involvement of the hippocampus in schizophrenia was discovered when it was learned that *in persons with schizophrenia, the size of the hippocampus is often reduced*, especially in the dominant hemisphere.

Dementia—Impaired Cognitive Function

Dementia is a general term for a group of symptoms characterized by impairment of memory, language, problem-solving, and other thinking skills that affect a person's ability to perform everyday activities. Several different types of brain changes can lead to dementia (see **Table 60.1**). The two most common causes of dementia are *Alzheimer disease* and *cerebrovascular disease*.

Table 60.1 Most Common Causes of Dementia

Type of Dementia	Characteristics
Alzheimer disease	Accumulation of beta-amyloid protein and twisted strands of tau protein, neuronal death, brain atrophy.
Cerebrovascular disease	Vascular damage, often secondary to hypertension and diabetes, leading to brain ischemia and neuronal death.
Hippocampal sclerosis	Neuronal loss and sclerosis of the hippocampus associated with accumulation of the misfolded protein TDP-43, a nuclear RNA/DNA-binding protein involved in RNA processing.
Frontotemporal degeneration	Neuronal loss and shrinkage in the frontal and temporal lobes associated with abnormal forms of tau and/or TDP-43.
Lewy body disease	Aggregations of the protein alpha-synuclein (Lewy bodies) appear in neurons of the cerebral cortex. Lewy bodies may also be found in Alzheimer disease and in Parkinson disease.
Parkinson disease	Clumps of alpha-synuclein protein (Lewy bodies) appear in neurons of the cerebral cortex and substantia nigra, which produces dopamine and modulates motor movement.
Mixed dementias	Brain changes of more than one cause of dementia occurring simultaneously. The most common form of mixed dementia is abnormal protein deposits associated with Alzheimer disease coexisting with vascular dementia.

Alzheimer Disease—Amyloid Plaques, Intraneuronal Tau, and Impaired Memory

Alzheimer disease is the most common contributor to dementia and is associated with premature aging of the brain, usually beginning in mid-adult life and progressing rapidly to extreme loss of mental powers—similar to that seen in very old age. The clinical features of Alzheimer disease include (1) an amnesic type of memory impairment, (2) deterioration of language, and (3) visuospatial deficits. Motor and sensory abnormalities, gait disturbances, and seizures are uncommon until the late phases of the disease. One consistent finding in Alzheimer disease is loss of neurons in the part of the limbic pathway that drives the memory process.

Alzheimer disease is a progressive and fatal neurodegenerative disorder that results in impairment of the person's ability to perform activities of daily living, as well as a variety of neuropsychiatric symptoms and behavioral disturbances in the later stages of the disease. Patients with Alzheimer disease usually require continuous care within a few years after the disease begins.

Approximately 7 million people in the United States are estimated to be afflicted by Alzheimer disease. About two-thirds of Americans with Alzheimer disease are women. On average, women live longer than men, and older age is the most important risk factor for Alzheimer disease. The percentage of persons with Alzheimer disease approximately doubles every 5 years beyond age 65, with about 30% of 85-year-olds having the disease.

Alzheimer Disease Is Associated With Accumulation of Brain Beta-Amyloid Peptide. Pathologically, one finds increased amounts of *beta-amyloid peptide* in the brains of patients with Alzheimer disease (**Fig. 60.8**). The peptide accumulates in *amyloid plaques*, which range in diameter from 10 micrometers to several hundred micrometers and are found in widespread areas of the brain, including in the cerebral cortex, hippocampus, basal ganglia, thalamus, and even the cerebellum. Thus, Alzheimer disease appears to be a metabolic degenerative disease.

A role for excess accumulation of beta-amyloid peptide in the pathogenesis of Alzheimer disease is suggested by the following observations: (1) all currently known mutations associated with Alzheimer disease increase the production of beta-amyloid peptide; (2) patients with trisomy 21 (Down syndrome) have three copies of the gene for amyloid precursor protein and develop neurological characteristics of Alzheimer disease by midlife; (3) patients who have abnormality of a gene that controls *apolipoprotein E*, a blood protein that transports cholesterol to the tissues, have accelerated deposition of amyloid and greatly increased risk for Alzheimer disease; (4) transgenic mice that overproduce the human amyloid precursor protein have learning and memory deficits in association with the accumulation of amyloid plaques; and (5) generation of anti-amyloid antibodies in humans with Alzheimer disease appears to attenuate the disease process. However, the mechanisms leading to the accumulation of amyloid plaques are still unclear. Also, interventions (e.g., monoclonal antibodies) that target and remove beta-amyloid plaques may slow but do not halt neurodegeneration and cognitive decline in patients with Alzheimer disease. Thus, the precise role of beta-amyloid toxicity in Alzheimer disease is still uncertain.

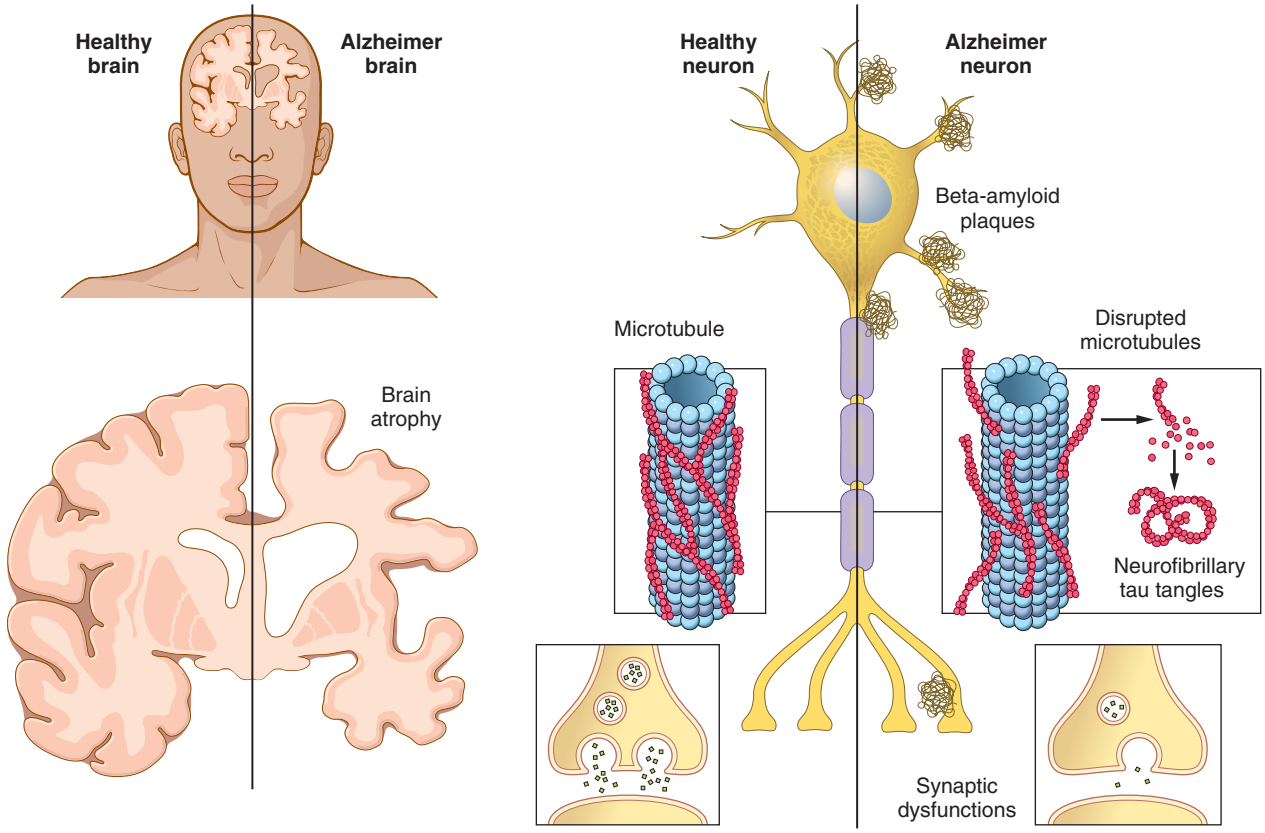

Figure 60.8 Characteristics of the brain in Alzheimer disease compared to the normal healthy brain. In Alzheimer disease there is an accumulation of beta-amyloid protein plaques and neurofibrillary tangles that are composed of hyperphosphorylated tau protein as paired helical filaments. The spread of tangles and plaques in Alzheimer disease is associated with synaptic dysfunction, neuronal death, brain atrophy, and enlarged ventricles. *(Adapted with permission from Perluigi M, Di Domenico F, Butterfield DA. Oxidative damage in neurodegeneration: Roles in the pathogenesis and progression of Alzheimer disease.* Physiol Rev. *2024;104:103-197.)*

Alzheimer Disease Is Associated With Abnormal Intraneuronal Tau Protein. Another hallmark of Alzheimer disease is the accumulation of twisted strands of *tau protein* inside neurons (**Fig. 60.8**). Tau is a protein normally found in cell microtubules and regulates the assembly and maintenance of structural stability of microtubules. In diseased brains, tau becomes hyperphosphorylated, causing the microtubules to disassemble and the free tau molecules to aggregate into clumps and tangles of paired helical filaments. Tau hyperphosphorylation results from abnormal cellular signaling, mainly due to an imbalance in activities of different protein kinases and phosphatases. In Alzheimer disease, brain ischemia and accumulation of beta-amyloid peptide may play a role in triggering this imbalance. The loss of microtubules and accumulation of tau clumps and tangles are thought to stimulate neuroinflammation, contributing to further neuronal injury and to the pathology of Alzheimer disease, as well as other forms of dementia.

Cerebrovascular Disease Contributes to Dementia and Progression of Alzheimer Disease

There is also accumulating evidence that cerebrovascular disease caused by *hypertension, diabetes mellitus*, and *atherosclerosis* may play a key role in dementia and contribute to progression of Alzheimer disease. Cerebrovascular disease is the second most common cause of acquired cognitive impairment and dementia and likely contributes to cognitive decline in most persons with Alzheimer disease. In fact, many of the common risk factors for cerebrovascular disease, such as hypertension, diabetes, and hyperlipidemia, are also recognized to greatly increase the risk for developing dementia and progression of Alzheimer disease. About 10% to 20% of brains from individuals with dementia show evidence of *vascular dementia* alone. In older individuals with Alzheimer disease, vascular disease is common, with about 50% of patients having pathological evidence of "*silent strokes*"—small brain infarcts that cause no readily apparent symptoms but could contribute to cognitive impairment.

CHAPTER 61

The Autonomic Nervous System and the Adrenal Medulla

The *autonomic nervous system* controls most visceral functions of the body. This system helps to control arterial pressure, gastrointestinal motility, gastrointestinal secretion, urinary bladder emptying, sweating, body temperature, and many other activities. Some of these activities are controlled almost entirely and some only partially by the autonomic nervous system.

One of the most striking characteristics of the autonomic nervous system is the rapidity and intensity with which it can change visceral functions. For example, within 3 to 5 seconds, it can increase the heart rate to twice normal, and within 10 to 15 seconds the arterial pressure can be doubled. At the other extreme, the arterial pressure can be decreased low enough within 10 to 15 seconds to cause fainting. Sweating can begin within seconds, and the urinary bladder may empty involuntarily, also within seconds.

GENERAL ORGANIZATION OF THE AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system is activated mainly by centers located in the *spinal cord, brain stem*, and *hypothalamus*. In addition, portions of the cerebral cortex, especially of the limbic cortex, can transmit signals to the lower centers and in this way can influence autonomic control.

The autonomic nervous system also often operates through *visceral reflexes*. That is, subconscious sensory signals from visceral organs can enter the autonomic ganglia, the brain stem, or the hypothalamus and then return *subconscious reflex responses* directly back to the visceral organs to control their activities.

The efferent autonomic signals are transmitted to the various organs of the body through two major subdivisions called the *sympathetic nervous system* and the *parasympathetic nervous system*, the characteristics and functions of which are described in the following sections.

Physiological Anatomy of the Sympathetic Nervous System

Fig. 61.1 shows the general organization of the peripheral portions of the sympathetic nervous system. Shown specifically in the figure are (1) one of the two *paravertebral sympathetic chains of ganglia* that are interconnected with the spinal nerves on the side of the vertebral column, (2) *prevertebral ganglia* (the *celiac, superior mesenteric, aorticorenal, inferior mesenteric*, and *hypogastric*), and (3) nerves extending from the ganglia to the different internal organs.

The sympathetic nerve fibers originate in the spinal cord along with spinal nerves between cord segments T1 and L2 and pass first into the *sympathetic chain* and then to the tissues and organs that are stimulated by the sympathetic nerves.

Preganglionic and Postganglionic Sympathetic Neurons

The sympathetic nerves are different from skeletal motor nerves in the following way. Each sympathetic pathway from the cord to the stimulated tissue is composed of two neurons, a *preganglionic neuron* and a *postganglionic neuron*, in contrast to only a single neuron in the skeletal motor pathway. The cell body of each preganglionic neuron lies in the *intermediolateral horn* of the spinal cord; its fiber passes through a *ventral root* of the cord into the corresponding *spinal nerve*, as shown in **Fig. 61.2**.

Immediately after the spinal nerve leaves the spinal canal, the preganglionic sympathetic fibers leave the spinal nerve and pass through a *white ramus* into one of the *ganglia* of the *sympathetic chain*. The fibers then can take one of the following three courses: (1) they can synapse with postganglionic sympathetic neurons in the ganglion that they enter; (2) they can pass upward or downward in the chain and synapse in one of the other ganglia of the chain; or (3) they can pass for variable distances through the chain and then through one of the *sympathetic nerves* radiating outward from the chain, finally synapsing in a *peripheral sympathetic ganglion*.

Postganglionic sympathetic neurons thus originate either in one of the sympathetic chain ganglia or in one of the peripheral sympathetic ganglia. From either of these two sources, the postganglionic fibers then travel to their destinations in the various organs.

Sympathetic Nerve Fibers in the Skeletal Nerves. Some of the postganglionic fibers pass back from the sympathetic chain into the spinal nerves through *gray rami* at all levels of the cord, as shown in **Fig. 61.2**. These sympathetic fibers are all very small type C fibers, and they extend to all parts of the body via the skeletal nerves. They control the blood vessels, sweat glands, and piloerector muscles of the hairs. About 8% of the fibers in the average skeletal nerve are sympathetic fibers, indicating their great importance.

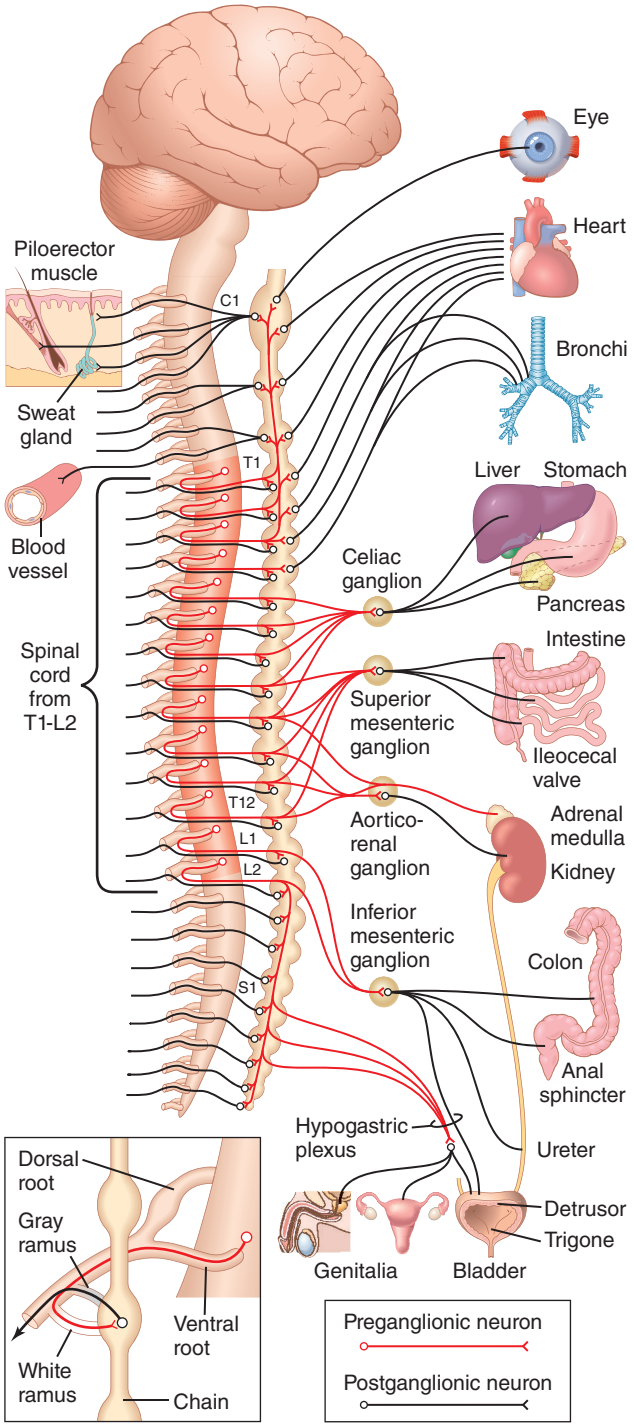

Figure 61.1 Sympathetic nervous system. The *black lines* represent postganglionic fibers, and the *red lines* show preganglionic fibers.

Segmental Distribution of the Sympathetic Nerve Fibers. The sympathetic pathways that originate in the different segments of the spinal cord are not necessarily distributed to the same part of the body as the somatic spinal nerve fibers from the same segments. Instead, the *sympathetic fibers from cord segment T1 generally pass as follows: (1) up the sympathetic chain to terminate in the head; (2) from T2 to terminate in the neck; (3) from T3, T4, T5, and T6 into the thorax; (4) from T7, T8, T9, T10, and T11 into the abdomen; and (5) from T12, L1, and L2 into the legs.* This distribution is only approximate and overlaps greatly.

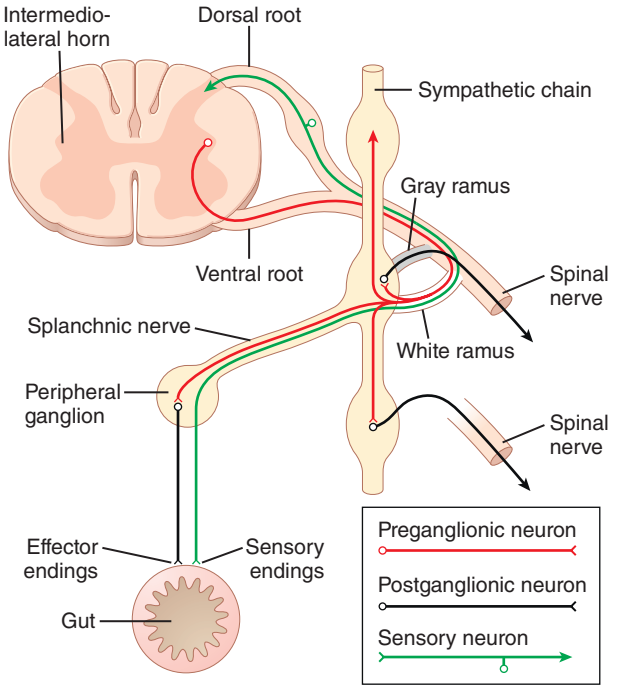

Figure 61.2 Nerve connections among the spinal cord, spinal nerves, sympathetic chain, and peripheral sympathetic nerves.

The distribution of sympathetic nerves to each organ is determined partly by the locus in the embryo from which the organ originated. For example, the heart receives many sympathetic nerve fibers from the neck portion of the sympathetic chain because the heart originated in the neck of the embryo before translocating into the thorax. Likewise, the abdominal organs receive most of their sympathetic innervation from the lower thoracic spinal cord segments because most of the primitive gut originated in this area.

Special Sympathetic Nerve Endings in the Adrenal Medullae. Preganglionic sympathetic nerve fibers pass, *without synapsing*, all the way from the intermediolateral horn cells of the spinal cord, through the sympathetic chains, then through the splanchnic nerves, and finally into the two adrenal medullae. There they end directly on modified neuronal cells that secrete *epinephrine* and *norepinephrine* into the bloodstream. These secretory cells embryologically are derived from nervous tissue and are actually postganglionic neurons; indeed, they even have rudimentary nerve fibers, and it is the endings of these fibers that secrete the adrenal hormones *epinephrine* and *norepinephrine.*

Physiological Anatomy of the Parasympathetic Nervous System

The *parasympathetic nervous system* is shown in **Fig. 61.3**, which demonstrates that parasympathetic fibers leave the central nervous system through cranial nerves III, VII, IX, and X; additional parasympathetic fibers leave the lowermost part of the spinal cord through the second and third sacral spinal nerves and occasionally the first and fourth sacral nerves. About 75% of all parasympathetic nerve fibers are in the *vagus nerves* (cranial nerve X), passing to

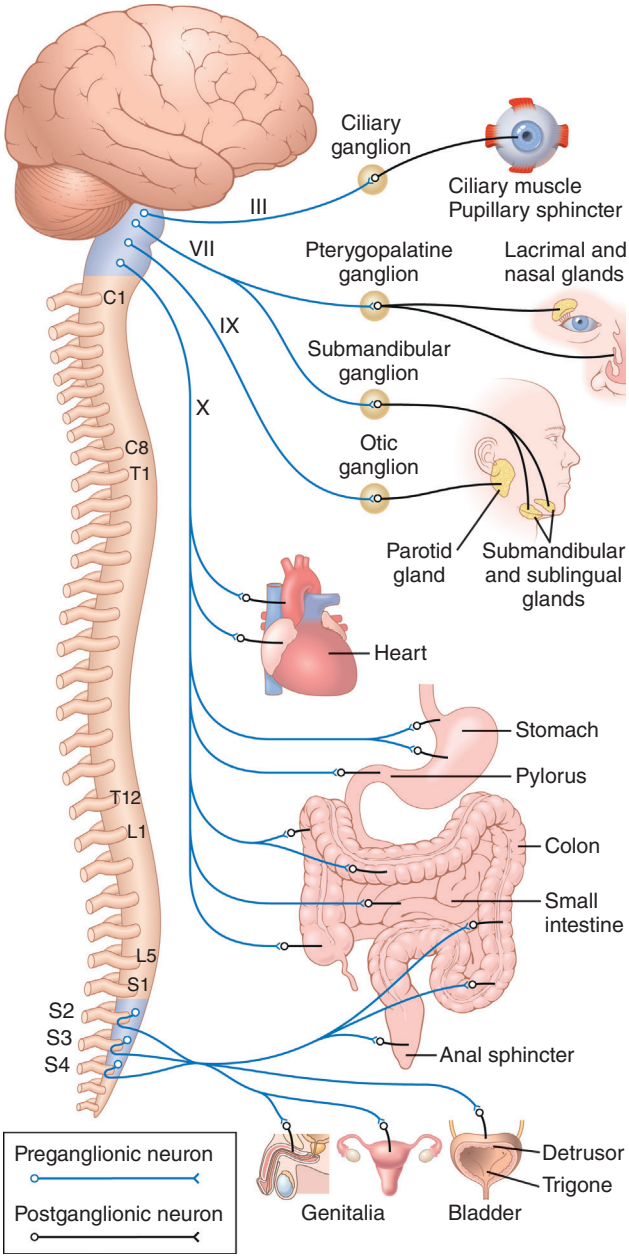

Figure 61.3 The parasympathetic nervous system. The *blue lines* represent preganglionic fibers and the *black lines* show postganglionic fibers.

the entire thoracic and abdominal regions of the body. The vagus nerves supply parasympathetic nerves to the heart, lungs, esophagus, stomach, entire small intestine, proximal half of the colon, liver, gallbladder, pancreas, kidneys, and upper portions of the ureters.

Parasympathetic fibers in the *third cranial nerve* go to the pupillary sphincter and ciliary muscle of the eye. Fibers from the *seventh cranial nerve* pass to the lacrimal, nasal, and submandibular glands, and fibers from the *ninth cranial nerve* go to the parotid gland.

The sacral parasympathetic fibers are in the *pelvic nerves*, which pass through the spinal nerve sacral plexus on each side of the cord at the S2 and S3 levels. These fibers then distribute to the descending colon, rectum, urinary bladder, and lower portions of the ureters. Also, this sacral group of parasympathetics supplies nerve signals to the external genitalia to cause erection.

Preganglionic and Postganglionic Parasympathetic Neurons. The parasympathetic system, like the sympathetic system, has both preganglionic and postganglionic neurons. However, except in the case of a few cranial parasympathetic nerves, the *preganglionic fibers* pass uninterrupted all the way to the organ that is to be controlled. The *postganglionic neurons* are located in the wall of the organ. The preganglionic fibers synapse with these neurons, and extremely short postganglionic fibers, a fraction of a millimeter to several centimeters in length, leave the neurons to innervate the tissues of the organ. This location of the parasympathetic postganglionic neurons in the visceral organ is quite different from the arrangement of the sympathetic ganglia because the cell bodies of the sympathetic postganglionic neurons are almost always located in the ganglia of the sympathetic chain or in various other discrete ganglia in the abdomen, rather than in the excited organ.

BASIC CHARACTERISTICS OF SYMPATHETIC AND PARASYMPATHETIC FUNCTION

CHOLINERGIC AND ADRENERGIC FIBERS—SECRETION OF ACETYLCHOLINE OR NOREPINEPHRINE

The sympathetic and parasympathetic nerve fibers secrete mainly one or the other of two synaptic transmitter substances, *acetylcholine* or *norepinephrine*. The fibers that secrete acetylcholine are said to be *cholinergic* and those that secrete norepinephrine are said to be *adrenergic*.

All *preganglionic neurons* are *cholinergic* in both the sympathetic and parasympathetic nervous systems (**Fig. 61.4**). Acetylcholine or acetylcholine-like substances, when applied to the ganglia, will excite sympathetic and parasympathetic postganglionic neurons. Either *all or almost all of the postganglionic neurons of the parasympathetic system are also cholinergic*. In contrast, *most of the postganglionic sympathetic neurons are adrenergic*. However, the postganglionic sympathetic nerve fibers to the sweat glands and perhaps to a few blood vessels are cholinergic.

Thus, the terminal nerve endings of the parasympathetic system *all or virtually all* secrete *acetylcholine*. Almost all of the sympathetic nerve endings secrete *norepinephrine*, but a few secrete acetylcholine. These neurotransmitters in turn act on the different organs to cause respective parasympathetic or sympathetic effects. Therefore, acetylcholine is called a *parasympathetic transmitter* and norepinephrine is called a *sympathetic transmitter*.

Mechanisms of Transmitter Secretion and Removal at Postganglionic Endings

Secretion of Acetylcholine and Norepinephrine By Postganglionic Nerve Endings. A few of the

postganglionic autonomic nerve endings, especially those of the parasympathetic nerves, are similar to but much smaller than those of the skeletal neuromuscular junction. However, many of the parasympathetic nerve fibers and almost all the sympathetic fibers merely touch the effector cells of the organs that they innervate as they pass by, or in some cases, they terminate in connective tissue located adjacent to the cells that are to be stimulated. Where these filaments touch or pass over or near the cells to be stimulated, they usually have bulbous enlargements called *varicosities* (see **Fig. 61.4**). It is in these varicosities that the transmitter vesicles of acetylcholine or norepinephrine are synthesized and stored. Also in the varicosities are large numbers of mitochondria that supply adenosine triphosphate (ATP), which is required to energize acetylcholine or norepinephrine synthesis.

When an action potential spreads over the terminal fibers, the depolarization process increases the permeability of the fiber membrane to calcium ions, allowing these ions to diffuse into the nerve terminals or nerve varicosities. The calcium ions, in turn, cause the terminals or varicosities to empty their contents to the exterior. Thus, the transmitter substance is secreted.

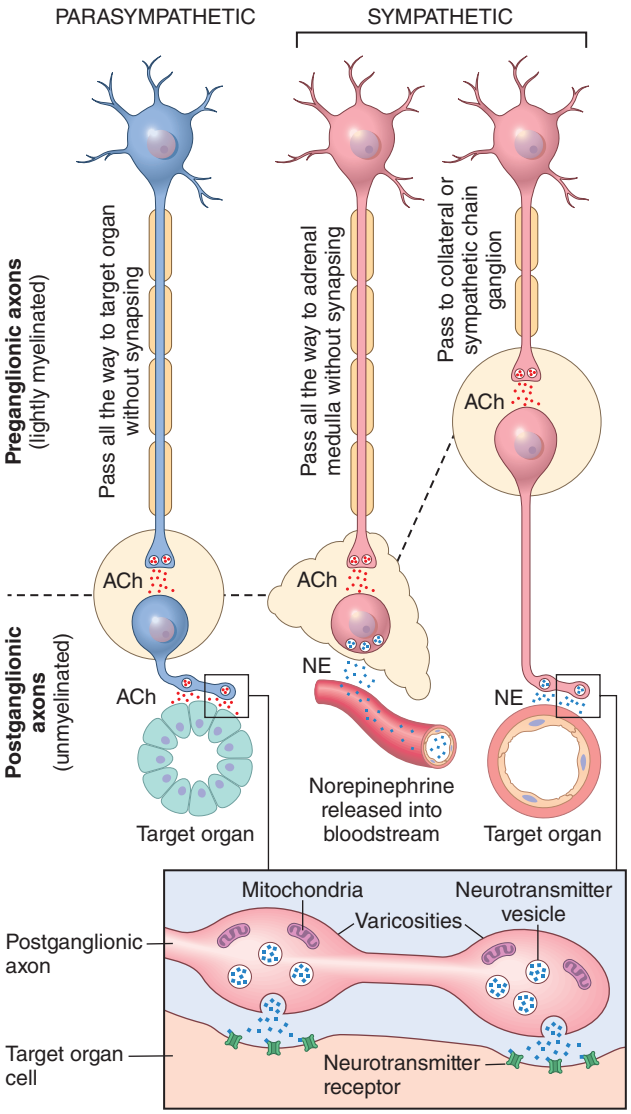

Figure 61.4 Preganglionic sympathetic and parasympathetic axons are both lightly myelinated, and both use acetylcholine (Ach) as the neurotransmitter. Postganglionic axons are unmyelinated. Most sympathetic postganglionic axons store norepinephrine (NE) in their varicosities and release this neurotransmitter over the surface of the target tissue. Postganglionic parasympathetic axons store Ach in varicosities and release Ach onto the target tissue surface.

Synthesis of Acetylcholine, Its Destruction After Secretion, and Its Duration of Action. Acetylcholine is synthesized in the terminal endings and varicosities of the cholinergic nerve fibers, where it is stored in vesicles in highly concentrated form until it is released. The basic chemical reaction of this synthesis is the following (CoA = coenzyme A):

$$\text{Acetyl–CoA} + \text{Choline} \xrightarrow[\text{acetyltransferase}]{\text{Choline}} \text{Acetylcholine}$$

Once acetylcholine is secreted into a tissue by a cholinergic nerve ending, it persists in the tissue for a few seconds while it performs its nerve signal transmitter function. Then it is split into an *acetate ion* and *choline*, catalyzed by the enzyme *acetylcholinesterase*, which is bound with collagen and glycosaminoglycans in the local connective tissue. This mechanism is the same as that for acetylcholine signal transmission and subsequent acetylcholine destruction that occurs at the neuromuscular junctions of skeletal nerve fibers. The choline that is formed is then transported back into the terminal nerve ending, where it is used again and again for synthesis of new acetylcholine.

Norepinephrine Synthesis, Removal, and Duration of Action. Synthesis of norepinephrine begins in the axoplasm of the terminal nerve endings of adrenergic nerve fibers but is completed inside the secretory vesicles. The basic steps are the following:

1. $\text{Tyrosine} \xrightarrow{\text{Hydroxylation}} \text{Dopa}$
2. $\text{Dopa} \xrightarrow{\text{Decarboxylation}} \text{Dopamine}$
3. Transport of dopamine into the vesicles
4. $\text{Dopamine} \xrightarrow{\text{Hydroxylation}} \text{Norepinephrine}$

In the adrenal medulla, this reaction goes still one step further to transform about 80% of the norepinephrine into epinephrine, as follows:

5. $\text{Norepinephrine} \xrightarrow{\text{Methylation}} \text{Epinephrine}$

After secretion of norepinephrine by the terminal nerve endings, it is removed from the secretory site in three ways: (1) reuptake into the adrenergic nerve endings by an active transport process, accounting for removal of 50% to 80% of the secreted norepinephrine; (2) diffusion away from the nerve endings into the surrounding body fluids and then into the blood, accounting for removal of most of the remaining norepinephrine; and (3) destruction of small amounts by tissue enzymes. One of these enzymes is *monoamine oxidase*, which is found in the

nerve endings, and another is *catechol-O-methyl transferase*, which is present diffusely in the tissues.

Ordinarily, the norepinephrine secreted directly into a tissue remains active for only a few seconds, as its reuptake and diffusion away from the tissue are rapid. However, the norepinephrine and epinephrine secreted into the blood by the adrenal medullae remain active until they diffuse into some tissue, where they can be destroyed by catechol-*O*-methyl transferase; this action occurs mainly in the liver. Therefore, when secreted into the blood, both norepinephrine and epinephrine remain active for 10 to 30 seconds, but their activity declines to extinction over 1 minute to several minutes.

RECEPTORS ON EFFECTOR ORGANS

Before acetylcholine, norepinephrine, or epinephrine secreted at an autonomic nerve ending can stimulate an effector organ, it must first bind with specific *receptors* on the effector cells. The receptor is on the outside of the cell membrane, bound as a prosthetic group to a protein molecule that penetrates all the way through the cell membrane. Binding of the transmitter substance with the receptor causes a conformational change in the structure of the protein molecule. In turn, the altered protein molecule excites or inhibits the cell, most often by (1) causing a change in cell membrane permeability to one or more ions or (2) activating or inactivating an enzyme attached to the other end of the receptor protein, where it protrudes into the interior of the cell.

Effector Cell Excitation or Inhibition By Changing Its Membrane Permeability. Because the receptor protein is an integral part of the cell membrane, a conformational change in structure of the receptor protein often *opens or closes an ion channel* through the interstices of the protein molecule, thus altering the permeability of the cell membrane to various ions. For example, sodium and/or calcium ion channels frequently become opened and allow rapid influx of the respective ions into the cell, usually depolarizing the cell membrane and *exciting* the cell. At other times, potassium channels are opened, allowing potassium ions to diffuse out of the cell, which usually *inhibits* the cell because loss of electropositive potassium ions creates hypernegativity inside the cell. In some cells, the changed intracellular ion environment will cause an internal cell action, such as a direct effect of calcium ions to promote smooth muscle contraction.

Receptor Action By Altering Intracellular "Second Messenger" Enzymes. Another way a receptor often functions is to activate or inactivate an enzyme (or other intracellular chemical) inside the cell. The enzyme often is attached to the receptor protein where the receptor protrudes into the interior of the cell. For example, binding of norepinephrine with its receptor on the outside of many cells increases the activity of the enzyme *adenylate cyclase* on the inside of the cell, which causes formation of *cyclic adenosine monophosphate* (cAMP). The cAMP in turn can initiate any one of many different intracellular actions, with the exact effect depending on the specific effector cell and its chemical machinery.

An autonomic transmitter substance can therefore cause inhibition in some organs or excitation in others, depending on the type of receptor protein in the cell membrane and the effect of receptor binding on its conformational state. In each organ, the resulting effects are likely to be different from those in other organs.

Two Principal Types of Acetylcholine Receptors—Muscarinic and Nicotinic Receptors

Acetylcholine activates mainly two types of *receptors*, which are called *muscarinic* and *nicotinic receptors*. The reason for these names is that muscarine, a poison from toadstools, activates only muscarinic receptors and will not activate nicotinic receptors, whereas nicotine activates only nicotinic receptors. Acetylcholine activates both of them.

Muscarinic receptors, which use G proteins as their signaling mechanism, are found on all effector cells that are stimulated by the postganglionic cholinergic neurons of either the parasympathetic nervous system or the sympathetic system.

Nicotinic receptors are ligand-gated ion channels found in autonomic ganglia at the synapses between the preganglionic and postganglionic neurons of both the sympathetic and parasympathetic systems. Nicotinic receptors are also present at many nonautonomic nerve endings—for example, at the neuromuscular junctions in skeletal muscle, discussed in Chapter 7.

An understanding of the two types of receptors is especially important because specific drugs are frequently used as medicine to stimulate or block one or the other of the two types of receptors.

Alpha and Beta Adrenergic Receptors

The two major classes of adrenergic receptors are called *alpha receptors* and *beta receptors*. There are two major subtypes of alpha receptors, $alpha_1$ and $alpha_2$, which are linked to different G proteins. The beta receptors are divided into $beta_1$, $beta_2$, and $beta_3$ receptors because certain chemicals affect only certain beta receptors. The beta receptors also use G proteins for signaling.

Norepinephrine and epinephrine, both of which are secreted into the blood by the adrenal medulla, have slightly different effects in exciting the alpha and beta receptors. Norepinephrine excites mainly alpha receptors but excites the beta receptors to a lesser extent as well. Epinephrine excites both types of receptors approximately equally. Therefore, the relative effects of norepinephrine and epinephrine on different effector organs are determined by the types of receptors in the organs. If they are all beta receptors, epinephrine will be the more effective excitant.

Table 61.1 Adrenergic Receptors and Function

Alpha Receptor	Beta Receptor
Vasoconstriction	Vasodilation (β_2)
Iris dilation	Cardioacceleration (β_1)
Intestinal relaxation	Increased myocardial strength (β_1)
Intestinal sphincter contraction	Intestinal relaxation (β_2)
	Uterus relaxation (β_2)
Pilomotor contraction	Bronchodilation (β_2)
Bladder sphincter contraction	Calorigenesis (β_2)
Inhibits neurotransmitter release (α_2)	Glycogenolysis (β_2)
	Lipolysis (β_1)
	Bladder wall relaxation (β_2)
	Thermogenesis (β_3)

Table 61.1 lists the distribution of alpha and beta receptors in some of the organs and systems controlled by the sympathetic nerves. Note that certain alpha functions are excitatory, whereas others are inhibitory. Likewise, certain beta functions are excitatory and others are inhibitory. Therefore, alpha and beta receptors are not necessarily associated with excitation or inhibition but simply with the affinity of the hormone for the receptors in the given effector organ.

As discussed later in the chapter, several *sympathomimetic* drugs have been developed that mimic the actions of the endogenous catecholamines, norepinephrine and epinephrine. Some of these compounds selectively activate alpha or beta adrenergic receptors. For example, a synthetic drug chemically similar to epinephrine and norepinephrine, *isoprenaline (isoproterenol)*, has an extremely strong action on beta receptors but essentially no action on alpha receptors. In contrast, *phenylephrine* is an alpha$_1$ receptor agonist with little or no beta receptor agonist activity.

EXCITATORY AND INHIBITORY ACTIONS OF SYMPATHETIC AND PARASYMPATHETIC STIMULATION

Table 61.2 lists the effects on different visceral functions of the body caused by stimulating either the parasympathetic nerves or the sympathetic nerves. Note again that *sympathetic stimulation causes excitatory effects in some organs but inhibitory effects in others. Likewise, parasympathetic stimulation causes excitation in some organs but inhibition in others.* Also, when sympathetic stimulation excites a particular organ, parasympathetic stimulation sometimes inhibits it, demonstrating that the two systems may act reciprocally to each other. However, most organs are dominantly controlled by one or the other of the two systems.

There is no generalization one can use to explain whether sympathetic or parasympathetic stimulation will cause excitation or inhibition of a particular organ. Therefore, to understand sympathetic and parasympathetic function, one must learn all the separate functions of these two nervous systems on each organ, as listed in **Table 61.2**. Some of these functions need to be clarified in greater detail, as follows.

Effects of Sympathetic and Parasympathetic Stimulation on Specific Organs

Eyes. Two important functions of the eyes are controlled by the autonomic nervous system: (1) the pupillary opening and (2) the focus of the lens.

Sympathetic stimulation *contracts the meridional fibers of the iris to dilate the pupil*, whereas parasympathetic stimulation *contracts the circular muscle of the iris to constrict the pupil*.

The parasympathetics that control the pupil are reflexly stimulated when excess light enters the eyes, which is explained in Chapter 52; this reflex reduces the pupillary opening and decreases the amount of light that strikes the retina. Conversely, the sympathetics become stimulated during periods of excitement and increase pupillary opening at these times.

Focusing of the lens is controlled almost entirely by the parasympathetic nervous system. The lens is normally held in a flattened state by intrinsic elastic tension of its radial ligaments. Parasympathetic excitation contracts the *ciliary muscle*, which is a ringlike body of smooth muscle fibers that encircles the outside ends of the lens radial ligaments. This contraction releases the tension on the ligaments and allows the lens to become more convex, causing the eye to focus on nearby objects. The detailed focusing mechanism is discussed in Chapters 50 and 52 in relation to function of the eyes.

Glands of the Body. The *nasal, lacrimal, salivary*, and many *gastrointestinal glands* are strongly stimulated by the parasympathetic nervous system, usually resulting in copious quantities of watery secretion. The glands of the alimentary tract most strongly stimulated by the parasympathetics are those of the upper tract, especially those of the mouth and stomach. On the other hand, the glands of the small and large intestines are controlled principally by local factors in the intestinal tract and by the *intestinal enteric nervous system;* they are controlled much less by the autonomic nerves.

Sympathetic stimulation has a direct effect on most alimentary gland cells to cause formation of a concentrated secretion that contains high percentages of enzymes and mucus. However, it also causes vasoconstriction of the blood vessels that supply the glands and in this way sometimes reduces their rates of secretion.

The *sweat glands* increase their secretion of sweat when the sympathetic nerves are stimulated, but no effect is caused by stimulating the parasympathetic nerves. However, the sympathetic fibers to most sweat glands are *cholinergic* (except for a few adrenergic fibers to the palms and soles), in contrast to almost all other sympathetic fibers, which are adrenergic. Furthermore, the sweat glands are stimulated

Table 61.2 Autonomic Effects on Various Organs of the Body

Organ	Effect of Sympathetic Stimulation	Effect of Parasympathetic Stimulation
Eye		
Pupil	Dilation	Constriction
Ciliary muscle	Slight relaxation (far vision)	Constriction (near vision)
Glands	Vasoconstriction and slight secretion	Stimulation of copious secretion (containing many enzymes for enzyme-secreting glands)
Nasal Lacrimal Parotid Submandibular Gastric Pancreatic		
Sweat glands	Copious sweating (cholinergic)	Sweating on palms of hands
Apocrine glands	Thick, odoriferous secretion	None
Blood vessels	Most often constriction	Most often little or no effect
Heart		
Sinus node rhythm	Increased rate	Slowed rate
Cardiac muscle	Increased force of contraction	Slight decreased force of contraction (atria)
Coronaries	Dilated (β_2); constriction (α)	Dilation (slight)
Lungs		
Bronchi	Dilation	Constriction
Blood vessels	Mild constriction	? Dilation (slight)
Gut		
Lumen	Decreased peristalsis and tone	Increased peristalsis and tone
Sphincter	Increased tone (most times)	Relaxation (most times)
Liver	Glucose released	Slight glycogen synthesis
Gallbladder and bile ducts	Relaxation	Contraction
Kidney	Decreased urine output and increased renin secretion	None
Bladder		
Detrusor	Relaxation (slight)	Contraction
Trigone	Contraction	Relaxation
Penis	Ejaculation	Erection
Systemic arterioles		
Abdominal viscera	Constriction	None
Muscle	Constriction (α-adrenergic) Dilation (β_2-adrenergic) Dilation (slight, cholinergic)	None
Skin	Constriction	None
Blood		
Coagulation	Increased	None
Glucose	Increased	None
Lipids	Increased	None
Basal metabolism	Increased up to 100%	None
Adrenal medullary secretion	Increased	None
Mental activity	Increased	None
Piloerector muscles	Contracted	None
Skeletal muscle	Increased glycogenolysis Increased strength	None
Fat cells	Lipolysis	None

primarily by centers in the hypothalamus that are usually considered to be parasympathetic centers. Therefore, sweating could be called a parasympathetic function, even though it is controlled by nerve fibers that anatomically are distributed through the sympathetic nervous system.

The *apocrine glands* in the axillae secrete a thick, odoriferous secretion as a result of sympathetic stimulation, but they do not respond to parasympathetic stimulation. This secretion actually functions as a lubricant to allow easy sliding motion of the inside surfaces under the shoulder joint. The apocrine glands, despite their close embryological relation to sweat glands, are activated by adrenergic fibers rather than by cholinergic fibers and are also controlled by the sympathetic centers of the central nervous system rather than by the parasympathetic centers.

Intramural Nerve Plexus of the Gastrointestinal System. The gastrointestinal system has its own intrinsic set of nerves known as the *intramural plexus* or the *intestinal enteric nervous system*, located in the walls of the gut. Also, both parasympathetic and sympathetic stimulation originating in the brain can affect gastrointestinal activity, mainly by increasing or decreasing specific actions in the gastrointestinal intramural plexus. Parasympathetic stimulation, in general, increases the overall activity of the gastrointestinal tract by promoting peristalsis and relaxing the sphincters, thus allowing rapid propulsion of contents along the tract. This propulsive effect is associated with simultaneous increases in rates of secretion by many of the gastrointestinal glands, described earlier.

Normal motility functions of the gastrointestinal tract are not very dependent on sympathetic stimulation. However, strong sympathetic stimulation inhibits peristalsis and increases the tone of the sphincters. The net result is greatly slowed propulsion of food through the tract and sometimes decreased secretion as well—even to the extent of sometimes causing constipation.

Heart. In general, sympathetic stimulation increases the overall activity of the heart. This effect is accomplished by increasing both the rate and force of heart contraction.

Parasympathetic stimulation causes mainly opposite effects—decreased heart rate and strength of contraction, although the effects on cardiac muscle contraction are modest. To express these effects in another way, sympathetic stimulation increases the effectiveness of the heart as a pump, as required during heavy exercise, whereas parasympathetic stimulation decreases heart pumping, allowing the heart to rest between bouts of strenuous activity.

Systemic Blood Vessels. Most systemic blood vessels, especially those of the abdominal viscera and skin of the limbs, are constricted by sympathetic stimulation. Parasympathetic stimulation has almost no effect on most blood vessels. Under some conditions, the beta adrenergic function of the sympathetics causes vascular dilation instead of the usual vascular constriction; however, this dilation occurs rarely except after drugs have paralyzed the sympathetic alpha vasoconstrictor effects, which, in most blood vessels, are usually far dominant over the beta effects.

Effect of Sympathetic and Parasympathetic Stimulation on Arterial Pressure. The arterial pressure is determined by two factors, propulsion of blood by the heart, as reflected by cardiac output, and resistance to flow of blood through the peripheral blood vessels. Sympathetic stimulation increases both propulsion by the heart and resistance to flow, which usually causes a marked *acute* increase in arterial pressure but often very little change in long-term pressure unless the sympathetics also stimulate the kidneys to retain salt and water at the same time.

Conversely, moderate parasympathetic stimulation via the vagal nerves decreases pumping by the heart but has virtually no effect on vascular peripheral resistance. Therefore, the usual effect is a slight decrease in arterial pressure. However, *very strong vagal parasympathetic* stimulation can almost stop or occasionally stop the heart entirely for a few seconds and cause a drastic decrease of arterial pressure.

Effects of Sympathetic and Parasympathetic Stimulation on Other Functions of the Body. Because of the great importance of the sympathetic and parasympathetic control systems, they are discussed many times in this text in relation to multiple body functions. In general, most of the entodermal structures, such as the ducts of the liver, gallbladder, ureter, urinary bladder, and bronchi, are inhibited by sympathetic stimulation but excited by parasympathetic stimulation. Sympathetic stimulation also has multiple metabolic effects, such as release of glucose from the liver and an increase in blood glucose concentration, glycogenolysis in liver and muscle, skeletal muscle strength, basal metabolic rate, and mental activity. Finally, the sympathetics and parasympathetics are involved in execution of the male and female sexual acts, as explained in Chapters 81 and 82.

FUNCTION OF THE ADRENAL MEDULLAE

Stimulation of the sympathetic nerves to the adrenal medullae causes large quantities of epinephrine and norepinephrine to be released into the circulating blood, and these two hormones in turn are carried in the blood to all tissues of the body. On average, about 80% of the secretion is epinephrine and 20% is norepinephrine, although the relative proportions can change considerably under different physiological conditions.

The circulating epinephrine and norepinephrine have almost the same effects on the different organs as the effects caused by direct sympathetic stimulation, except that *the effects last 5 to 10 times as long* because both of these hormones are removed from the blood over a period of 2 to 4 minutes.

The circulating norepinephrine causes constriction of most of the blood vessels of the body; it also increases activity of the heart, inhibits the gastrointestinal tract, dilates the pupils of the eyes, and so forth.

Epinephrine causes almost the same effects as those caused by norepinephrine, but the effects differ in the following respects. First, epinephrine, because of its greater effect in stimulating the beta receptors, has a greater effect on cardiac stimulation than does norepinephrine. Second, epinephrine causes only weak constriction of the blood vessels in the muscles, in comparison with much stronger constriction caused by norepinephrine. Because the

muscle vessels represent a major segment of the vessels of the body, this difference is of special importance because norepinephrine greatly increases the total peripheral resistance and elevates arterial pressure, whereas epinephrine raises the arterial pressure to a lesser extent but increases the cardiac output more.

A third difference between the actions of epinephrine and norepinephrine relates to their effects on tissue metabolism. Epinephrine has 5 to 10 times greater metabolic effect as does norepinephrine. Indeed, the epinephrine secreted by the adrenal medullae can increase the metabolic rate of the whole body as much as 100% above normal, in this way increasing the activity and excitability of the body. It also increases the rates of other metabolic activities, such as glycogenolysis in the liver and muscle and glucose release into the blood.

In summary, stimulation of the adrenal medullae causes release of the hormones epinephrine and norepinephrine, which together have many of the same effects throughout the body as direct sympathetic stimulation, except that the effects are more prolonged, lasting 2 to 4 minutes after the stimulation is over.

The Adrenal Medullae Support Sympathetic Nervous System Functions. Epinephrine and norepinephrine are almost always released by the adrenal medullae at the same time that the different organs are stimulated directly by generalized sympathetic activation. Therefore, the organs are actually stimulated in two ways—directly by the sympathetic nerves and indirectly by the adrenal medullary hormones. The two means of stimulation support each other and either can, in most cases, substitute for the other. For example, destruction of the direct sympathetic pathways to the different body organs does not abrogate sympathetic excitation of the organs because norepinephrine and epinephrine are still released into the circulating blood and indirectly cause stimulation. Likewise, loss of the two adrenal medullae usually has little effect on the operation of the sympathetic nervous system because the direct pathways can still perform almost all the necessary duties. Thus, the dual mechanism of sympathetic stimulation provides a safety factor, with one mechanism substituting for the other if it is missing.

Another important value of the adrenal medullae is the capability of epinephrine and norepinephrine to stimulate structures of the body that are not innervated by direct sympathetic fibers. For example, the metabolic rate of almost every cell of the body is increased by these hormones, especially by epinephrine, even though only a small proportion of all the cells in the body are innervated directly by sympathetic fibers.

RELATION OF STIMULUS RATE TO SYMPATHETIC AND PARASYMPATHETIC EFFECTS

A special difference between the autonomic nervous system and the skeletal motor nervous system is that only a low frequency of stimulation is required for full activation of autonomic effectors. In general, only one nerve impulse every few seconds suffices to maintain normal sympathetic or parasympathetic effect, and full activation occurs when the nerve fibers discharge 10 to 20 times/sec. This rate compares with full activation in the skeletal nervous system at 50 to 500 or more impulses/sec.

SYMPATHETIC AND PARASYMPATHETIC "TONE"

Normally, the sympathetic and parasympathetic systems are continually active, and the basal rates of activity are known, respectively, as *sympathetic tone* and *parasympathetic tone*. The value of tone is that *it allows a single nervous system to both increase and decrease the activity of a stimulated organ*. For example, sympathetic tone normally keeps almost all the systemic arterioles constricted to about one-half their maximum diameter. By increasing the degree of sympathetic stimulation above normal, these vessels can be constricted even more; conversely, by decreasing the stimulation below normal, the arterioles can be dilated. Thus, the sympathetic system can cause vasoconstriction or vasodilation by increasing or decreasing its activity, respectively.

Another interesting example of tone is the background "tone" of the parasympathetics in the gastrointestinal tract. Surgical removal of the parasympathetic supply to most of the gut by cutting the vagus nerves can cause serious and prolonged gastric and intestinal "atony" with resulting blockage of much of the normal gastrointestinal propulsion and consequent serious constipation, thus demonstrating that parasympathetic tone to the gut is normally very much required. This tone can be decreased by the brain, thereby inhibiting gastrointestinal motility, or it can be increased, thereby promoting increased gastrointestinal activity.

Tone Caused By Basal Secretion of Epinephrine and Norepinephrine By the Adrenal Medullae. The normal resting rate of secretion by the adrenal medullae is about 0.2 μg/kg/min of epinephrine and about 0.05 μg/kg/min of norepinephrine. These quantities are enough to maintain the blood pressure almost normal even if all direct sympathetic pathways to the cardiovascular system are removed. Therefore, it is obvious that much of the overall tone of the sympathetic nervous system results from basal secretion of epinephrine and norepinephrine, in addition to the tone resulting from direct sympathetic stimulation.

Effect of Loss of Sympathetic or Parasympathetic Tone After Denervation. Immediately after sympathetic or parasympathetic nerves are cut, the innervated organ loses its sympathetic or parasympathetic tone. In many blood vessels, for example, cutting the sympathetic nerves results in substantial vasodilation within 5 to 30 seconds. However, over minutes, hours, days, or

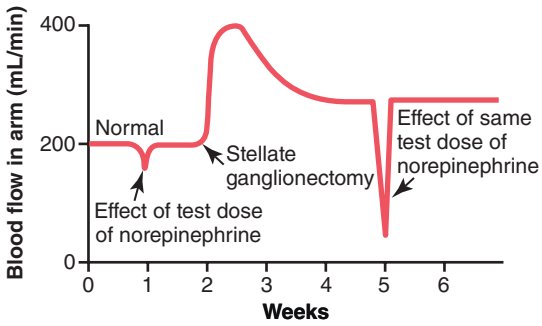

Figure 61.5 Effect of sympathectomy on blood flow in the arm and effect of a test dose of norepinephrine before and after sympathectomy, showing *supersensitization* of the vasculature to norepinephrine.

weeks, *intrinsic tone* in the smooth muscle of the vessels increases. This increased tone is caused by increased smooth muscle contractile force that is *not* the result of sympathetic stimulation but of chemical adaptations in the smooth muscle fibers, including increased sensitivity to the effects of circulating catecholamines secreted by the adrenal medullae. This intrinsic tone and increased sensitivity to circulating catecholamines eventually restore almost normal vasoconstriction.

Essentially the same effects occur in most other effector organs whenever sympathetic or parasympathetic tone is lost. That is, intrinsic compensation soon develops to return the function of the organ almost to its normal basal level. However, in the parasympathetic system, the compensation sometimes requires many months. For example, loss of parasympathetic tone to the heart after cardiac vagotomy increases the heart rate from ~70 beats/min to ~160 beats/min in a dog, and this rate will still be partially elevated 6 months later. Likewise, loss of parasympathetic tone to the gastrointestinal system has long-lasting effects on the gut.

"Supersensitivity" to Norepinephrine and Acetylcholine After Denervation

During the first week or so after a sympathetic or parasympathetic nerve is destroyed, the innervated organ becomes more sensitive to injected norepinephrine or acetylcholine, respectively. This effect is demonstrated in **Fig. 61.5**, which shows that blood flow in the forearm before removal of the sympathetics is about 200 mL/min; a test dose of norepinephrine causes only a slight depression in flow, lasting a minute or so. Then the stellate ganglion is removed, and normal sympathetic tone is lost. At first, the blood flow rises markedly because of the lost vascular tone, but over a period of days to weeks the blood flow returns much of the way back toward normal because of a progressive increase in the intrinsic tone of the vascular musculature, thus partially compensating for the loss of sympathetic tone. Then, another test dose of norepinephrine is administered, and the blood flow decreases much more than before, demonstrating that the blood vessels have become about two to four times as responsive to norepinephrine as previously. This phenomenon is called *denervation supersensitivity*. It occurs in both sympathetic and parasympathetic organs but to a far greater extent in some organs than in others, occasionally increasing the response more than 10-fold.

Mechanism of Denervation Supersensitivity. The cause of denervation supersensitivity is only partially known. Part of the answer is that the synthesis of receptors in postsynaptic membranes of the effector cells increases, increasing the number of receptors—sometimes many times—when norepinephrine or acetylcholine is no longer released at the synapses. This process is called *up-regulation* of the receptors, and when a dose of the hormone is now injected into the circulating blood, the effector reaction is vastly enhanced.

Autonomic Reflexes

Many visceral functions of the body are regulated by *autonomic reflexes*. Throughout this text, the functions of these reflexes are discussed in relation to individual organ systems; to illustrate their importance, a few are briefly presented here.

Cardiovascular Autonomic Reflexes. Several reflexes in the cardiovascular system help control the arterial blood pressure and heart rate. One of these reflexes is the *baroreceptor reflex*, which is described in Chapter 18 along with other cardiovascular reflexes. Briefly, stretch receptors called *baroreceptors* are located in the walls of several major arteries, especially in the internal carotid arteries and the arch of the aorta. When these become stretched by high pressure, signals are transmitted to the brain stem, where they inhibit the sympathetic impulses to the heart and blood vessels and excite the parasympathetics; this allows the arterial pressure to fall back toward normal.

Gastrointestinal Autonomic Reflexes. The uppermost part of the gastrointestinal tract and the rectum are controlled principally by autonomic reflexes. For example, the smell of appetizing food or the presence of food in the mouth initiates signals from the nose and mouth to the vagal, glossopharyngeal, and salivatory nuclei of the brain stem. These nuclei in turn transmit signals through the parasympathetic nerves to the secretory glands of the mouth and stomach, causing secretion of digestive juices sometimes even before food enters the mouth.

When fecal matter fills the rectum at the other end of the alimentary canal, sensory impulses initiated by stretching the rectum are sent to the sacral portion of the spinal cord, and a reflex signal is transmitted back through the sacral parasympathetics to the distal parts of the colon; these signals result in strong peristaltic contractions that cause defecation.

Other Autonomic Reflexes. Emptying of the urinary bladder is controlled in the same way as emptying of the rectum; stretching of the bladder sends impulses to the sacral cord, which in turn causes reflex contraction of the bladder and relaxation of the urinary sphincters, thereby promoting micturition.

Also important are the sexual reflexes, which are initiated both by psychic stimuli from the brain and by stimuli from the sexual organs. Impulses from these sources converge on the sacral cord and, in the male, result first in *erection, mainly a parasympathetic function*, and then *ejaculation, partially a sympathetic function*.

Other autonomic control functions include reflex contributions to the regulation of pancreatic secretion, gallbladder emptying, kidney excretion of urine, sweating, blood glucose concentration, and many other visceral functions, all of which are discussed in detail at other points in this text.

SELECTIVE STIMULATION OF TARGET ORGANS BY SYMPATHETIC AND PARASYMPATHETIC SYSTEMS OR "MASS DISCHARGE"

The Sympathetic System Sometimes Responds By Mass Discharge. In some cases, almost all portions of the sympathetic nervous system discharge simultaneously as a complete unit, a phenomenon called *mass discharge*. This frequently occurs when the hypothalamus is activated by fright or severe pain. The result is a widespread reaction throughout the body called the *alarm* or *stress response*, which is discussed shortly.

At other times, selective activation occurs in isolated portions of the sympathetic nervous system. Important examples are the following:

1. During the process of heat regulation, the sympathetics control sweating and blood flow in the skin without affecting other organs innervated by the sympathetics.
2. Many "local reflexes" involving sensory afferent fibers travel centrally in the peripheral nerves to the sympathetic ganglia and spinal cord and cause highly localized reflex responses. For example, heating a skin area causes local vasodilation and enhanced local sweating, whereas cooling causes opposite effects.
3. Many of the sympathetic reflexes that control gastrointestinal functions operate by way of nerve pathways that do not even enter the spinal cord, merely passing from the gut mainly to the paravertebral ganglia, and then back to the gut through sympathetic nerves to control motor or secretory activity.

The Parasympathetic System Usually Causes Specific Localized Responses. Control functions by the parasympathetic system are often highly specific. For example, parasympathetic cardiovascular reflexes usually act on the heart only to increase or decrease its rate of beating with little direct effect on its force of contraction. Likewise, other parasympathetic reflexes cause secretion mainly by the mouth glands, and in other cases, secretion is mainly by the stomach glands. Finally, the rectal emptying reflex does not affect other parts of the bowel to a major extent.

Yet, there is often association between closely allied parasympathetic functions. For example, although salivary secretion can occur independently of gastric secretion, these two often occur together, and pancreatic secretion frequently occurs at the same time. Also, the rectal emptying reflex often initiates a urinary bladder emptying reflex, resulting in simultaneous emptying of both the bladder and the rectum. Conversely, the bladder emptying reflex can help initiate rectal emptying.

"Alarm" or "Stress" Response of the Sympathetic Nervous System

When large portions of the sympathetic nervous system discharge at the same time—that is, a *mass discharge*—this action increases the ability of the body to perform vigorous muscle activity in many ways, as summarized in the following list:

1. Increased arterial pressure
2. Increased blood flow to active muscles concurrent with decreased blood flow to organs such as the gastrointestinal tract and the kidneys that are not needed for rapid motor activity
3. Increased rates of cellular metabolism throughout the body
4. Increased blood glucose concentration
5. Increased glycolysis in the liver and in muscle
6. Increased muscle strength
7. Increased mental activity
8. Increased rate of blood coagulation

The sum of these effects permits a person to perform far more strenuous physical activity than would otherwise be possible. Because either *mental* or *physical stress* can excite the sympathetic system, it is frequently said that the purpose of the sympathetic system is to provide extra activation of the body in states of stress, which is called the *sympathetic stress response*.

The sympathetic system is especially strongly activated in many emotional states. For example, in the state of *rage*, which is elicited to a great extent by stimulating the hypothalamus, signals are transmitted downward through the reticular formation of the brain stem and into the spinal cord to cause massive sympathetic discharge; most aforementioned sympathetic events ensue immediately. This is called the *sympathetic alarm reaction*. It is also called the *fight-or-flight reaction* because an animal in this state decides almost instantly whether to stay and fight or to run. In either event, the sympathetic alarm reaction makes the animal's subsequent activities vigorous.

MEDULLARY, PONTINE, AND MESENCEPHALIC CONTROL OF THE AUTONOMIC NERVOUS SYSTEM

Many neuronal areas in the brain stem reticular substance and along the course of the tractus solitarius of the medulla, pons, and mesencephalon, as well as in many special nuclei (**Fig. 61.6**), control different autonomic functions, such as arterial pressure, heart rate, glandular secretion in the gastrointestinal tract, gastrointestinal peristalsis, and degree of contraction of the urinary bladder. Control of each of these is discussed at appropriate points in this text. Some of the *most important factors controlled in the brain stem are arterial pressure, heart*

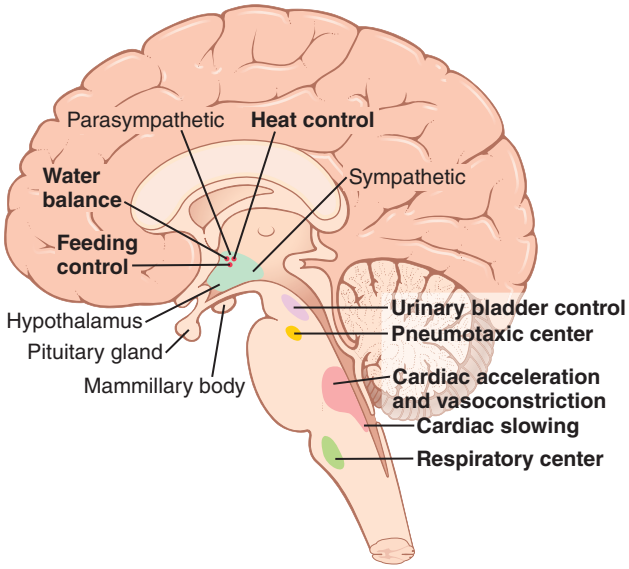

Figure 61.6 Autonomic control areas in the brain stem and hypothalamus.

rate, and respiratory rate. Indeed, transection of the brain stem above the midpontine level allows basal control of arterial pressure to continue as before but prevents its modulation by higher nervous centers such as the hypothalamus. Conversely, transection immediately below the medulla causes the arterial pressure to fall to less than one-half normal.

Closely associated with the cardiovascular regulatory centers in the brain stem are the medullary and pontine centers for regulation of respiration, which are discussed in Chapter 42. Although regulation of respiration is not considered to be an autonomic function, it is one of the *involuntary* functions of the body.

Control of Brain Stem Autonomic Centers By Higher Areas. Signals from the hypothalamus and even from the cerebrum can affect activities of almost all the brain stem autonomic control centers. For example, stimulation in appropriate areas—mainly of the posterior hypothalamus—can activate the medullary cardiovascular control centers strongly enough to increase arterial pressure to more than twice normal. Likewise, other hypothalamic centers control body temperature, increase or decrease salivation and gastrointestinal activity, and cause bladder emptying. To some extent, the autonomic centers in the brain stem act as relay stations for control activities initiated at higher levels of the brain, especially in the hypothalamus.

In Chapters 59 and 60, we also pointed out that many of our behavioral responses are mediated through the following: (1) the hypothalamus, (2) the reticular areas of the brain stem, and (3) the autonomic nervous system. Indeed, some higher areas of the brain can alter function of the whole autonomic nervous system or of portions of it strongly enough to cause severe autonomic-induced diseases such as constipation, heart palpitation, or even heart attack.

Pharmacology of the Autonomic Nervous System

Sympathomimetic Drugs That Act on Adrenergic Effector Organs. From the foregoing discussion, it is obvious that intravenous injection of norepinephrine causes essentially the same effects throughout the body as sympathetic stimulation. Therefore, norepinephrine is called a *sympathomimetic* or *adrenergic drug. Epinephrine* and *methoxamine* are also sympathomimetic drugs, and there are many others. They differ from one another in the degree to which they stimulate different receptors in sympathetic effector organs and in their duration of action. Norepinephrine and epinephrine have actions as short as 1 to 2 minutes, whereas the actions of some other commonly used sympathomimetic drugs last for 30 minutes to 2 hours.

Important drugs that *stimulate* specific adrenergic receptors are *phenylephrine* (alpha receptors), *isoproterenol* (beta receptors), and *albuterol* (only $beta_2$ receptors).

Drugs That Cause Release of Norepinephrine From Nerve Endings. Certain drugs have an indirect sympathomimetic action instead of directly exciting adrenergic effector organs. These drugs include *ephedrine, tyramine*, and *amphetamine*. Their effect is to cause release of norepinephrine from its storage vesicles in the sympathetic nerve endings. The released norepinephrine in turn causes the sympathetic effects.

Drugs That Block Adrenergic Activity. Adrenergic activity can be blocked at several points in the stimulatory process, as follows:

1. The synthesis and storage of norepinephrine in the sympathetic nerve endings can be prevented by *reserpine*.
2. Release of norepinephrine from the sympathetic endings can be blocked by *guanethidine*.
3. The sympathetic *alpha* receptors can be blocked. Two drugs that block both $alpha_1$ and $alpha_2$ adrenergic receptors are *phenoxybenzamine* and *phentolamine*. Selective $alpha_1$ adrenergic blockers include *prazosin* and *terazosin*, whereas *yohimbine* blocks $alpha_2$ receptors.
4. The sympathetic *beta* receptors can be blocked. A drug that blocks both $beta_1$ and $beta_2$ receptors is *propranolol*. Drugs that block mainly $beta_1$ receptors are *atenolol*, *nebivolol*, and *metoprolol*.
5. Sympathetic activity can be blocked by drugs that block transmission of nerve impulses through the autonomic ganglia. They are discussed in a later section, but drugs that block both sympathetic and parasympathetic transmission through the ganglia include *hexamethonium* and *pentolinium*.

Parasympathomimetic Drugs That Act on Cholinergic Receptors. Acetylcholine injected intravenously usually does not cause exactly the same effects throughout the body as parasympathetic stimulation because most of the acetylcholine is destroyed by cholinesterase in the blood and body fluids before it can reach all the effector organs. Yet, several other drugs that are not so rapidly destroyed can produce typical widespread parasympathetic effects; these are called *parasympathomimetic drugs*.

Two commonly used parasympathomimetic drugs are *pilocarpine* and *methacholine*. They act directly on the muscarinic type of cholinergic receptors.

Drugs That Have a Parasympathetic Potentiating Effect—Anticholinesterase Drugs. Some drugs do not

have a direct effect on parasympathetic effector organs but do potentiate the effects of the naturally secreted acetylcholine at the parasympathetic endings. They are the same drugs as those discussed in Chapter 7 that potentiate the effect of acetylcholine at the neuromuscular junction. These drugs include *neostigmine, pyridostigmine*, and *ambenonium*. They inhibit acetylcholinesterase, thus *preventing rapid destruction of the acetylcholine* liberated at parasympathetic nerve endings. As a consequence, the quantity of acetylcholine increases with successive stimuli, and the degree of action also increases.

Drugs That Block Cholinergic Activity at Effector Organs—Antimuscarinic Drugs. *Atropine* and similar drugs, such as *homatropine* and *scopolamine, block the action of acetylcholine on the muscarinic type of cholinergic effector organs*. These drugs *do not* affect the nicotinic action of acetylcholine on the postganglionic neurons or on skeletal muscle.

Drugs That Stimulate Sympathetic and Parasympathetic Postganglionic Neurons. The preganglionic neurons of both the parasympathetic and the sympathetic nervous systems secrete acetylcholine at their endings, and the acetylcholine in turn stimulates the postganglionic neurons. Furthermore, injected acetylcholine can also stimulate the postganglionic neurons of both systems, thereby causing at the same time both sympathetic and parasympathetic effects throughout the body.

Nicotine is another drug that can stimulate postganglionic neurons in the same manner as acetylcholine, because the membranes of these neurons all contain the *nicotinic type of acetylcholine receptor*. Therefore, drugs that cause autonomic effects by stimulating postganglionic neurons are called *nicotinic drugs*. Some other drugs, such as *methacholine*, have both nicotinic and muscarinic actions, whereas *pilocarpine* has only muscarinic actions.

Nicotine excites both the sympathetic and parasympathetic postganglionic neurons at the same time, resulting in strong sympathetic vasoconstriction in the abdominal organs and limbs but at the same time resulting in parasympathetic effects, such as increased gastrointestinal activity.

Ganglionic Blocking Drugs Inhibit Impulse Transmission From Autonomic Preganglionic Neurons. Drugs that block impulse transmission from the autonomic preganglionic neurons to the postganglionic neurons include *tetraethyl ammonium ion, hexamethonium ion*, and *pentolinium*. These drugs block acetylcholine stimulation of the postganglionic neurons in both the sympathetic and the parasympathetic systems simultaneously. They are often used for blocking sympathetic activity but seldom for blocking parasympathetic activity because their effects of sympathetic blockade usually far overshadow the effects of parasympathetic blockade. The ganglionic blocking drugs especially can reduce the arterial pressure rapidly, but they are not very useful clinically because their effects are difficult to control.

Cerebral Blood Flow, Cerebrospinal Fluid, and Brain Metabolism

Thus far, we have discussed the function of the brain as if it were independent of its blood flow, its metabolism, and its fluids. However, this is far from true because abnormalities of any of these aspects can profoundly affect brain function. For example, total cessation of blood flow to the brain causes unconsciousness within 5 to 10 seconds because lack of oxygen (O_2) delivery to the brain cells nearly shuts down metabolism in these cells. Also, on a longer time scale, abnormalities of the cerebrospinal fluid, either its composition or its fluid pressure, can have equally severe effects on brain function.

CEREBRAL BLOOD FLOW

Blood flow of the brain is supplied by four large arteries—two carotid and two vertebral arteries—that merge to form the *circle of Willis* at the base of the brain (**Fig. 62.1**). The arteries arising from the circle of Willis travel along the brain surface and give rise to *pial* arteries, which branch out into smaller vessels called *penetrating arteries* and *arterioles* (**Fig. 62.2**). The penetrating vessels are separated slightly from the brain tissue by an extension of the subarachnoid space called the *Virchow-Robin space*. The penetrating vessels dive down into the brain tissue, giving rise to intracerebral arterioles, which eventually branch into capillaries where exchange among the blood and the tissues of O_2, nutrients, carbon dioxide (CO_2), and metabolites occurs.

REGULATION OF CEREBRAL BLOOD FLOW

Normal blood flow through the brain of the adult person averages 50 to 65 mL/100 g of brain tissue/min. For the entire brain, this amounts to 750 to 900 mL/min. Thus, the brain constitutes only about 2% of the body weight but receives 15% of the resting cardiac output.

As in most other tissues, cerebral blood flow is highly related to the tissue metabolism. Several metabolic factors are believed to contribute to cerebral blood flow regulation: (1) CO_2 concentration; (2) hydrogen ion (H^+) concentration; (3) O_2 concentration; and (4) substances released from *astrocytes*, which are specialized, nonneuronal cells that appear to couple neuronal activity with local blood flow regulation (see **Fig. 62.2**).

Excesses of CO_2 or H^+ Concentration Increase Cerebral Blood Flow. An increase in CO_2 concentration in the arterial blood perfusing the brain greatly increases cerebral blood flow. This effect is demonstrated in **Fig. 62.3**, which shows that a 70% increase in arterial partial pressure of CO_2 (P_{CO_2}) approximately doubles cerebral blood flow.

CO_2 is believed to increase cerebral blood flow by combining first with water in the body fluids to form carbonic acid, with subsequent dissociation of this acid to form H^+. The H^+ then causes vasodilation of the cerebral vessels, with the dilation being almost directly proportional to the increase in H^+ concentration up to a blood flow limit of about twice normal.

Other substances that increase the acidity of the brain tissue and therefore increase H^+ concentration will likewise increase cerebral blood flow. Such substances include

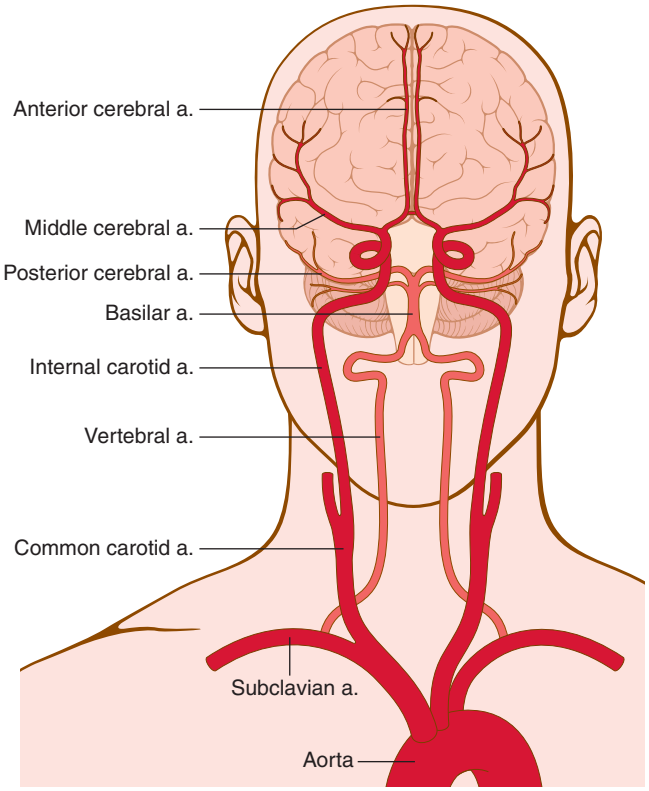

Figure 62.1 Arterial blood supply of the brain.

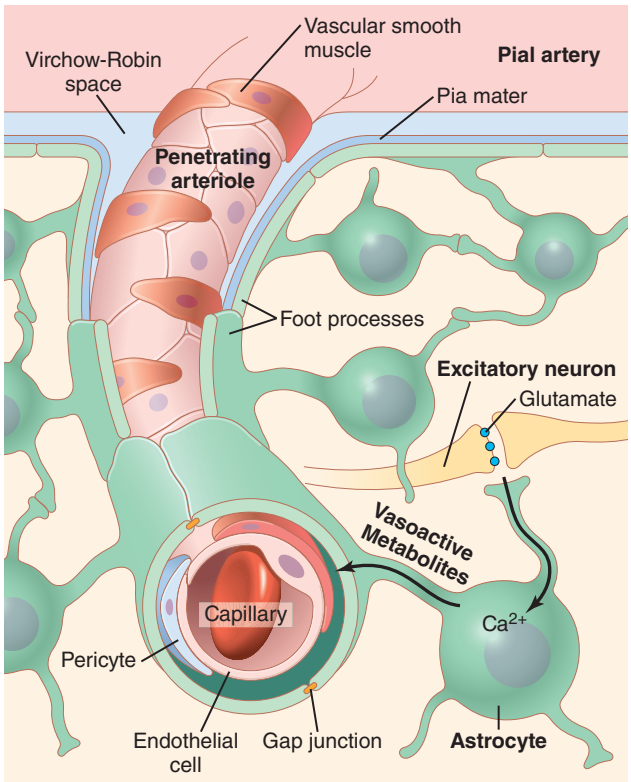

Figure 62.2 Architecture of cerebral blood vessels and potential mechanism for blood flow regulation by astrocytes. The pial arteries lie on the glia limitans, and the penetrating arteries are surrounded by astrocyte foot processes. Note that the astrocytes also have fine processes that are closely associated with synapses.

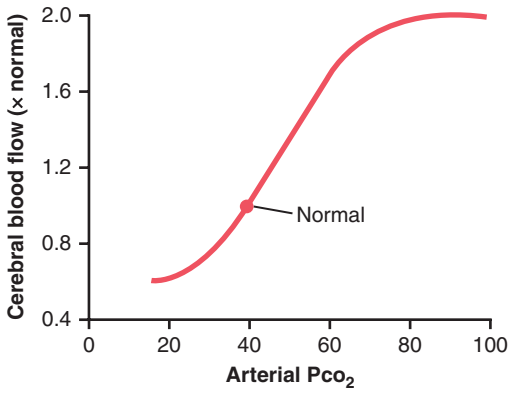

Figure 62.3 Relationship between arterial P_{CO_2} and cerebral blood flow.

lactic acid, pyruvic acid, and any other acidic material formed by tissue metabolism.

Importance of Cerebral Blood Flow Control By CO_2 and H^+. Increased H^+ concentration greatly depresses neuronal activity. Therefore, it is fortunate that increased H^+ concentration also elicits increased blood flow, which, in turn, carries H^+, CO_2, and other acid-forming substances away from the brain tissues. Loss of CO_2 removes carbonic acid from the tissues; this action, along with removal of other acids, reduces the H^+ concentration back toward normal. Thus, this mechanism helps maintain a constant H^+ concentration in the cerebral fluids and thereby helps to maintain a normal, constant level of neuronal activity.

Oxygen Deficiency as a Regulator of Cerebral Blood Flow. Except during periods of intense brain activity, the rate of O_2 utilization by the brain tissue remains within narrow limits—almost exactly 3.5 (±0.2) mL of O_2/100 g of brain tissue/min. If brain blood flow becomes insufficient to supply adequate O_2, the O_2 deficiency almost immediately causes vasodilation, returning the brain blood flow and transport of O_2 to the cerebral tissues to near normal. Thus, this local blood flow regulatory mechanism is almost exactly the same in the brain as in coronary blood vessels, in skeletal muscle, and in most other circulatory areas of the body.

Experiments have shown that a decrease in cerebral *tissue* partial pressure of O_2 (P_{O_2}) below about 30 mm Hg (normal value is 35–40 mm Hg) immediately begins to increase cerebral blood flow. This is fortuitous because brain function becomes deranged at lower values of P_{O_2}, especially at P_{O_2} levels below 20 mm Hg. Even coma can result at these low levels. Thus, the O_2 mechanism for local regulation of cerebral blood flow is an important protective response against diminished cerebral neuronal activity and, therefore, against derangement of mental capability.

Substances Released From Astrocytes Regulate Cerebral Blood Flow. The close coupling between neuronal activity and cerebral blood flow is due, in part, to substances released from *astrocytes* (also called *astroglial cells*) that surround blood vessels of the central nervous system. Astrocytes are star-shaped *non-neuronal cells* that support and protect neurons, as well as provide nutrition. They have numerous projections that make contact with neurons and the surrounding blood vessels, providing a potential mechanism for neurovascular communication. Gray matter astrocytes *(protoplasmic astrocytes)* extend fine processes that cover most synapses and large *foot processes* that are closely apposed to the vascular wall (see **Fig. 62.2**).

Experimental studies have shown that electrical stimulation of excitatory glutaminergic neurons leads to increased intracellular calcium ion concentration in astrocyte foot processes and vasodilation of nearby arterioles. Additional studies have suggested that the vasodilation is mediated by several vasoactive metabolites released from astrocytes. Although the precise mediators are still unclear, nitric oxide, metabolites of arachidonic acid, potassium ions, adenosine, and other substances generated by astrocytes in response to stimulation of adjacent excitatory neurons have all been suggested to be important in mediating local vasodilation.

Measurement of Cerebral Blood Flow and Effect of Brain Activity on Blood Flow. A method has been developed to record blood flow in as many as 256 isolated segments of the human cerebral cortex simultaneously. To record blood flow in these segments, a radioactive substance, such as radioactive xenon (Xe), is injected into the carotid artery; then the radioactivity of each segment of

the cortex is recorded as the radioactive substance passes through the brain tissue. For this purpose, 256 small radioactive scintillation detectors are pressed against the surface of the cortex. The rapidity of rise and decay of radioactivity in each tissue segment is a direct measure of the rate of blood flow through that segment.

Using this technique, it has become clear that blood flow in each individual segment of the brain changes as much as 100% to 150% within seconds in response to changes in local neuronal activity. For example, simply clenching the hand into a fist causes an immediate increase in blood flow in the motor cortex of the opposite side of the brain. Reading a book increases the blood flow, especially in the visual areas of the occipital cortex and in the language perception areas of the temporal cortex. This measuring procedure can also be used for localizing the origin of epileptic attacks because local brain blood flow increases acutely and markedly at the focal point of each attack.

Fig. 62.4 demonstrates the effect of local neuronal activity on cerebral blood flow by showing a typical increase in occipital blood flow recorded in a cat's brain when intense light is shined into its eyes for one-half minute.

Blood flow and neural activity in different regions of the brain can also be assessed indirectly by *functional magnetic resonance imaging* (fMRI). This method is based on the observation that oxygen-rich hemoglobin (oxyhemoglobin) and oxygen-poor hemoglobin (deoxyhemoglobin) in the blood behave differently in a magnetic field. *Deoxyhemoglobin is a paramagnetic* molecule (i.e., attracted by an externally applied magnetic field), whereas *oxyhemoglobin is diamagnetic* (i.e., repelled by a magnetic field). The presence of deoxyhemoglobin in a blood vessel causes a measurable difference of the magnetic resonance (MR) proton signal of the vessel and its surrounding tissue. The *blood oxygen level–dependent* (BOLD) signals obtained from fMRI, however, depend on the total amount of deoxyhemoglobin in the specific three-dimensional space (voxel) of brain tissue being assessed. This, in turn, is influenced by the rate of blood flow, volume of blood, and rate of O_2 consumption in the specific voxel of brain tissue. For this reason, BOLD fMRI provides only an indirect estimate of regional blood flow, although it can also be used to produce maps showing which parts of the brain are activated in a particular mental process.

An alternative MRI method called *arterial spin labeling* (ASL) can be used to provide a more quantitative assessment of regional blood flow. ASL works by manipulating the MR signal of arterial blood before it is delivered to different areas of the brain. By subtracting two images in which the arterial blood is manipulated differently, the static proton signal in the rest of the tissue subtracts out, leaving only the signal arising from the delivered arterial blood. ASL and BOLD imaging can be used together simultaneously to provide a probe of regional brain blood flow and neuronal function.

Cerebral Blood Flow Autoregulation Protects the Brain From Changes in Arterial Pressure. During normal daily activities, arterial pressure can fluctuate widely, rising to high levels during states of excitement or strenuous activity and falling to low levels during sleep. However, cerebral blood flow is "autoregulated" extremely well between arterial pressure limits of approximately 60 and 150 mm Hg (**Fig. 62.5**). That is, acute reductions in mean arterial pressure to as low as 60 mm Hg or increases to as high as 150 mm Hg do not cause major changes in cerebral blood flow in people who have normal autoregulation.

In people who have *chronic hypertension* there is hypertrophic remodeling of their cerebral blood vessels, as well as blood vessels in other organs (discussed in Chapter 17), and the autoregulatory curve is shifted to higher blood pressures. This vascular remodeling and resetting of cerebral blood flow autoregulation partially protects the brain from the damaging effects of the high blood pressure but also makes the brain vulnerable to severe ischemia if blood pressure is reduced too rapidly below the range of autoregulation. If arterial pressure falls below the limits of autoregulation, cerebral blood flow becomes severely decreased.

Impairment of autoregulation makes cerebral blood flow much more dependent on arterial pressure. For example, in *preeclampsia*, a disorder of pregnancy associated with vascular dysfunction and hypertension, cerebral blood flow autoregulation may be impaired, leading to pressure-dependent increases in cerebral blood flow, disruption of the vascular endothelium, edema, and seizures in some cases. In old age, atherosclerosis, and in various brain disorders, cerebral

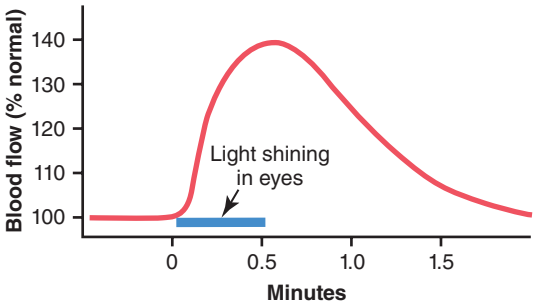

Figure 62.4 Increase in blood flow to the occipital regions of a cat's brain when light is shined into its eyes.

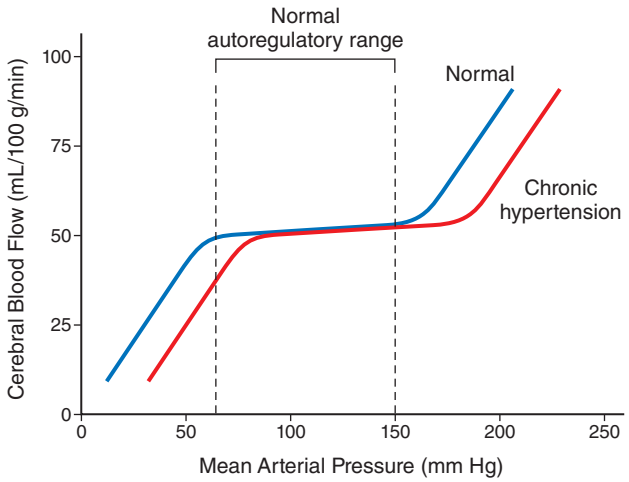

Figure 62.5 Autoregulation of cerebral blood flow during acute changes in mean arterial pressure in subjects with normotension *(blue curve)* and chronic hypertension *(red curve)*. The *dashed vertical lines* indicate the approximate normal autoregulatory range.

blood flow autoregulation may also be impaired, increasing the risk for blood pressure–dependent injury of the brain.

Role of the Sympathetic Nervous System in Controlling Cerebral Blood Flow. The cerebral circulatory system has strong sympathetic innervation that passes upward from the superior cervical sympathetic ganglia in the neck and then into the brain along with the cerebral arteries. This innervation supplies both the large brain arteries and the arteries that penetrate into the substance of the brain. However, transection of the sympathetic nerves or mild to moderate stimulation of them usually causes little change in cerebral blood flow because the blood flow autoregulation mechanism can override the nervous effects.

When mean arterial pressure rises acutely to an exceptionally high level, such as during strenuous exercise or during other states of excessive circulatory activity, the sympathetic nervous system normally can constrict the large and intermediate-sized brain arteries enough to prevent the high pressure from reaching the smaller brain blood vessels. This mechanism is important in preventing vascular hemorrhages into the brain—that is, for preventing cerebral stroke.

CEREBRAL MICROCIRCULATION

As is true for almost all other tissues of the body, the number of blood capillaries in the brain is greatest where the metabolic needs are greatest. The overall metabolic rate of the brain gray matter where the neuronal cell bodies lie is about four times as great as that of white matter; correspondingly, the number of capillaries and rate of blood flow are also about four times as great in the gray matter.

An important structural characteristic of the brain capillaries is that most of them are much less "leaky" than the blood capillaries in almost any other tissue of the body. One reason for this phenomenon is that the capillaries are supported on all sides by "glial feet," which are small projections from the surrounding *glial cells* (e.g., *astroglial cells*) that abut against all surfaces of the capillaries and provide physical support to prevent overstretching of the capillaries in case of high capillary blood pressure.

The walls of the small arterioles leading to the brain capillaries become greatly thickened as high blood pressure develops, and these arterioles remain significantly constricted all the time to prevent transmission of the high pressure to the capillaries. We shall see later in the chapter that whenever these systems for protecting against transudation of fluid into the brain break down, serious brain edema ensues, which can lead rapidly to coma and death.

Cerebral "Stroke" Occurs When Cerebral Blood Vessels Are Blocked or Ruptured

Almost all elderly people have blockage of some small arteries in the brain, and up to 10% eventually have enough blockage to cause serious disturbance of brain function, a condition called a "stroke."

Many strokes are caused by arteriosclerotic plaques that occur in one or more of the feeder arteries to the brain. The plaques can activate the blood clotting mechanisms, causing a blood clot and blocking blood flow in the artery, thereby leading to an *ischemic stroke* and acute loss of brain function in a localized area. The main risk factors for ischemic stroke (sometimes called a "brain attack") are the same as for atherosclerosis in other organs, such as the heart (where it can cause a "heart attack"), and include hypertension, obesity, diabetes, hyperlipidemia, and smoking (see Chapter 69 for further discussion).

In 15% to 20% of people in whom strokes develop, one of the cerebral blood vessels bursts; hemorrhage then occurs, compressing the local brain tissue and further compromising its functions. The most important risk factor for *hemorrhagic stroke* is high blood pressure (*hypertension*) although excessive anticoagulant therapy, smoking, cocaine or amphetamine use, brain tumors, and other disorders can increase the risk for hemorrhagic stroke.

The neurological effects of a stroke are determined by the brain area affected. One of the most common types of stroke is blockage of the *middle cerebral artery* that supplies the midportion of one brain hemisphere. For example, if the middle cerebral artery is blocked on the left side of the brain, the person is likely to lose function of the Wernicke speech comprehension area in the left cerebral hemisphere, and they also become unable to speak words because of loss of the Broca motor area for word formation. In addition, loss of function of neural motor control areas of the left hemisphere can create spastic paralysis of most muscles on the opposite side of the body.

In a similar manner, blockage of a *posterior cerebral artery* will cause infarction of the occipital pole of the hemisphere on the same side as the blockage, which causes loss of vision in both eyes in the half of the retina on the opposite side as the stroke lesion. Especially devastating are strokes that involve the blood supply to the midbrain because this effect can block nerve conduction in major pathways between the brain and spinal cord, causing *both sensory and motor abnormalities.*

As discussed in Chapter 60, small infarcts or microbleeds in small blood vessels may cause *"silent strokes,"* with no readily apparent symptoms other than subtle cognitive decline. These small areas where infarction has occurred, however, may be detectable using magnetic resonance imaging (MRI) or computed tomography (CT) imaging. It is estimated that approximately 25% of people greater than 80 years of age have had one or more silent brain infarcts.

CEREBROSPINAL FLUID SYSTEM

The entire cerebral cavity enclosing the brain and spinal cord has a capacity of about 1600 to 1700 mL. About 150 mL of this capacity is occupied by *cerebrospinal fluid* and the remainder by the brain and cord. This fluid, as shown in **Fig. 62.6**, is present in the *ventricles of the brain*, in the *cisterns around the outside of the brain*, and in the *subarachnoid space around both the brain and the spinal cord.* All these chambers are connected with one another, and the pressure of the fluid is maintained at a surprisingly constant level.

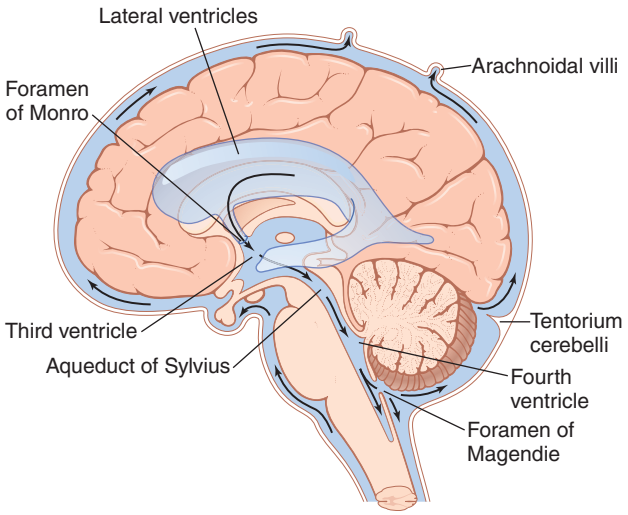

Figure 62.6 The *arrows* show the pathway of cerebrospinal fluid flow from the choroid plexuses in the lateral ventricles to the arachnoidal villi protruding into the dural sinuses.

CUSHIONING FUNCTION OF THE CEREBROSPINAL FLUID

A major function of the cerebrospinal fluid is to cushion the brain within its solid vault. The brain and the cerebrospinal fluid have about the same specific gravity (with only about a 4% difference), so the brain simply floats in the fluid. Therefore, a blow to the head, if it is not too intense, moves the entire brain simultaneously with the skull, causing no one portion of the brain to be momentarily contorted by the blow.

Contrecoup and Coup Brain Injuries. When a blow to the head is extremely severe, it may not damage the brain on the side of the head where the blow is struck but is likely to damage the opposite side. This phenomenon is known as "contrecoup," and the reason for this effect is the following: When the blow is struck, the fluid on the struck side is so incompressible that as the skull moves, the fluid pushes the brain at the same time in unison with the skull. On the side opposite to the area that is struck, the sudden movement of the whole skull causes the skull to pull away from the brain momentarily because of the brain's inertia, creating for a split second a vacuum space in the cranial vault in the area opposite to the blow. Then, when the skull is no longer being accelerated by the blow, the vacuum suddenly collapses and the brain strikes the inner surface of the skull.

The poles and the inferior surfaces of the frontal and temporal lobes, where the brain comes into contact with bony protuberances in the base of the skull, are often the sites of injury and *contusions* (bruises) after a severe blow to the head, such as that experienced by a boxer. If the contusion occurs on the same side as the impact injury, it is a *coup injury;* if it occurs on the opposite side, the contusion is a *contrecoup injury*.

Coup and contrecoup injuries can also be caused by rapid acceleration or deceleration alone in the absence of physical impact due to a blow to the head. In these cases, the brain may bounce off the wall of the skull, causing a coup injury, and then also bounce off the opposite side, causing a contrecoup contusion. Such injuries are thought to occur, for example, in "shaken baby syndrome" or sometimes in vehicular accidents.

FORMATION, FLOW, AND ABSORPTION OF CEREBROSPINAL FLUID

Cerebrospinal fluid is formed at a rate of about 500 mL/day, which is three to four times as much as the total volume of fluid in the entire cerebrospinal fluid system. About two-thirds or more of this fluid originates as *secretion from the choroid plexuses* in the four ventricles, *mainly in the two lateral ventricles.* Additional small amounts of fluid are secreted by the ependymal surfaces of all the ventricles and by the arachnoidal membranes. A small amount comes from the brain through the perivascular spaces that surround the blood vessels passing through the brain.

The arrows in **Fig. 62.6** show that the main channels of fluid flow from the *choroid plexuses* and then through the cerebrospinal fluid system. The fluid secreted in the *lateral ventricles* passes first into the *third ventricle;* then, after addition of minute amounts of fluid from the third ventricle, it flows downward along the *aqueduct of Sylvius* into the *fourth ventricle*, where still another minute amount of fluid is added. Finally, the fluid passes out of the fourth ventricle through three small openings, *two lateral foramina of Luschka* and a *midline foramen of Magendie*, entering the *cisterna magna*, a fluid space that lies behind the medulla and beneath the cerebellum.

The cisterna magna is continuous with the *subarachnoid space* that surrounds the entire brain and spinal cord. Almost all the cerebrospinal fluid then flows upward from the cisterna magna through the subarachnoid spaces surrounding the cerebrum. From here, the fluid flows into and through multiple *arachnoidal villi* that project into the large sagittal venous sinus and other venous sinuses of the cerebrum. Thus, any extra fluid empties into the venous blood through pores of these villi.

Secretion By the Choroid Plexus. The *choroid plexus*, a section of which is shown in **Fig. 62.7**, is a cauliflower-like growth of blood vessels covered by a thin layer of epithelial cells. This plexus projects into the temporal horn of each lateral ventricle, the posterior portion of the third ventricle, and the roof of the fourth ventricle.

Secretion of fluid into the ventricles by the choroid plexus depends mainly on active transport of sodium ions through the epithelial cells lining the outside of the plexus. The positive charges of sodium ions in turn pull along large amounts of negatively charged chloride ions. The two ions increase the quantity of osmotically active sodium chloride in the cerebrospinal fluid, which then

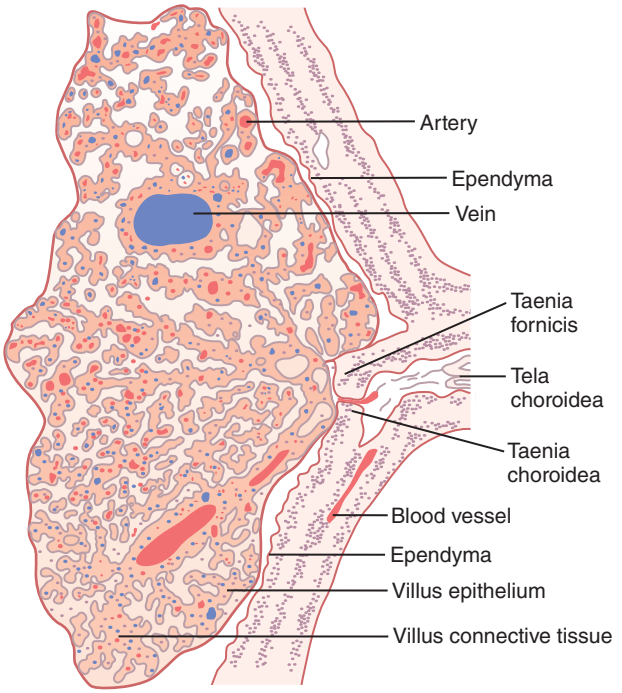

Figure 62.7 Choroid plexus in a lateral ventricle.

causes almost immediate osmosis of water through the membrane, thus providing the fluid of the secretion.

Less important transport processes move small amounts of glucose into the cerebrospinal fluid and both potassium and bicarbonate ions out of the cerebrospinal fluid into the capillaries. Therefore, the resulting characteristics of the cerebrospinal fluid become the following: osmotic pressure, approximately equal to that of plasma; sodium ion concentration, approximately equal to that of plasma; chloride ion, about 15% greater than in plasma; potassium ion, approximately 40% less than in plasma; and glucose, about 30% less than in plasma.

Absorption of Cerebrospinal Fluid Through the Arachnoidal Villi. The *arachnoidal villi* are microscopic fingerlike inward projections of the arachnoidal membrane through the walls and into the venous sinuses. Conglomerates of these villi form macroscopic structures called *arachnoidal granulations* that can be seen protruding into the sinuses. The endothelial cells covering the villi have vesicular passages directly through the bodies of the cells large enough to allow relatively free flow of (1) cerebrospinal fluid, (2) dissolved protein molecules, and (3) even particles as large as red and white blood cells into the venous blood.

Perivascular Spaces and Cerebrospinal Fluid. The large arteries and veins of the brain lie on the surface of the brain, but their ends penetrate inward, carrying with them a layer of *pia mater*, the membrane that covers the brain, as shown in **Fig. 62.8**. The pia is only loosely adherent to the vessels, so a space, the *perivascular space*, exists between it and each blood vessel. Therefore, perivascular spaces follow both the arteries and the veins into the brain as far as the arterioles and venules go.

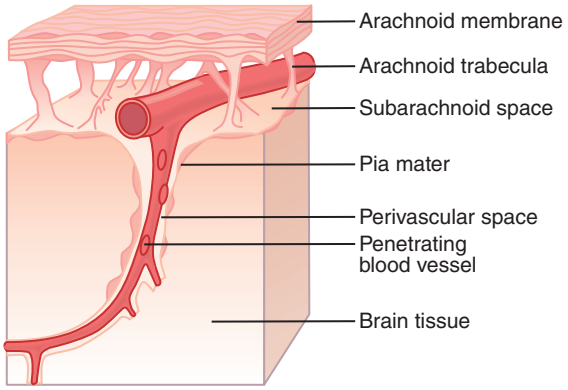

Figure 62.8 Drainage of a perivascular space into the subarachnoid space. *(Modified from Ranson SW, Clark SL.* Anatomy of the Nervous System. *Philadelphia: WB Saunders; 1959.)*

Lymphatic Function of the Perivascular Spaces. Like other capillaries in the body, the brain capillaries leak a small amount of protein into the interstitial spaces of the tissue. As discussed in Chapter 16, the central nervous system has true lymphatic vessels only in the meninges, the membranes that cover and protect the brain and spinal cord. However, the perivascular spaces of brain penetrating blood vessels serve as part of a *glial-lymphatic* (*glymphatic)* system that helps clear large molecules and waste products from the interstitial fluid (see Fig. 16.8). Cerebrospinal fluid flows into the brain parenchyma along the periarterial spaces, and protein that leaks into the brain interstitial spaces leaves the tissue along with fluid through the perivenous spaces into the subarachnoid spaces. On reaching the subarachnoid spaces, the protein then flows with the cerebrospinal fluid to be absorbed through the *arachnoidal villi* into the large cerebral veins. Therefore, the perivascular spaces, in effect, provide a specialized lymphatic system for the brain.

In addition to transporting fluid and proteins, the perivascular spaces transport extraneous particulate matter out of the brain. For example, whenever infection occurs in the brain, dead white blood cells and other infectious debris are carried away through the perivascular spaces.

Cerebrospinal Fluid Pressure

The normal pressure in the cerebrospinal fluid system *when one is lying in a horizontal position* averages about 130 mm of water (10 mm Hg), although this pressure may be as low as 65 mm of water or as high as 195 mm of water even in the normal healthy person.

Regulation of Cerebrospinal Fluid Pressure By the Arachnoidal Villi. The normal rate of cerebrospinal fluid formation remains nearly constant, so changes in fluid formation are seldom a factor in pressure control. The arachnoidal villi function like valves that allow cerebrospinal fluid and its contents to flow readily into the blood of the venous sinuses while not allowing blood to flow backward in the opposite direction. Normally, this valve action of the villi allows cerebrospinal fluid to begin to flow into the

blood when cerebrospinal fluid pressure is about 1.5 mm Hg greater than the pressure of the blood in the venous sinuses. Then, if the cerebrospinal fluid pressure rises still higher, the valves open more widely. Under normal conditions, the cerebrospinal fluid pressure almost never rises more than a few millimeters of mercury higher than the pressure in the cerebral venous sinuses.

In some disease states, the villi sometimes become blocked by large particulate matter, by fibrosis, or by blood cells that have leaked into the cerebrospinal fluid. Such blockage can cause high cerebrospinal fluid pressure, as described in the following section.

High Cerebrospinal Fluid Pressure in Pathological Conditions of the Brain. Often a large *brain tumor* elevates the cerebrospinal fluid pressure by decreasing reabsorption of the cerebrospinal fluid back into the blood. As a result, the cerebrospinal fluid pressure can rise to as much as 500 mm of water (37 mm Hg) or about four times normal.

The cerebrospinal fluid pressure also rises considerably when *hemorrhage* or *infection* occurs in the cranial vault. In both these conditions, large numbers of red and/or white blood cells appear in the cerebrospinal fluid and can cause serious blockage of the small absorption channels through the arachnoidal villi. This also sometimes elevates the cerebrospinal fluid pressure to 400 to 600 mm of water (about four times normal).

Some babies are born with high cerebrospinal fluid pressure, which is often caused by abnormally high resistance to fluid reabsorption through the arachnoidal villi, resulting either from too few arachnoidal villi or from villi with abnormal absorptive properties. This is discussed later in connection with *hydrocephalus*, a condition associated with fluid accumulation in the brain.

Obstruction to Flow of Cerebrospinal Fluid Can Cause Hydrocephalus. "Hydrocephalus" means excess water in the cranial vault. This condition is frequently divided into *communicating hydrocephalus* and *noncommunicating hydrocephalus*. In communicating hydrocephalus, fluid flows readily from the ventricular system into the subarachnoid space, whereas in noncommunicating hydrocephalus, fluid flow out of one or more of the ventricles is blocked.

Usually the *noncommunicating* type of hydrocephalus is caused by a *block in the aqueduct of Sylvius*, resulting from *atresia* (closure) before birth in many babies or from blockage by a brain tumor at any age. As fluid is formed by the choroid plexuses in the two lateral and the third ventricles, the volumes of these three ventricles increase greatly, which flattens the brain into a thin shell against the skull. In neonates, the increased pressure also causes the whole head to swell because the skull bones have not yet fused.

The *communicating* type of hydrocephalus is usually caused by blockage of fluid flow in the subarachnoid spaces around the basal regions of the brain or by blockage of the arachnoidal villi where the fluid is normally absorbed into the venous sinuses. Fluid therefore collects on the outside of the brain and, to a lesser extent, inside the ventricles. This will also cause the head to swell tremendously if it occurs in infancy when the skull is still pliable and can be stretched, and it can damage the brain at any age. A therapy for many types of hydrocephalus is surgical placement of a silicone tube shunt all the way from one of the brain ventricles to the peritoneal cavity, where the excess fluid can be absorbed into the blood.

Blood–Cerebrospinal Fluid and Blood–Brain Barriers

We have already pointed out that the concentrations of several important constituents of cerebrospinal fluid are not the same as in extracellular fluid elsewhere in the body. Furthermore, many large molecules hardly pass at all from the blood into the cerebrospinal fluid or into the interstitial fluid of the brain, even though these same substances pass readily into the usual interstitial fluids of the body. Therefore, it is said that barriers, called the *blood–cerebrospinal fluid barrier* and the *blood–brain barrier*, exist between the blood and the cerebrospinal fluid and brain fluid, respectively.

These barriers exist both at the choroid plexus and at the tissue capillary membranes in essentially all areas of the brain parenchyma *except in some areas of the hypothalamus, pineal gland*, and *area postrema*, where substances diffuse with greater ease into the tissue spaces. The ease of diffusion in these areas is important because they have sensory receptors that respond to specific changes in the body fluids, such as changes in osmolality and in glucose concentration, as well as receptors for peptide hormones that regulate thirst, such as angiotensin II. The blood–brain barrier also has specific carrier molecules that facilitate transport of hormones, such as leptin, from the blood into the hypothalamus, where the hormones bind to specific receptors that control other functions, such as appetite and sympathetic nervous system activity.

In general, the blood–cerebrospinal fluid and blood–brain barriers are highly permeable to water, CO_2, O_2, and most lipid-soluble substances such as alcohol and anesthetics; slightly permeable to electrolytes such as sodium, chloride, and potassium; and almost totally impermeable to plasma proteins and most non–lipid-soluble large organic molecules. Therefore, the blood–cerebrospinal fluid and blood–brain barriers often make it impossible to achieve effective concentrations of some therapeutic drugs, such as protein antibodies and non–lipid-soluble drugs, in the cerebrospinal fluid or parenchyma of the brain.

The cause of the low permeability of the blood–cerebrospinal fluid and blood–brain barriers is the *tight junctions* of the endothelial cells of the brain tissue capillaries. That is, the membranes of the adjacent endothelial cells are tightly fused rather than having large slit pores between them, as is the case for most other capillaries of the body.

Brain Edema

One of the most serious complications of abnormal cerebral fluid dynamics is the development of *brain edema*. Because the brain is encased in a solid cranial vault, accumulation of extra edema fluid compresses the blood vessels, often causing seriously decreased blood flow and destruction of brain tissue.

An important cause of brain edema discussed in Chapter 25 is rapid reduction of plasma osmolality and sodium concentration (*hyponatremia*), which causes osmotic flow of water into the cells. Hyponatremia can occur from sodium loss, excessive water intake, or water retention by the kidneys (e.g., inappropriately elevated antidiuretic

hormone secretion). Hyponatremia is a common electrolyte disorder encountered in clinical practice and may occur in up to 15% to 25% of hospitalized patients. Severe and potentially life-threatening hyponatremia and brain edema can also occur in healthy persons during or following prolonged exercise when large amounts of sodium are lost by sweating and large amounts of hypotonic fluids (e.g., water) are consumed, in excess of urinary and sweat losses. Consumption of sports drinks containing carbohydrate and electrolytes does not provide adequate protection against *exercise-associated hyponatremia* since most of these drinks are markedly hypotonic compared to plasma.

Brain edema can also be caused by increased capillary filtration of fluid due either to greatly increased capillary pressure or damage to the capillary wall that makes the wall leaky to fluid. A common cause is a serious blow to the head, leading to *brain concussion*, in which the brain tissues and capillaries are traumatized and capillary fluid leaks into the traumatized tissues.

Once brain edema begins, it often initiates two vicious circles because of the following positive feedbacks:

1. Edema compresses the vasculature, which in turn decreases blood flow and causes brain ischemia. The ischemia in turn causes arteriolar dilation with still further increase in capillary pressure. The increased capillary pressure then causes more edema fluid, so the edema becomes progressively worse.
2. The decreased cerebral blood flow also decreases O_2 delivery, which increases the permeability of the capillaries, allowing still more fluid leakage. The diminished blood flow also reduces delivery of substrates needed to produce adequate adenosine triphosphate (ATP) that, in turn, is required for the sodium pumps of the neuronal tissue cells, thus allowing these cells to swell.

Once these vicious circles have begun, heroic measures must be used to prevent total destruction of the brain. One such measure is to infuse intravenously a concentrated osmotic substance, such as a concentrated mannitol solution, which pulls fluid by osmosis from the brain tissue and breaks up the vicious circles. Another procedure is to remove fluid quickly from the lateral ventricles of the brain by means of ventricular needle puncture, thereby relieving the intracerebral pressure.

BRAIN METABOLISM

Like other tissues, the brain requires O_2 and food nutrients to supply its metabolic needs. However, brain metabolism features special attributes that require mention.

Total Brain Metabolic Rate and Metabolic Rate of Neurons. Under resting but awake conditions, brain metabolism accounts for about 15% of the total metabolism in the body, even though brain mass is only 2% of the total body mass. Therefore, under resting conditions, brain metabolic rate per unit mass of tissue is about 7.5 times the average metabolic rate in non–nervous system tissues.

Most of this brain metabolism occurs in the neurons, not in the glial supportive tissues. The major need for metabolism in the neurons is to pump ions through their membranes, mainly to transport sodium and calcium ions to the outside of the neuronal membrane and potassium ions to the interior. Each time a neuron conducts an action potential, these ions move through the membranes, increasing the need for additional membrane transport to restore proper ionic concentration differences across the neuron membranes. Therefore, during high levels of brain activity, neuronal metabolism can increase as much as 100% to 150%.

Special Requirement of the Brain for Oxygen—Lack of Significant Anaerobic Metabolism. Most tissues of the body can live without O_2 for several minutes and some for as long as 30 minutes. During this time, the tissue cells obtain their energy through anaerobic metabolism, which releases energy by partially breaking down glucose and glycogen without combining these substances with O_2. This process delivers energy and keeps the tissues alive but at the expense of consuming tremendous amounts of glucose and glycogen.

The brain is not capable of much anaerobic metabolism after sudden reduction in O_2 delivery. One reason for this is the high metabolic rate of the neurons, so most neuronal activity depends on second-by-second delivery of O_2 from the blood. Putting these factors together, one can understand why sudden cessation of blood flow to the brain or sudden total lack of O_2 in the blood can cause unconsciousness within 5 to 10 seconds.

Under Normal Conditions, Most Brain Energy Is Supplied By Glucose. Under normal conditions, almost all the energy used by the brain cells is supplied by glucose derived from the blood. As is true for O_2, most of this glucose is derived minute by minute and second by second from the capillary blood, with a total of only about a 2-minute supply of glucose normally stored as glycogen in the brain at any given time.

A special feature of glucose delivery to neurons is that its transport into the neurons through the cell membrane is not dependent on insulin, even though insulin is required for normal glucose transport into most other body cells. Therefore, in patients who have serious diabetes with essentially zero secretion of insulin, glucose still diffuses readily into the neurons, which is most fortunate in preventing loss of mental function in persons with diabetes. Yet, when a diabetic patient is overtreated with insulin, the blood glucose concentration can fall to an extremely low level because the excess insulin causes most of the blood glucose to be transported rapidly into the vast numbers of insulin-sensitive non-neural cells throughout the body, especially into muscle and liver cells. When this happens, not enough glucose is left in the blood to supply the neurons properly, and mental function becomes seriously deranged, leading sometimes to coma and even more often to mental imbalances and psychotic disturbances—all caused by overtreatment with insulin.

CHAPTER 63

General Principles of Gastrointestinal Function—Motility, Nervous and Hormonal Control, Blood Circulation, and Microbiota

The alimentary tract provides the body with a continual supply of water, electrolytes, vitamins, and nutrients, which requires the following: (1) movement of food through the alimentary tract; (2) secretion of digestive juices and digestion of the food; (3) absorption of water, various electrolytes, vitamins, and digestive products; (4) circulation of blood through the gastrointestinal organs to carry away the absorbed substances; and (5) control of all these functions by local, nervous, and hormonal systems.

Fig. 63.1 shows the entire alimentary tract. Each part is adapted to its specific functions— some parts to simple passage of food, such as the esophagus; others to temporary storage of food, such as the stomach; and others to digestion and absorption, such as the small intestine. In this chapter we discuss the basic principles of function in the entire alimentary tract, and in subsequent chapters the specific functions of different segments of the tract will be addressed.

GENERAL PRINCIPLES OF GASTROINTESTINAL MOTILITY

Physiologic Anatomy of the Gastrointestinal Wall

Fig. 63.2 shows a typical cross section of the intestinal wall, including the following layers from the outer surface inward: (1) the *serosa*, (2) a *longitudinal smooth muscle layer*, (3) a *circular smooth muscle layer*, (4) the *submucosa*, and (5) the *mucosa*. In addition, sparse bundles of smooth muscle fibers, the *mucosal muscle*, lie in the deeper layers of the mucosa. The motor functions of the gut are performed by the different layers of smooth muscle.

The general characteristics of smooth muscle and its function are discussed in Chapter 8, which should be reviewed as a background for the following sections of this chapter.

Gastrointestinal Smooth Muscle Functions as a Syncytium. The individual smooth muscle fibers in the gastrointestinal tract are 200 to 500 micrometers in length and 2 to 10 micrometers in diameter, and they are arranged in bundles of as many as 1000 parallel fibers. In the *longitudinal muscle layer*, the bundles extend longitudinally down the intestinal tract; in the *circular muscle layer*, they extend around the gut.

Within each bundle, the muscle fibers are electrically connected with one another through large numbers of *gap junctions* that allow low-resistance movement of ions from one muscle cell to the next. Therefore, electrical signals that initiate muscle contractions can travel readily from one fiber to the next within each bundle but more rapidly along the length of the bundle than sideways.

Each bundle of smooth muscle fibers is partly separated from the next by loose connective tissue; however, the muscle bundles fuse with one another at many points, so in reality each muscle layer represents a branching latticework of smooth muscle bundles. Therefore, each muscle layer functions as a *syncytium;* that is, when an action potential is elicited anywhere within the muscle mass, it generally travels in all directions in the muscle. The distance that it travels depends on the excitability of the muscle; sometimes it stops after only a few millimeters, and at other times it travels many centimeters or even the entire length and breadth of the intestinal tract.

Also, because a few connections exist between the longitudinal and circular muscle layers, excitation of one of these layers often excites the other as well.

Electrical Activity of Gastrointestinal Smooth Muscle

The smooth muscle of the gastrointestinal tract is excited by almost continual slow, intrinsic electrical activity along the membranes of the muscle fibers. This activity has two basic types of electrical waves: (1) *slow waves* and (2) *spikes*, both of which are shown in **Fig. 63.3**. In addition, the voltage of the resting membrane potential of the gastrointestinal smooth muscle can change to different levels, which can also have important effects in controlling motor activity of the gastrointestinal tract.

"Slow Waves" Caused By Undulating Changes in Resting Membrane Potential. Most gastrointestinal contractions occur rhythmically, and this rhythm is determined mainly by the frequency of so-called "slow waves" of smooth muscle membrane potential. These waves, shown in **Fig. 63.3**, are not action potentials. Instead,

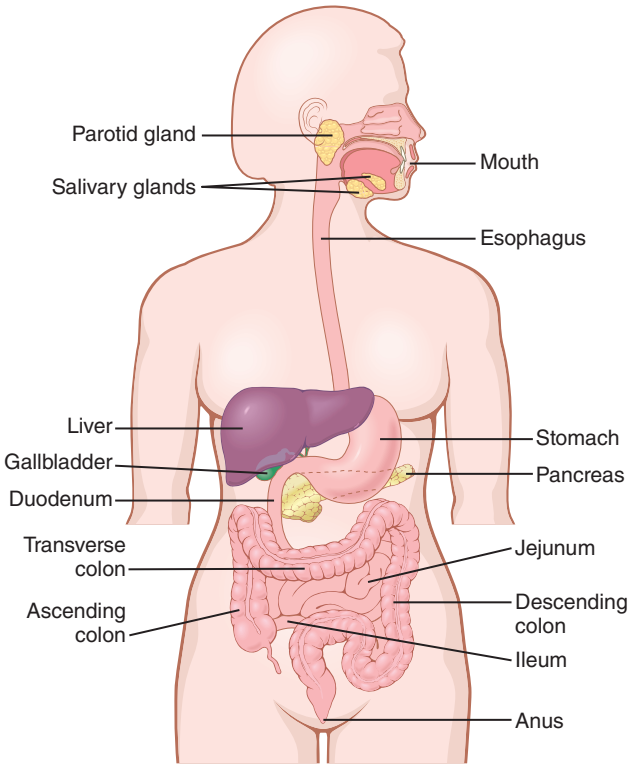

Figure 63.1 Alimentary tract.

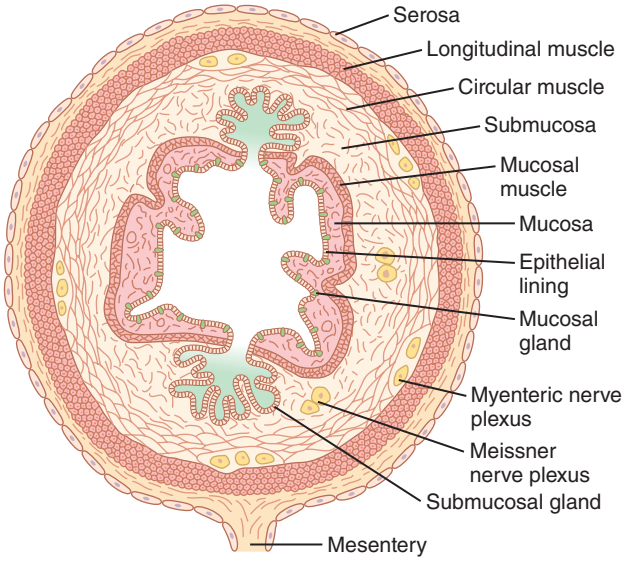

Figure 63.2 Typical cross section of the gut.

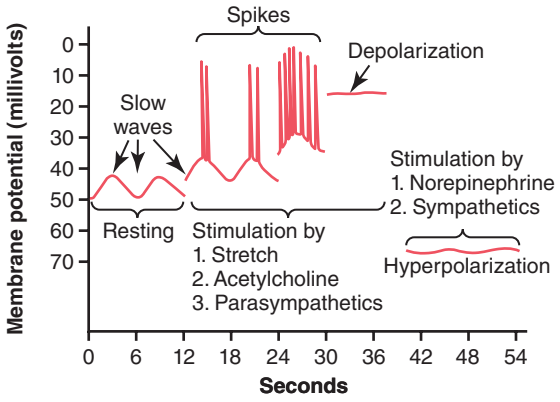

Figure 63.3 Membrane potentials in intestinal smooth muscle. Note the slow waves, the spike potentials, total depolarization, and hyperpolarization, all of which occur under different physiological conditions of the intestine.

they are slow, undulating changes in the resting membrane potential. Their intensity usually varies between 5 and 15 millivolts, and their frequency ranges in different parts of the human gastrointestinal tract from 3 to 12/min—about 3/min in the body of the stomach, as much as 12/min in the duodenum, and about 8 or 9/min in the terminal ileum.

The precise cause of the slow waves is not completely understood, although they appear to be caused by complex interactions among the smooth muscle cells and specialized cells, called the *interstitial cells of Cajal*, which are believed to act as *electrical pacemakers* for smooth muscle cells. These interstitial cells form a network with each other and are interposed between the smooth muscle layers, with synaptic-like contacts to smooth muscle cells. The interstitial cells of Cajal undergo cyclic changes in membrane potential due to unique ion channels that periodically open and produce inward (pacemaker) currents that may generate slow wave activity.

The slow waves usually do not by themselves cause muscle contraction in most parts of the gastrointestinal tract, *except perhaps in the stomach*. Instead, they mainly excite the appearance of intermittent spike potentials, and the spike potentials in turn actually excite the muscle contraction.

Spike Potentials Are True Action Potentials. Spike potentials occur automatically when the resting membrane potential of the gastrointestinal smooth muscle becomes more positive than about −40 millivolts (the normal resting membrane potential in the smooth muscle fibers of the gut is between −50 and −60 millivolts). Note in **Fig. 63.3** that each time the peaks of the slow waves temporarily become more positive than −40 millivolts, spike potentials appear on these peaks. The higher the slow wave potential rises, the greater the frequency of the spike potentials, usually ranging between 1 and 10 spikes per second. The spike potentials last 10 to 40 times as long in gastrointestinal muscle as action potentials in large nerve fibers, with each gastrointestinal spike lasting as long as 10 to 20 milliseconds.

Another important difference between the action potentials of the gastrointestinal smooth muscle and those of nerve fibers is the manner in which they are generated. In nerve fibers, the action potentials are caused almost entirely by rapid entry of sodium ions through sodium channels to the interior of the fibers. In gastrointestinal smooth muscle fibers, the channels responsible for the action potentials are somewhat different, allowing large numbers of calcium ions to enter along with smaller

numbers of sodium ions and therefore are called *calcium-sodium channels*. These channels are much slower to open and close than are the rapid sodium channels of large nerve fibers. The slowness of opening and closing of the calcium-sodium channels accounts for the long duration of the action potentials. Also, the movement of large amounts of calcium ions to the interior of the muscle fiber during the action potential plays a special role in causing the intestinal muscle fibers to contract, as we discuss shortly.

Changes in Voltage of the Resting Membrane Potential. In addition to the slow waves and spike potentials, the baseline voltage level of the smooth muscle resting membrane potential can also change. Although the resting membrane potential averages about −56 millivolts, multiple factors can change this level. When the potential becomes less negative, which is called *depolarization* of the membrane, the muscle fibers become more excitable. When the potential becomes more negative, which is called *hyperpolarization*, the fibers become less excitable.

Factors that depolarize the membrane and make it more excitable are (1) *stretching* of the muscle, (2) stimulation by *acetylcholine* released from the endings of *parasympathetic nerves*, and (3) stimulation by several *specific gastrointestinal hormones*.

Important factors that hyperpolarize the membrane and make the muscle fibers less excitable are (1) the effect of *norepinephrine* or *epinephrine* on the fiber membrane and (2) stimulation of the sympathetic nerves that secrete mainly norepinephrine at their endings.

Entry of Calcium Ions Causes Smooth Muscle Contraction. Smooth muscle contraction occurs in response to entry of calcium ions into the muscle fiber. As explained in Chapter 8, calcium ions act through a calmodulin control mechanism to activate the myosin filaments in the fiber, causing attractive forces to develop between the myosin filaments and the actin filaments, thereby causing the muscle to contract.

The slow waves do not cause calcium ions to enter the smooth muscle fiber (they only cause entry of sodium ions). Therefore, the slow waves by themselves usually do not cause muscle contraction. Instead, it is during the spike potentials, generated at the peaks of the slow waves, that significant quantities of calcium ions enter the fibers and cause most of the contraction.

Tonic Contraction of Some Gastrointestinal Smooth Muscle. Some smooth muscle of the gastrointestinal tract exhibits *tonic contraction*, as well as (or instead of) rhythmic contractions. Tonic contraction is continuous; it is not associated with the basic electrical rhythm of the slow waves but often lasts several minutes or even hours. The tonic contraction may increase or decrease in intensity, but it continues.

Tonic contraction is sometimes caused by continuous repetitive spike potentials—the greater the frequency, the greater the degree of contraction. At other times, tonic contraction is caused by hormones or other factors that bring about continuous partial depolarization of the smooth muscle membrane without causing action potentials. A third cause of tonic contraction is continuous entry of calcium ions into the interior of the cell brought about in ways not associated with changes in membrane potential. The details of these mechanisms are still unclear.

NEURAL CONTROL OF GASTROINTESTINAL FUNCTION—ENTERIC NERVOUS SYSTEM

The gastrointestinal tract has a nervous system all its own called the *enteric nervous system*. It lies entirely in the wall of the gut, beginning in the esophagus and extending all the way to the anus. The number of neurons in this enteric system is greater than 100 million, more than the number in the entire spinal cord. This highly developed enteric nervous system is especially important in controlling gastrointestinal movements and secretion.

The enteric nervous system is composed mainly of two plexuses, shown in **Fig. 63.4**: (1) an outer plexus lying between the longitudinal and circular muscle layers, called the *myenteric plexus* or *Auerbach plexus;* and (2) an inner plexus, called the *submucosal plexus* or *Meissner plexus*, which lies in the submucosa. The nervous connections within and between these two plexuses are also shown in **Fig. 63.4**.

The myenteric plexus controls mainly the gastrointestinal movements, and the submucosal plexus controls mainly gastrointestinal secretion and local blood flow.

In **Fig. 63.4**, note especially the extrinsic sympathetic and parasympathetic fibers that connect to both the myenteric and submucosal plexuses. Although the enteric nervous system can function independently of these extrinsic nerves, stimulation by the parasympathetic and sympathetic systems can greatly enhance or inhibit gastrointestinal functions, as we discuss later.

Also shown in **Fig. 63.4** are sensory nerve endings that originate in the gastrointestinal epithelium or gut wall and send afferent fibers to both plexuses of the enteric system, as well as (1) to the prevertebral ganglia of the sympathetic nervous system, (2) the spinal cord, and (3) in the vagus nerves, all the way to the brain stem. These sensory nerves can elicit local reflexes within the gut wall, as well as additional reflexes that are relayed to the gut from either the prevertebral ganglia or the basal regions of the brain.

DIFFERENCES BETWEEN THE MYENTERIC AND SUBMUCOSAL PLEXUSES

The *myenteric plexus* consists mostly of a linear chain of many interconnecting neurons that extends the entire length of the gastrointestinal tract. A section of this chain is shown in **Fig. 63.4**.

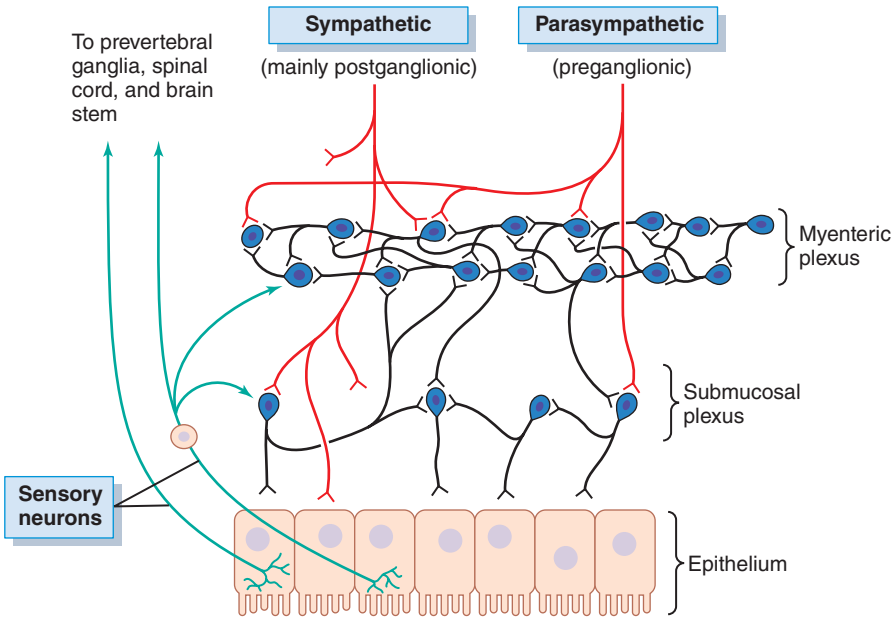

Figure 63.4 Neural control of the gut wall, showing the following: (1) the myenteric and submucosal plexuses *(black fibers);* (2) extrinsic control of these plexuses by the sympathetic and parasympathetic nervous systems (*red fibers*); and (3) sensory fibers passing from the luminal epithelium and gut wall to the enteric plexuses, and then to the prevertebral ganglia of the spinal cord and directly to the spinal cord and brain stem *(green fibers)*.

Because the myenteric plexus extends all the way along the intestinal wall and lies between the longitudinal and circular layers of intestinal smooth muscle, it is especially important for controlling muscle activity along the length of the gut. When this plexus is stimulated, its principal effects are as follows: (1) increased tonic contraction, or "tone," of the gut wall; (2) increased intensity of rhythmic contractions; (3) slightly increased rate of rhythmic contractions; and (4) increased velocity of conduction of excitatory waves along the gut wall, causing more rapid movement of the gut peristaltic waves. The excitatory motor neurons contain neurotransmitters such as *acetylcholine*, *substance P*, and *glutamate*.

The *myenteric plexus* should not be considered entirely excitatory because some of its neurons are *inhibitory;* their fiber endings secrete inhibitory transmitters, including *vasoactive intestinal polypeptide, nitric oxide*, and *adenosine triphosphate (ATP)*. The resulting inhibitory signals are especially useful for inhibiting some of the intestinal sphincter muscles that impede movement of food along successive segments of the gastrointestinal tract, such as the *pyloric sphincter*, which controls emptying of the stomach into the duodenum, and the *sphincter of the ileocecal valve*, which controls emptying from the small intestine into the cecum.

The *submucosal plexus*, in contrast to the myenteric plexus, is mainly important for controlling function in the inner wall of each minute segment of the intestine. For example, many sensory signals originate from the gastrointestinal epithelium and are then integrated in the submucosal plexus to help control local *intestinal secretion*, local *absorption*, and local *contraction of the submucosal muscle* that causes various degrees of infolding of the gastrointestinal mucosa.

TYPES OF NEUROTRANSMITTERS SECRETED BY ENTERIC NEURONS

More than 25 potential neurotransmitter substances released by the nerve endings of different types of enteric neurons have been identified, including the following: (1) *acetylcholine*, (2) *norepinephrine*, (3) *adenosine triphosphate*, (4) *serotonin*, (5) *dopamine*, (6) *cholecystokinin*, (7) *substance P*, (8) *vasoactive intestinal polypeptide*, (9) *somatostatin*, (10) *leu-enkephalin*, (11) *met-enkephalin*, (12) *bombesin*, (13) neuropeptide Y, and (14) nitric oxide. The specific functions of many of these substances are not known well enough to justify discussion here other than to point out the following characteristics.

Acetylcholine most often excites gastrointestinal activity. *Norepinephrine* almost always inhibits gastrointestinal activity, as does *epinephrine*, which reaches the gastrointestinal tract mainly via the blood after it is secreted by the adrenal medullae into the circulation. The other aforementioned transmitter substances are a mixture of excitatory and inhibitory agents, some of which we will discuss in Chapter 64.

AUTONOMIC CONTROL OF THE GASTROINTESTINAL TRACT

Parasympathetic Stimulation Increases Activity of the Enteric Nervous System. The parasympathetic supply to the gut is divided into *cranial* and *sacral divisions*, which were discussed in Chapter 61.

Except for a few parasympathetic fibers to the mouth and pharyngeal regions of the alimentary tract, the *cranial parasympathetic* nerve fibers are almost entirely in the *vagus nerves*. These fibers provide extensive innervation to the esophagus, stomach, and pancreas and somewhat less to the intestines down through the first half of the large intestine.

The *sacral parasympathetics* originate in the second, third, and fourth sacral segments of the spinal cord and pass through the *pelvic nerves* to the distal half of the large intestine and all the way to the anus. The sigmoidal, rectal, and anal regions are considerably better supplied with parasympathetic fibers than are the other intestinal areas. These fibers function especially to execute the defecation reflexes, discussed in Chapter 64.

The *postganglionic neurons* of the gastrointestinal parasympathetic system are located mainly in the myenteric and submucosal plexuses. Stimulation of these parasympathetic nerves generally increases activity of the entire enteric nervous system, which in turn enhances activity of most gastrointestinal functions.

Sympathetic Stimulation Usually Inhibits Gastrointestinal Tract Activity. The sympathetic fibers to the gastrointestinal tract originate in the spinal cord between segments T5 and L2. Most of the preganglionic fibers that innervate the gut, after leaving the cord, enter the *sympathetic chains* that lie lateral to the spinal column, and many of these fibers then pass on through the chains to outlying ganglia such as to the *celiac ganglion* and various *mesenteric ganglia*. Most of the *postganglionic sympathetic neuron bodies* are in these ganglia, and postganglionic fibers then spread through postganglionic sympathetic nerves to all parts of the gut. The sympathetics innervate essentially all of the gastrointestinal tract, rather than being more extensive nearest the oral cavity and anus, as is true of the parasympathetics. The sympathetic nerve endings secrete mainly *norepinephrine*.

In general, stimulation of the sympathetic nervous system *inhibits* activity of the gastrointestinal tract, causing many effects opposite to those of the parasympathetic system. It exerts its effects in two ways: (1) to a slight extent by the direct effect of secreted norepinephrine to inhibit intestinal tract smooth muscle (except the mucosal muscle, which it excites) and (2) to a major extent by an inhibitory effect of norepinephrine on the neurons of the entire enteric nervous system.

Strong stimulation of the sympathetic system can inhibit motor movements of the gut so greatly that this can literally block movement of food through the gastrointestinal tract.

Afferent Sensory Nerve Fibers From the Gut

Many afferent sensory nerve fibers innervate the gut. Some of the nerve fibers have their cell bodies in the enteric nervous system, and some have them in the dorsal root ganglia of the spinal cord. These sensory nerves can be stimulated by (1) irritation of the gut mucosa, (2) excessive gut distention, or (3) the presence of specific chemical substances in the gut. Signals transmitted through the fibers can then cause *excitation* or, under other conditions, *inhibition* of intestinal movements or intestinal secretion.

In addition, other sensory signals from the gut go all the way to multiple areas of the spinal cord and even to the brain stem. For example, 80% of the nerve fibers in the vagus nerves are afferent rather than efferent. These afferent fibers transmit sensory signals from the gastrointestinal tract into the brain medulla, which, in turn, initiates vagal reflex signals that return to the gastrointestinal tract to control many of its functions.

Gastrointestinal Reflexes

The anatomical arrangement of the enteric nervous system and its connections with the sympathetic and parasympathetic systems support three types of gastrointestinal reflexes that are essential to gastrointestinal control.

1. *Reflexes that are integrated entirely within the gut wall enteric nervous system*. These reflexes include, for example, those that control gastrointestinal secretion, peristalsis, mixing contractions, local inhibitory effects, and so forth.
2. *Reflexes from the gut to the prevertebral sympathetic ganglia and then back to the gastrointestinal tract*. These reflexes transmit signals long distances to other areas of the gastrointestinal tract, such as signals from the stomach to cause evacuation of the colon (the *gastrocolic reflex*), signals from the colon and small intestine to inhibit stomach motility and stomach secretion (the *enterogastric reflexes*), and reflexes from the colon to inhibit emptying of ileal contents into the colon (the *colonoileal reflex*).
3. *Reflexes from the gut to the spinal cord or brain stem and then back to the gastrointestinal tract*. These reflexes include especially the following: (1) reflexes from the stomach and duodenum to the brain stem and back to the stomach—via the vagus nerves—to control gastric motor and secretory activity; (2) pain reflexes that cause general inhibition of the entire gastrointestinal tract; and (3) defecation reflexes that travel from the colon and rectum to the spinal cord and back again to produce the powerful colonic, rectal, and abdominal contractions required for defecation (the *defecation reflexes*).

HORMONAL CONTROL OF GASTROINTESTINAL MOTILITY

The gastrointestinal hormones are released into the portal circulation and exert physiological actions on target cells with specific receptors for the hormone. The effects of the hormones persist even after all nervous connections between the site of release and the site of action have been severed. **Table 63.1** outlines the actions of the major gastrointestinal hormones, as well as the stimuli for secretion and sites at which secretion takes place.

In Chapter 65, we discuss the importance of several hormones for controlling gastrointestinal secretion. Most of these same hormones also affect motility in some parts

Table 63.1 Major Gastrointestinal Hormone Actions, Stimuli for Secretion, and Sites of Secretion

Hormone	Stimuli for Secretion	Site of Secretion	Actions
Gastrin	Protein Distention Nervous *(Acid inhibits release)*	G cells of the antrum, duodenum, and jejunum	Stimulates • Gastric acid secretion • Mucosal growth
Cholecystokinin	Protein Fat Acid	I cells of the duodenum, jejunum, and ileum	Stimulates • Pancreatic enzyme secretion • Pancreatic bicarbonate secretion • Gallbladder contraction • Growth of exocrine pancreas Inhibits • Gastric emptying
Secretin	Acid Fat	S cells of the duodenum, jejunum, and ileum	Stimulates • Pepsin secretion • Pancreatic bicarbonate secretion • Biliary bicarbonate secretion • Growth of exocrine pancreas Inhibits • Gastrin release and gastric acid secretion • Gastric emptying
Glucose-dependent insulinotropic peptide (also called gastric inhibitory peptide [GIP])	Protein Fat Carbohydrate	K cells of the duodenum and jejunum	Stimulates • Insulin secretion Inhibits • Gastric acid secretion • Food intake
Motilin	Fat Acid Nervous	M cells of the duodenum and jejunum	Stimulates • Gastric motility • Intestinal motility
Glucagon-like peptide 1 (GLP-1)	Carbohydrate Fat Protein	L-cells of duodenum, jejunum, ileum, and colon	Stimulates • Insulin secretion (glucose-dependent) Inhibits • Gastric emptying • Acid secretion • Food intake

of the gastrointestinal tract. Although the motility effects are usually less important than the secretory effects of the hormones, some of the more important motility effects are described in the following paragraphs.

Gastrin is secreted by the "G" cells of the *antrum of the stomach* in response to stimuli associated with ingestion of a meal, such as distention of the stomach, the products of proteins, and *gastrin-releasing peptide*, which is released by the nerves of the gastric mucosa during vagal stimulation. The primary actions of gastrin are (1) *stimulation of gastric acid secretion* and (2) *stimulation of growth of the gastric mucosa*.

Cholecystokinin (CCK) is secreted by "I" cells in the *mucosa of the duodenum and jejunum*, mainly in response to digestive products of fat, fatty acids, and monoglycerides in the intestinal contents. This hormone strongly contracts the gallbladder, expelling bile into the small intestine, where the bile, in turn, plays important roles in emulsifying fatty substances and allowing them to be digested and absorbed. CCK also inhibits stomach contraction moderately. Therefore, at the same time that this hormone causes emptying of the gallbladder, it also slows the emptying of food from the stomach to give adequate time for digestion of the fats in the upper intestinal tract. CCK also promotes satiety to help prevent overeating during meals by stimulating sensory afferent nerve fibers in the duodenum; these fibers, in turn, send signals by way of the vagus nerve to inhibit feeding centers in the brain as discussed in Chapter 72.

Secretin, the first gastrointestinal hormone discovered, is secreted by the "S" cells in the *mucosa of the duodenum* in response to acidic gastric juice emptying into the duodenum from the pylorus of the stomach. Secretin has a mild effect on motility of the gastrointestinal tract and acts to promote pancreatic secretion of bicarbonate which, in turn, helps to neutralize acid in the small intestine.

Glucose-dependent insulinotropic peptide (also called gastric inhibitory peptide [GIP]) is secreted by the *mucosa of the upper small intestine*, mainly in response to fatty acids and amino acids but to a lesser extent in response to carbohydrates. It has a mild effect in decreasing motor activity of the stomach and therefore slows emptying of gastric contents into the duodenum when the upper small intestine is already overloaded with food products. Glucose-dependent insulinotropic peptide, at blood levels even lower than those needed to inhibit gastric motility, also stimulates insulin secretion.

Motilin is secreted by the stomach and *upper duodenum* during fasting, and the major function of this hormone is to *increase gastrointestinal motility*. Motilin is released cyclically and stimulates waves of gastrointestinal motility called *interdigestive myoelectric complexes* that move through the stomach and small intestine every 90 minutes in a person who has fasted.

Motilin Secretion Is Inhibited After Ingestion of Food. *Glucagon-like peptide-1 (GLP-1)* is secreted by the intestinal L-cells. The density of L-cells is low in the duodenum and jejunum and increases distally along the gut, with the greatest density in the ileum and colon. The L-cells face the gut lumen where they have direct contact with and sense luminal nutrients. In healthy humans, ingestion of carbohydrates or proteins stimulates a rapid (within 10 to 15 mins) increase in plasma GLP-1 concentration with a peak 30 to 60 minutes following nutrient ingestion, whereas lipid ingestion elicits a later but more prolonged increase in GLP-1. Important effects of GLP-1 include glucose-dependent stimulation of insulin secretion (discussed in Chapter 79), inhibition of gastric emptying and acid secretion, and promotion of satiety and reduction in food intake (discussed in Chapter 72).

In addition to these gastrointestinal hormones, there are several other important peptides and paracrine factors that influence various gastrointestinal functions, including motility, and many of these are discussed in subsequent chapters.

FUNCTIONAL MOVEMENTS IN THE GASTROINTESTINAL TRACT

Two types of movements occur in the gastrointestinal tract: (1) *propulsive movements*, which cause food to move forward along the tract at an appropriate rate to accommodate digestion and absorption, and (2) *mixing movements*, which keep the intestinal contents thoroughly mixed at all times.

PROPULSIVE MOVEMENTS—PERISTALSIS

The basic propulsive movement of the gastrointestinal tract is *peristalsis*, which is illustrated in **Fig. 63.5A**. A contractile ring appears around the gut and then moves forward; this mechanism is analogous to putting one's fingers around a thin distended tube, then constricting the fingers and sliding them forward along the tube. Any material in front of the contractile ring is moved forward.

Peristalsis is an inherent property of many syncytial smooth muscle tubes; stimulation at any point in the gut can cause a contractile ring to appear in the circular muscle, and this ring then spreads along the gut tube. (Peristalsis also occurs in the bile ducts, glandular ducts, ureters, and many other smooth muscle tubes of the body.)

The usual stimulus for intestinal peristalsis is *distention of the gut*. That is, if a large amount of food collects at any point in the gut, stretching of the gut wall stimulates the enteric nervous system to contract the gut wall 2 to 3 centimeters behind this point, and a contractile ring appears that initiates a peristaltic movement. Other stimuli that can initiate peristalsis include chemical or physical irritation of the epithelial lining in the gut. Also, strong parasympathetic nervous signals to the gut will elicit strong peristalsis.

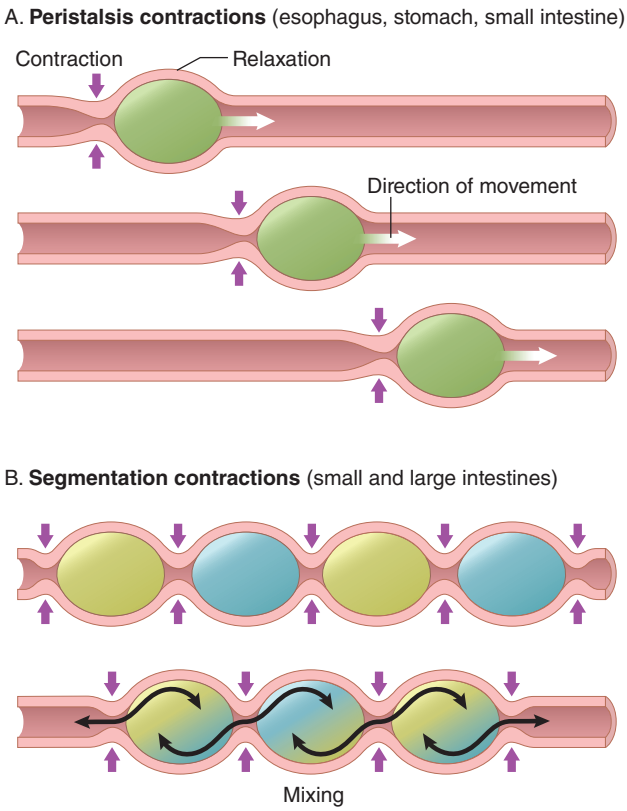

Figure 63.5 Peristalsis involves contraction and downstream relaxation in the esophagus, stomach, and small intestine as they propel their contents toward the anus. Intermittent segmentation contractions in separate sections of the small and large intestines mix their contents with little forward movement.

Function of the Myenteric Plexus in Peristalsis. Peristalsis occurs only weakly or not at all in portions of the gastrointestinal tract that have congenital absence of the myenteric plexus. Also, it is greatly depressed or completely blocked in the entire gut when a person is treated with atropine, which paralyzes the cholinergic nerve endings of the myenteric plexus. Therefore, *effectual* peristalsis requires an active myenteric plexus.

Peristaltic Waves Move Toward the Anus With Downstream Receptive Relaxation—"Law of the Gut." Peristalsis, theoretically, can occur in either direction from a stimulated point, but it normally dies out rapidly in the orad (toward the mouth) direction while continuing for a considerable distance toward the anus. The exact cause of this directional transmission of peristalsis is uncertain, although it probably results mainly from the fact that the myenteric plexus is "polarized" in the anal direction, which can be explained as follows.

When a segment of the intestinal tract is excited by distention and thereby initiates peristalsis, the contractile ring causing the peristalsis normally begins on the orad side of the distended segment and moves toward the distended segment, pushing the intestinal contents in the anal direction for 5 to 10 centimeters before dying out (**Video 63.1**). At the same time, the gut sometimes relaxes several centimeters downstream toward the anus, which is called "receptive relaxation," thus allowing the food to be propelled more easily toward the anus than toward the mouth.

This complex pattern does not occur in the absence of the myenteric plexus. Therefore, the complex is called the *myenteric reflex* or the *peristaltic reflex*. The peristaltic reflex plus the anal direction of movement of the peristalsis is called the "law of the gut."

SEGMENTATION CONTRACTIONS—MIXING MOVEMENTS

Mixing movements differ in different parts of the alimentary tract. In some areas, the peristaltic contractions cause most of the mixing. This is especially true when forward progression of the intestinal contents is blocked by a sphincter so that a peristaltic wave can then only churn the intestinal contents, rather than propelling them forward. At other times, *local intermittent segmentation contractions* occur every few centimeters in the gut wall (see **Fig. 63.5B**). These constrictions usually last only 5 to 30 seconds; new constrictions then occur at other points in the gut, thus "chopping" and "shearing" the contents first here and then there. These peristaltic and constrictive movements are modified in different parts of the gastrointestinal tract for proper propulsion and mixing, as discussed in Chapter 64.

GASTROINTESTINAL BLOOD FLOW—SPLANCHNIC CIRCULATION

The blood vessels of the gastrointestinal system are part of a more extensive system called the *splanchnic circulation*, shown in **Fig. 63.6**. It includes the blood flow through the gut plus blood flows through the spleen, pancreas, and liver. The design of this system is such that all the blood that courses through the gut, spleen, and pancreas then flows immediately into the liver by way of the *portal vein*.

In the liver, the blood passes through millions of minute *liver sinusoids* and finally leaves the liver via *hepatic veins* that empty into the vena cava of the general circulation. This flow of blood through the liver, before it empties into the vena cava, allows the *reticuloendothelial cells* that line the liver sinusoids to remove bacteria and other particulate matter that might enter the blood from the gastrointestinal tract, thus preventing direct transport of potentially harmful agents into the remainder of the body.

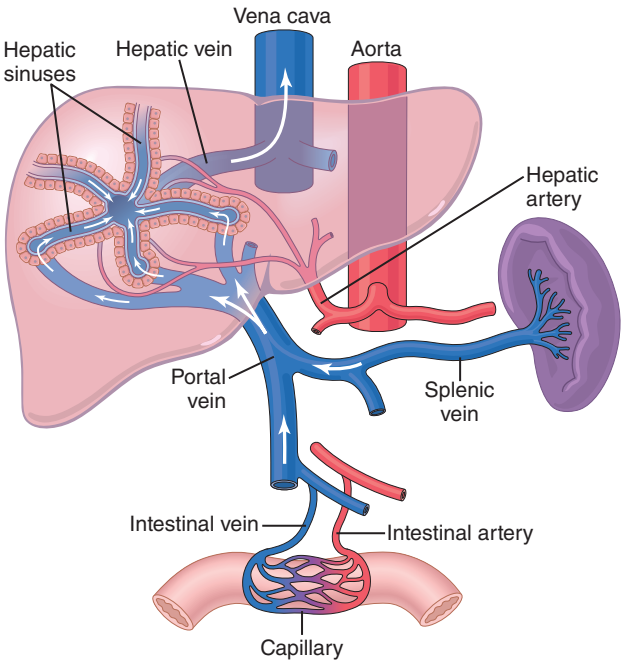

Figure 63.6 Splanchnic circulation.

The *nonfat, water-soluble nutrients* absorbed from the gut (e.g., carbohydrates and proteins) are transported in the portal venous blood to the same liver sinusoids. Here, both the reticuloendothelial cells and the principal parenchymal cells of the liver, the *hepatic cells*, absorb and store temporarily 50% to 75% of the nutrients. Also, much chemical intermediary processing of these nutrients occurs in the liver cells. These nutritional functions of the liver are discussed in Chapters 68 through 71. Almost all of the *fats* absorbed from the intestinal tract *are not carried in the portal blood* but instead are absorbed into the intestinal lymphatics and then conducted to the systemic circulating blood by way of the *thoracic duct*, bypassing the liver.

ANATOMY OF THE GASTROINTESTINAL BLOOD SUPPLY

Fig. 63.7 shows the general features of the arterial blood supply to the gut, including the *superior mesenteric* and *inferior mesenteric arteries* supplying the walls of the small and large intestines via an arching arterial system. Not shown in the figure is the *celiac artery*, which provides a similar blood supply to the stomach.

On entering the wall of the gut, the arteries branch and send smaller arteries circling in both directions around the gut, with the tips of these arteries meeting on the side of the gut wall opposite the mesenteric attachment. From the circling arteries, still much smaller arteries penetrate into the intestinal wall and spread (1) along the muscle bundles, (2) into the intestinal villi, and (3) into submucosal vessels beneath the epithelium to serve the secretory and absorptive functions of the gut.

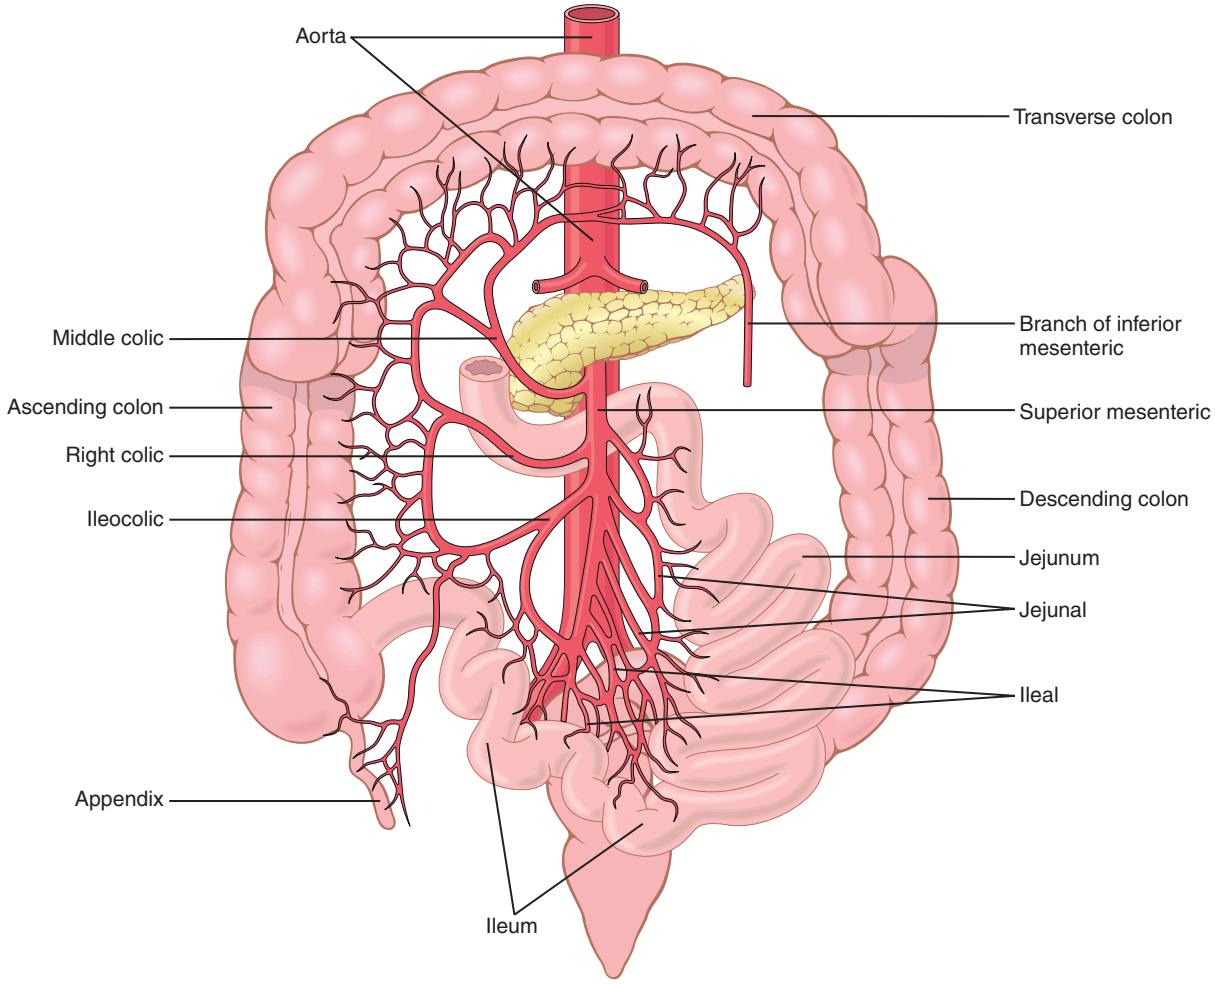

Figure 63.7 Arterial blood supply to the intestines through the mesenteric web.

Fig. 63.8 shows the special organization of the blood flow through an intestinal villus, including a small arteriole and venule that interconnect with a system of multiple looping capillaries. The walls of the arterioles are highly muscular and highly active in controlling villus blood flow.

GUT ACTIVITY AND METABOLIC FACTORS REGULATE GASTROINTESTINAL BLOOD FLOW

Under normal conditions, the blood flow in each area of the gastrointestinal tract, as well as in each layer of the gut wall, is directly related to the level of local activity. For example, during active absorption of nutrients, blood flow in the villi and adjacent regions of the submucosa increases as much as 8-fold. Likewise, blood flow in the muscle layers of the intestinal wall increases with increased motor activity in the gut. After a meal, the motor activity, secretory activity, and absorptive activity all increase; likewise, the blood flow increases greatly but then decreases back to the resting level over another 2 to 4 hours.

Mechanisms of Increased Blood Flow During Gastrointestinal Activity. Although the precise causes of the increased blood flow during increased gastrointestinal activity are still unclear, some facts are known.

First, several vasodilator substances are released from the mucosa of the intestinal tract during the digestive process. Most of these substances are peptide hormones, including *cholecystokinin, vasoactive intestinal peptide, gastrin*, and *secretin*. These same hormones control specific motor and secretory activities of the gut, as discussed in Chapters 64 and 65.

Second, some of the gastrointestinal glands also release into the gut wall two kinins, *kallidin* and *bradykinin*, at the same time that they secrete other substances into the lumen. These kinins are powerful vasodilators that are believed to cause much of the increased mucosal vasodilation that occurs along with secretion.

Third, *decreased oxygen concentration* in the gut wall can increase intestinal blood flow at least 50% to 100%; therefore, the increased mucosal and gut wall metabolic rate during gut activity probably lowers the oxygen concentration enough to cause much of the vasodilation. The decrease in oxygen can also lead to as much as a 4-fold increase of *adenosine*, a well-known vasodilator that could be responsible for much of the increased flow.

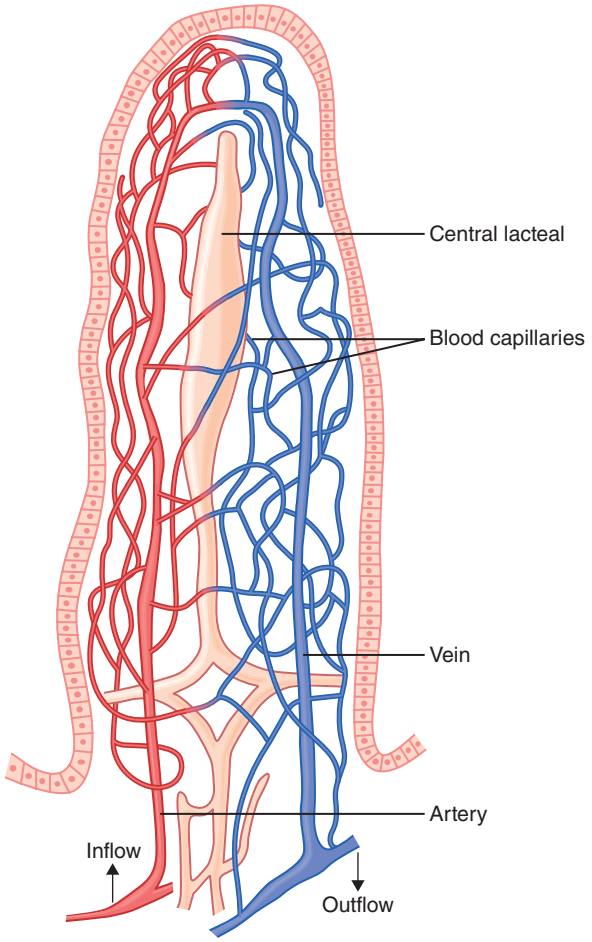

Figure 63.8 Microvasculature of the villus showing a countercurrent arrangement of blood flow in the arterioles and venules.

Thus, the increased blood flow during increased gastrointestinal activity is probably a combination of many of the aforementioned factors plus others yet undiscovered.

Countercurrent Blood Flow in the Villi. Note in **Fig. 63.8** that the arterial flow into the villus and the venous flow out of the villus are in directions opposite to each other and that the vessels lie in close apposition to each other. Because of this vascular arrangement, much of the blood oxygen diffuses out of the arterioles directly into the adjacent venules without ever being carried in the blood to the tips of the villi. As much as 80% of the oxygen may take this short-circuit route and is therefore not available for local metabolic functions of the villi. This type of countercurrent mechanism in the villi is analogous to the countercurrent mechanism in the vasa recta of the kidney medulla, which was discussed in Chapter 29.

Under normal conditions, this shunting of oxygen from the arterioles to the venules is not harmful to the villi, but in disease conditions in which blood flow to the gut becomes greatly curtailed, such as in circulatory shock, the oxygen deficit in the tips of the villi can become so great that the villus tip or even the whole villus undergoes ischemic death and disintegrates. For this reason and other reasons, in many gastrointestinal diseases the villi become seriously damaged, leading to greatly diminished intestinal absorptive capacity.

NERVOUS CONTROL OF GASTROINTESTINAL BLOOD FLOW

Stimulation of the parasympathetic nerves going to the *stomach* and *lower colon* increases local blood flow at the same time that it increases glandular secretion. This increased flow probably results secondarily from the increased glandular activity, not as a direct effect of the nervous stimulation.

Sympathetic stimulation, by contrast, has a direct effect on essentially all the gastrointestinal tract to cause intense vasoconstriction of the arterioles and greatly decreased blood flow. After a few minutes of this vasoconstriction, the flow often returns to near normal by means of a mechanism called "autoregulatory escape," if sympathetic activation is not too severe. That is, the local metabolic vasodilator mechanisms that are elicited by ischemia override the sympathetic vasoconstriction, returning toward normal the necessary nutrient blood flow to the gastrointestinal glands and muscle.

Importance of Sympathetic Nervous Depression of Gastrointestinal Blood Flow When Other Parts of the Body Need Extra Blood Flow. A major value of sympathetic vasoconstriction in the gut is that it allows shutoff of gastrointestinal and other splanchnic blood flow for short periods during heavy exercise when the skeletal muscle and heart need increased flow. Also, in circulatory shock, when all the body's vital tissues are in danger of cellular death for lack of blood flow—especially the brain and the heart—sympathetic stimulation can decrease splanchnic blood flow to very little for many hours.

Sympathetic stimulation also causes strong vasoconstriction of the large-volume *intestinal* and *mesenteric veins*. This vasoconstriction decreases the volume of these veins, thereby displacing large amounts of blood into other parts of the circulation. In persons experiencing hemorrhagic shock or other states of low blood volume, this mechanism can provide as much as 200 to 400 mL of extra blood to sustain the general circulation.

GASTROINTESTINAL MICROBIOTA

The human gastrointestinal tract is colonized by trillions of microorganisms, collectively called the *microbiota*, that play a key role in homeostasis. The term *microbiome* is often used interchangeably with microbiota but is slightly different and includes the genomes of the microbiota.

Although the gastrointestinal tract is essentially sterile at birth, microorganisms living in symbiosis with one another and with the host rapidly colonize the gut after birth. The composition of the microbiota in infants is influenced by multiple factors, including the birth modality (cesarean section versus vaginal delivery), diet (breast milk versus formula feeding), and the use of antibiotics.

With the cessation of breastfeeding and the start of a more diverse diet, there is rapid diversification of gut microbiota, which eventually consists of 400 to 1000 different species of bacteria and other types of microbes.

In healthy humans, most gut microbes are strictly anaerobic and about 90% belong to the phyla *Bacteroidetes* and *Firmicutes*, although there are many different types of bacteria in each of these phyla. The concentration of these microbes increases steadily along the gastrointestinal tract, with relatively small numbers in the stomach and extremely large numbers in the colon. The estimated number of bacterial cells present in the mammalian stomach and duodenum averages 10^1 to 10^3 bacteria per gram of contents, progressing to 10^4 to 10^7 bacteria per gram in the jejunum and ileum, and reaching 10^{11} to 10^{12} microbes per gram in the colon. Also, the microbial composition varies among these sites due to differences in pH, mucus thickness, bile acids, immune factors, transit time of intestinal contents, and other factors.

Functions of the Gastrointestinal Microbiota

The dense and diverse microbiota inhabiting the gut contributes to many physiological functions, including protection against pathogen colonization and overgrowth of indigenous microbes. For example, intestinal bacteria produce antimicrobial compounds and compete for nutrients and sites of attachment in the gut lining, thereby preventing colonization by pathogenic microbes.

To manage the constant threat of the tremendous numbers of gut bacteria, the intestinal immune system has evolved unique adaptations to prevent overgrowth and to ensure that bacteria rarely breach the intestinal barrier. Key components of this protection include enhancement of the physical barrier by production of mucus, antimicrobial proteins, and immunoglobulin A. Whenever bacteria do invade the intestinal barrier, as a result of a "leaky gut," they are usually killed before they penetrate to systemic sites. However, despite these protective measures, a change in the microbiota from a healthy to an unhealthy pattern (*dysbiosis*) has been associated with multiple disorders of the gastrointestinal tract, as well as various systemic diseases. For example, gut dysbiosis increases the risk of pathogen infection and overgrowth of harmful microbes.

The gut microbiota is also involved in regulating multiple other intestinal functions, including digestion, nutrient extraction from food, and the production of vitamins, as well as systemic hormonal functions, modification and elimination of specific toxins and drugs, and regulation of bone density, among other functions.

Factors such as the amount of dietary fat, proteins, and fiber, influence the composition of gut microbiota and eventually contribute to the regulation of host energy metabolism and other physiological functions through specific microbial metabolites that may have immune-dependent and immune-independent effects. For example, an excessively high-calorie, Western-style diet is associated with gut dysbiosis and inflammation, which, in extreme cases, may result in a leaky gut and translocation of gut-derived bacteria that promote liver inflammation and *nonalcoholic steatohepatitis (NASH)*.

The importance of microbial balance is also readily apparent when considering the effects of chronic antibiotic treatment, which often causes diarrhea and gut dysbiosis that may last for several weeks after stopping the treatment. The specific mechanisms by which the gut microbiota exerts its beneficial effects in health or its adverse effects in various diseases remain largely undefined and represent an area of intense research.

Propulsion and Mixing of Food in the Alimentary Tract

The time that food remains in each part of the alimentary tract is critical for optimal processing and absorption of nutrients. In addition, appropriate mixing must be provided. Because the requirements for mixing and propulsion are quite different at each stage of processing, multiple automatic nervous and hormonal mechanisms control the timing of each of these activities so that they will occur optimally—not too rapidly and not too slowly.

This chapter discusses these movements, especially the automatic mechanisms of this control.

INGESTION OF FOOD

The amount of food that a person ingests is determined principally by an intrinsic desire for food called *hunger*. The type of food that a person preferentially seeks is determined by *appetite*. These mechanisms are extremely important for maintaining an adequate nutritional supply for the body and are discussed in Chapter 72 in relation to nutrition of the body. The current discussion is confined to the mechanics of food ingestion, especially *mastication* and *swallowing*.

MASTICATION (CHEWING)

The teeth are well designed for chewing. The anterior teeth (incisors) provide a strong cutting action, and the posterior teeth (molars) provide a grinding action. All the jaw muscles working together can close the teeth with a force as great as 55 pounds on the incisors and 200 pounds on the molars.

Most of the muscles of chewing are innervated by the motor branch of the fifth cranial nerve, and the chewing process is controlled by nuclei in the brain stem. Stimulation of specific reticular areas in the brain stem taste centers will cause rhythmic chewing movements. In addition, stimulation of areas in the hypothalamus, amygdala, and even the cerebral cortex near the sensory areas for taste and smell can cause chewing.

Although chewing can be initiated by voluntary control, part of the chewing process is caused by a *chewing reflex*. The presence of a bolus of food in the mouth at first initiates reflex inhibition of the muscles of mastication, which allows the lower jaw to drop. This drop, in turn, initiates a stretch reflex of the jaw muscles that leads to *rebound* contraction. This action automatically raises the jaw to cause closure of the teeth, but it also compresses the bolus again against the linings of the mouth, which inhibits the jaw muscles once again, allowing the jaw to drop and rebound another time; this process is repeated again and again.

Chewing is important for digestion of all foods, but it is especially important for most fruits and raw vegetables because they have indigestible cellulose membranes around their nutrient portions that must be broken before the food can be digested. Furthermore, chewing aids the digestion of food for another simple reason—*digestive enzymes act only on the surfaces of food particles*. Therefore, the rate of digestion depends on the total surface area exposed to the digestive secretions. In addition, grinding the food to a very fine particulate consistency prevents excoriation of the gastrointestinal tract and increases the ease with which food is emptied from the stomach into the small intestine, then into all succeeding segments of the gut.

SWALLOWING (DEGLUTITION)

Swallowing is a complicated mechanism, principally because the pharynx subserves respiration and swallowing. The pharynx is converted for only a few seconds at a time into a tract for propulsion of food. It is especially important that respiration not be compromised because of swallowing.

In general, swallowing can be divided into the following stages: (1) a *voluntary stage*, which initiates the swallowing process; (2) a *pharyngeal stage*, which is involuntary and constitutes passage of food through the pharynx into the esophagus; and (3) an *esophageal stage*, another involuntary phase that transports food from the esophagus to the stomach.

Voluntary Stage of Swallowing. When the food is ready for swallowing, it is "voluntarily" squeezed or rolled posteriorly into the pharynx by pressure of the tongue upward and backward against the palate, as shown in **Fig. 64.1**. From here on, swallowing becomes entirely—or almost entirely—automatic and ordinarily cannot be stopped.

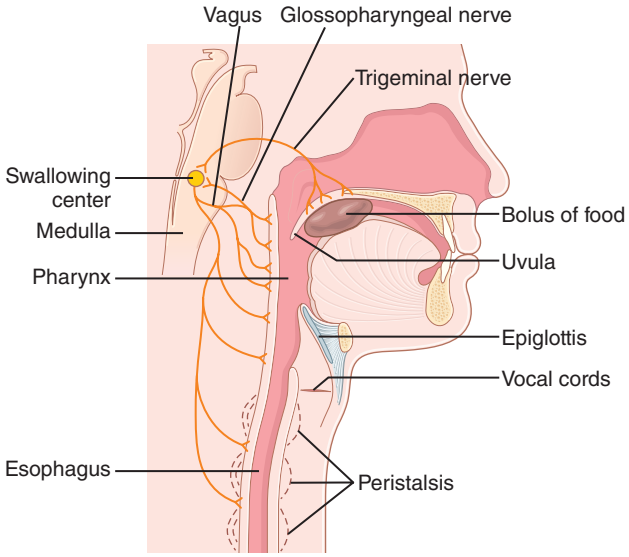

Figure 64.1 Swallowing mechanism.

Involuntary Pharyngeal Stage of Swallowing. As the bolus of food enters the posterior mouth and pharynx, it stimulates *epithelial swallowing receptor areas* all around the opening of the pharynx, especially on the tonsillar pillars, and impulses from these areas pass to the brain stem to initiate a series of automatic pharyngeal muscle contractions as follows:

1. The soft palate is pulled upward to close the posterior nares to prevent reflux of food into the nasal cavities.
2. The palatopharyngeal folds on each side of the pharynx are pulled medially to approximate each other. In this way, these folds form a sagittal slit through which the food must pass into the posterior pharynx. This slit performs a selective action, allowing food that has been masticated sufficiently to pass with ease. Because this stage of swallowing lasts less than 1 second, any large object is usually impeded too much to pass into the esophagus.
3. The vocal cords of the larynx are strongly approximated, and the larynx is pulled upward and anteriorly by the neck muscles. These actions, combined with the presence of ligaments that prevent upward movement of the epiglottis, cause the epiglottis to swing backward over the opening of the larynx. All these effects acting together prevent passage of food into the nose and trachea. Most essential is the tight approximation of the vocal cords, but the epiglottis helps to prevent food from ever getting as far as the vocal cords. Destruction of the vocal cords or of the muscles that approximate them increases the risk of airway obstruction and choking while swallowing food or drink..
4. The upward movement of the larynx also pulls up and enlarges the opening to the esophagus. At the same time, the upper 3 to 4 centimeters of the esophageal muscular wall, called the *upper esophageal sphincter* (also called the *pharyngoesophageal sphincter*), relaxes. Thus, food moves easily and freely from the posterior pharynx into the upper esophagus. Between swallows, this sphincter remains strongly contracted, thereby preventing air from going into the esophagus during respiration. The upward movement of the larynx also lifts the glottis out of the main stream of food flow, so the food mainly passes on each side of the epiglottis rather than over its surface; this action adds still another protection against entry of food into the trachea.
5. Once the larynx is raised and the pharyngoesophageal sphincter becomes relaxed, the entire muscular wall of the pharynx contracts, beginning in the superior part of the pharynx and then spreading downward over the middle and inferior pharyngeal areas, which propels the food by peristalsis into the esophagus.

To summarize the mechanics of the pharyngeal stage of swallowing: The trachea is closed, the esophagus is opened, and a fast peristaltic wave initiated by the nervous system of the pharynx forces the bolus of food into the upper esophagus, with the entire process occurring in less than 2 seconds.

Nervous Initiation of the Pharyngeal Stage of Swallowing. The most sensitive tactile areas of the posterior mouth and pharynx for initiating the pharyngeal stage of swallowing lie in a ring around the pharyngeal opening, with greatest sensitivity on the tonsillar pillars. Impulses are transmitted from these areas through the sensory portions of the trigeminal and glossopharyngeal nerves into the medulla oblongata, either into or closely associated with the *tractus solitarius*, which receives essentially all sensory impulses from the mouth.

The successive stages of the swallowing process are then automatically initiated in orderly sequence by neuronal areas of the reticular substance of the medulla and lower portion of the pons. The sequence of the swallowing reflex is the same from one swallow to the next, and the timing of the entire cycle also remains constant from one swallow to the next. The areas in the medulla and lower pons that control swallowing are collectively called the *deglutition* or *swallowing center*.

The motor impulses from the swallowing center to the pharynx and upper esophagus that cause swallowing are transmitted successively by the fifth, ninth, tenth, and twelfth cranial nerves and even a few of the superior cervical nerves.

In summary, the pharyngeal stage of swallowing is principally a reflex act. It is almost always initiated by voluntary movement of food into the back of the mouth, which in turn excites involuntary pharyngeal sensory receptors to elicit the swallowing reflex.

The Pharyngeal Stage of Swallowing Momentarily Interrupts Respiration. The entire pharyngeal stage

of swallowing usually occurs in less than 6 seconds, thereby interrupting respiration for only a fraction of a usual respiratory cycle. The swallowing center specifically inhibits the respiratory center of the medulla during this time, halting respiration at any point in its cycle to allow swallowing to proceed. Yet, even while a person is talking, swallowing interrupts respiration for such a short time that it is hardly noticeable.

The Esophageal Stage of Swallowing Involves Two Types of Peristalsis. The esophagus functions primarily to conduct food rapidly from the pharynx to the stomach, and its movements are organized specifically for this function.

The esophagus normally exhibits two types of peristaltic movements: *primary peristalsis* and *secondary peristalsis*. Primary peristalsis is simply continuation of the peristaltic wave that begins in the pharynx and spreads into the esophagus during the pharyngeal stage of swallowing. This wave passes all the way from the pharynx to the stomach in about 8 to 10 seconds. Food swallowed by a person who is in the upright position is usually transmitted to the lower end of the esophagus even more rapidly than the peristaltic wave itself, in about 5 to 8 seconds, because of the additional effect of gravity pulling the food downward.

If the primary peristaltic wave fails to move all the food that has entered the esophagus into the stomach, *secondary peristaltic waves* result from distention of the esophagus by the retained food; these waves continue until all the food has emptied into the stomach. The secondary peristaltic waves are initiated partly by intrinsic neural circuits in the myenteric nervous system and partly by reflexes that begin in the pharynx and are then transmitted upward through *vagal afferent fibers* to the medulla and back again to the esophagus through *glossopharyngeal* and *vagal efferent nerve fibers*.

The musculature of the pharyngeal wall and upper third of the esophagus is *striated muscle*. Therefore, the peristaltic waves in these regions are controlled by skeletal nerve impulses from the glossopharyngeal and vagus nerves. In the lower two-thirds of the esophagus, the musculature is *smooth muscle*, but this portion of the esophagus is also strongly controlled by the vagus nerves that act through connections with the esophageal myenteric nervous system. When the vagus nerves to the esophagus are cut, the myenteric nerve plexus of the esophagus becomes excitable enough after several days to cause strong secondary peristaltic waves even without support from the vagal reflexes. Therefore, even after paralysis of the brain stem swallowing reflex, food fed by tube or in some other way into the esophagus still passes readily into the stomach.

Receptive Relaxation of the Stomach. When the esophageal peristaltic wave approaches the stomach, a wave of relaxation, transmitted through myenteric inhibitory neurons, precedes the peristalsis. Furthermore, the entire stomach and, to a lesser extent, even the duodenum become relaxed as this wave reaches the lower end of the esophagus and thus are prepared ahead of time to receive the food propelled into the esophagus during the swallowing act.

Function of the Lower Esophageal Sphincter (Gastroesophageal Sphincter). At the lower end of the esophagus, extending upward about 3 centimeters above its juncture with the stomach, the esophageal circular muscle functions as a broad *lower esophageal sphincter*, also called the *gastroesophageal sphincter*. This sphincter normally remains tonically constricted with an intraluminal pressure at this point in the esophagus of about 30 mm Hg, in contrast to the midportion of the esophagus, which normally remains relaxed. When a peristaltic swallowing wave passes down the esophagus, "receptive relaxation" of the lower esophageal sphincter occurs ahead of the peristaltic wave, which allows easy propulsion of the swallowed food into the stomach. Rarely, the sphincter does not relax satisfactorily, resulting in a condition called *achalasia*, discussed in Chapter 67.

The stomach secretions are highly acidic and contain many proteolytic enzymes. The esophageal mucosa, except in the lower one-eighth of the esophagus, is not capable of resisting the digestive action of gastric secretions for long. Fortunately, the tonic constriction of the lower esophageal sphincter helps prevent significant reflux of stomach contents into the esophagus except under abnormal conditions.

Prevention of Esophageal Reflux By Valvelike Closure of the Distal End of the Esophagus. Another factor that helps prevent reflux is a valvelike mechanism of a short portion of the esophagus that extends slightly into the stomach. Increased intraabdominal pressure caves the esophagus inward at this point. Thus, this valvelike closure of the lower esophagus helps to prevent high intraabdominal pressure from forcing stomach contents backward into the esophagus. Otherwise, whenever we walk, cough, or breathe hard, stomach acid might be expelled into the esophagus.

MOTOR FUNCTIONS OF THE STOMACH

The motor functions of the stomach are 3-fold: (1) storage of large quantities of food until the food can be processed in the stomach, duodenum, and lower intestinal tract; (2) mixing of this food with gastric secretions until it forms a semifluid mixture called *chyme;* and (3) slow emptying of the chyme from the stomach into the small intestine at a rate suitable for proper digestion and absorption by the small intestine.

Fig. 64.2 shows the basic anatomy of the stomach, which is usually divided into two major parts: (1) the *body* and (2) the *antrum*. Physiologically, it is more appropriately divided into (1) the "*orad*" portion, comprising about the first two-thirds of the body, and (2) the "*caudad*" portion, comprising the remainder of the body plus the antrum.

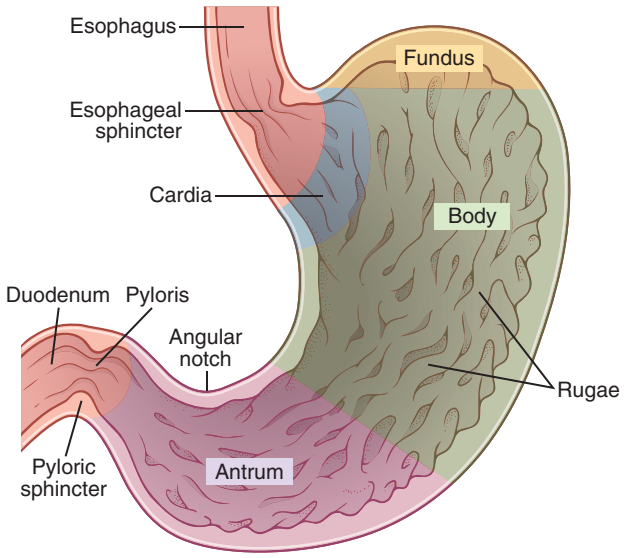

Figure 64.2 Physiological anatomy of the stomach.

STORAGE FUNCTION OF THE STOMACH

As food enters the stomach, it forms concentric circles of the food in the orad portion of the stomach, with the newest food lying closest to the esophageal opening and the oldest food lying nearest the outer wall of the stomach. Normally, when food stretches the stomach, a "vagovagal reflex" from the stomach to the brain stem and then back to the stomach reduces the tone in the muscular wall of the body of the stomach so that the wall bulges progressively outward, accommodating greater and greater quantities of food up to a limit in the completely relaxed stomach of 0.8 to 1.5 liters. The pressure in the stomach remains low until this limit is approached.

BASIC ELECTRICAL RHYTHM OF THE STOMACH WALL FOR FOOD MIXING AND PROPULSION

The digestive juices of the stomach are secreted by *gastric glands* in almost the entire wall of the body of the stomach except along a narrow strip on the lesser curvature of the stomach. These secretions come immediately into contact with that portion of the stored food lying against the mucosal surface of the stomach. As long as food is in the stomach, weak peristaltic *constrictor waves*, called *mixing waves*, begin in the mid to upper portions of the stomach wall and move toward the antrum about once every 15 to 20 seconds. These waves are initiated by the gut wall *basic electrical rhythm*, discussed in Chapter 63, consisting of electrical "slow waves" that occur spontaneously in the stomach wall. As the constrictor waves progress from the body of the stomach into the antrum, they become more intense, some becoming extremely intense and providing powerful *peristaltic action potential*–driven constrictor rings that force the antral contents under higher and higher pressure toward the pylorus.

These constrictor rings also play an important role in mixing the stomach contents in the following way: Each time a peristaltic wave passes down the antral wall toward the pylorus, it digs deeply into the food contents in the antrum. Yet, the opening of the pylorus is still small enough that only a few milliliters or less of antral contents are expelled into the duodenum with each peristaltic wave. Also, as each peristaltic wave approaches the pylorus, the pyloric muscle often contracts, which further impedes emptying through the pylorus. Therefore, most of the antral contents are squeezed upstream through the peristaltic ring toward the body of the stomach, not through the pylorus. Thus, the moving peristaltic constrictive ring, combined with this upstream squeezing action, called "retropulsion," is an exceedingly important mixing mechanism in the stomach.

Chyme—a Mixture of Food and Stomach Secretions. After food in the stomach has become thoroughly mixed with the stomach secretions, the resulting mixture that passes down the gut is called *chyme*. The degree of fluidity of the chyme leaving the stomach depends on the relative amounts of food, water, and stomach secretions and on the degree of digestion that has occurred. The appearance of chyme is that of a murky semifluid or paste.

Hunger Contractions of the Stomach. Besides the peristaltic contractions that occur when food is present in the stomach, another type of intense contractions, called *hunger contractions*, often occurs *when the stomach has been empty* for several hours or more. These contractions are rhythmic peristaltic contractions in the *body* of the stomach. When the successive contractions become extremely strong, they often fuse to cause a continuing tetanic contraction that sometimes lasts for 2 to 3 minutes.

Hunger contractions are most intense in young, healthy people who have high degrees of gastrointestinal tonus; they are also greatly increased when a person has lower than normal levels of blood sugar. When hunger contractions occur in the stomach, the person sometimes experiences mild pain in the pit of the stomach, called *hunger pangs*. Hunger pangs usually do not begin until 12 to 24 hours after the last ingestion of food; in people who are in a state of starvation, they reach their greatest intensity in 3 to 4 days and gradually weaken in succeeding days.

STOMACH EMPTYING

Stomach emptying is promoted by intense peristaltic contractions in the stomach antrum. At the same time, emptying is opposed by varying degrees of resistance to passage of chyme at the pylorus.

Intense Antral Peristaltic Contractions During Stomach Emptying—"Pyloric Pump." Most of the time, the rhythmic stomach contractions are weak and function

mainly to cause mixing of food and gastric secretions. However, for about 20% of the time while food is in the stomach, the contractions become intense, beginning in midstomach and spreading through the caudad stomach. These contractions are strong peristaltic, very tight ringlike constrictions that can cause stomach emptying. As the stomach becomes progressively more and more empty, these constrictions begin farther and farther up the body of the stomach, gradually pinching off the food in the body of the stomach and adding this food to the chyme in the antrum. These intense peristaltic contractions often create 50 to 70 centimeters of water pressure, which is about six times as powerful as the usual mixing type of peristaltic waves.

When pyloric tone is normal, each strong peristaltic wave forces up to several milliliters of chyme into the duodenum. Thus, the peristaltic waves, in addition to causing mixing in the stomach, also provide a pumping action called the "pyloric pump."

Role of the Pylorus in Controlling Stomach Emptying. The distal opening of the stomach is the *pylorus*. Here the thickness of the circular wall muscle becomes 50% to 100% greater than in the earlier portions of the stomach antrum, and it remains slightly tonically contracted almost all the time. Therefore, the pyloric circular muscle is called the *pyloric sphincter*.

Despite normal tonic contraction of the pyloric sphincter, the pylorus usually is open enough for water and other fluids to empty from the stomach into the duodenum with ease. Yet, the constriction usually prevents passage of food particles until they have become mixed in the chyme to almost fluid consistency. The degree of constriction of the pylorus is increased or decreased under the influence of nervous and hormonal signals from the stomach and the duodenum, as discussed shortly.

REGULATION OF STOMACH EMPTYING

The rate at which the stomach empties is regulated by signals from the stomach and the duodenum. However, the duodenum provides far more potent signals, controlling the emptying of chyme into the duodenum at a rate no greater than the rate at which the chyme can be digested and absorbed in the small intestine.

Gastric Factors That Promote Emptying

Effect of Gastric Food Volume on Rate of Emptying. Increased food volume in the stomach promotes increased emptying from the stomach. However, it is not increased storage pressure of the food in the stomach that causes the increased emptying because, in the usual normal range of volume, the increase in volume does not increase the pressure much. However, stretching of the stomach wall does elicit local myenteric reflexes in the wall that greatly accentuate activity of the pyloric pump and at the same time inhibit the pylorus.

Powerful Duodenal Factors That Inhibit Stomach Emptying

Duodenum Enterogastric Nervous Reflexes Inhibit Stomach Emptying. When food enters the duodenum, multiple nervous reflexes are initiated from the duodenal wall. These reflexes pass back to the stomach to slow or even stop stomach emptying if the volume of chyme in the duodenum becomes too much. These *enterogastric reflexes* are mediated by three routes: (1) directly from the duodenum to the stomach through the enteric nervous system in the gut wall; (2) through extrinsic nerves that go to the prevertebral sympathetic ganglia and then back through inhibitory sympathetic nerve fibers to the stomach; and (3) through the vagus nerves all the way to the brain stem, where they inhibit the normal excitatory signals transmitted to the stomach through the vagi. All these parallel reflexes have two effects on stomach emptying. First, they strongly inhibit the "pyloric pump" propulsive contractions, and second, they increase the tone of the pyloric sphincter.

The types of factors that are continually monitored in the duodenum and can initiate enterogastric inhibitory reflexes include the following:

1. Distention of the duodenum
2. The presence of any irritation of the duodenal mucosa
3. Acidity of the duodenal chyme
4. Osmolality of the chyme
5. The presence of certain breakdown products in the chyme, especially breakdown products of proteins and, perhaps to a lesser extent, of fats

The enterogastric inhibitory reflexes are especially sensitive to the presence of irritants and acids in the duodenal chyme, and they often become strongly activated in as little as 30 seconds. For example, whenever the pH of the chyme in the duodenum falls below about 3.5 to 4, the reflexes frequently block further release of acidic stomach contents into the duodenum until the duodenal chyme can be neutralized by pancreatic and other secretions.

Breakdown products of protein digestion also elicit inhibitory enterogastric reflexes; by slowing the rate of stomach emptying, sufficient time is ensured for adequate protein digestion in the duodenum and small intestine.

Finally, either hypotonic fluids or, especially, hypertonic fluids elicit the inhibitory reflexes. Thus, flow of nonisotonic fluids into the small intestine at too rapid a rate is prevented, thereby also preventing rapid changes in electrolyte concentrations in the whole-body extracellular fluid during absorption of the intestinal contents.

Hormonal Feedback From the Duodenum Inhibits Gastric Emptying. Hormones released from the upper intestine also inhibit stomach emptying. The stimulus for releasing these inhibitory hormones is mainly the digestion products of fats and proteins in the chyme entering the duodenum, although carbohydrates can also increase secretion of some of these hormones to a lesser degree.

On entering the duodenum, substances in the chyme stimulate release of several different hormones from the duodenal and jejunal epithelium. In turn, the hormones are carried via the blood to the stomach, where they inhibit the pyloric pump and at the same time increase the strength of contraction of the pyloric sphincter. These effects are important because the inhibition of stomach emptying allows the chyme to enter the duodenum at a rate that is slow enough to permit nutrient absorption and to allow neutralization of the highly acidic chyme from the stomach for proper function of the digestive enzymes.

One of the most potent of these hormones is *cholecystokinin* (CCK), which is released from the I cells of the duodenum, jejunum, and ileum in response to fatty acids and amino acids in the chyme. This hormone inhibits gastric motility and therefore delays emptying of the stomach.

Secretin is released mainly from the S cells of the duodenum in response to gastric acid passed from the stomach through the pylorus. Secretin may have a weak effect to delay gastric emptying but plays an important role in regulating pH of the duodenum by inhibiting gastrin release and acid secretion by the stomach, as well as by stimulating pancreatic bicarbonate secretion.

Gastric inhibitory peptide (GIP) has a general but weak effect to decrease gastrointestinal motility. GIP is released from the K cells of the duodenum mainly in response to fat in the chyme, but also to a lesser extent in response to carbohydrates. Although GIP inhibits gastric motility under some conditions, its main effect at physiological concentrations is probably to stimulate insulin secretion by the pancreas.

Glucagon-like peptide 1(GLP-1) is released by L cells of the duodenum in response to digestion products of carbohydrates in the chyme, although the density of these cells is greatest in the ileum and colon. GLP-1 appears to have multiple effects that slow gastric emptying, which, along with other actions that reduce food intake, appear to contribute to the efficacy of *GLP-1 agonists* as important therapeutics for promoting weight loss in people with obesity.

In summary, several intestinal hormones, especially CCK, can inhibit gastric emptying when excess quantities of chyme, especially acidic or fatty chyme, enter the duodenum from the stomach. These hormones are discussed at greater length elsewhere in this text.

Summary of the Control of Stomach Emptying

Emptying of the stomach is controlled only to a moderate degree by stomach factors such as the degree of filling in the stomach. The more important control of stomach emptying resides in inhibitory feedback signals from the duodenum, including both enterogastric inhibitory nervous feedback reflexes and hormonal feedback by CCK and other intestinal hormones. These feedback inhibitory mechanisms work together to slow the rate of emptying when (1) too much chyme is already in the small intestine or (2) the chyme is excessively acidic, contains too much unprocessed protein or fat, is hypotonic or hypertonic, or is irritating. In this way, the rate of stomach emptying is limited to the amount of chyme that the small intestine can process.

MOVEMENTS OF THE SMALL INTESTINE

Movements of the small intestine, like those elsewhere in the gastrointestinal tract, can be divided into *mixing contractions* and *propulsive contractions*. To a great extent, this separation is artificial because essentially all movements of the small intestine cause at least some degree of both mixing and propulsion. The usual classification of these processes is described in the following sections.

MIXING CONTRACTIONS (SEGMENTATION CONTRACTIONS)

When a portion of the small intestine becomes distended with chyme, stretching of the intestinal wall elicits localized concentric contractions spaced at intervals along the intestine and lasting a fraction of a minute. The contractions cause "segmentation" of the small intestine, as shown in **Fig. 64.3** and Fig. 63.5—that is, they divide the intestine into spaced segments that have the appearance of a chain of sausages. As one set of segmentation contractions relaxes, a new set often begins, but the contractions this time occur mainly at new points between the previous contractions. Therefore, the segmentation contractions "chop" the chyme two to three times per minute, in this way promoting progressive mixing of the food with secretions of the small intestine.

The maximum frequency of the segmentation contractions in the small intestine is determined by the frequency of *electrical slow waves* in the intestinal wall, which is the basic electrical rhythm described in Chapter 63. Because this frequency normally is not greater than 12 per minute in the duodenum and proximal jejunum, the *maximum* frequency of the segmentation contractions in these areas is also about 12 per minute, but this maximum frequency

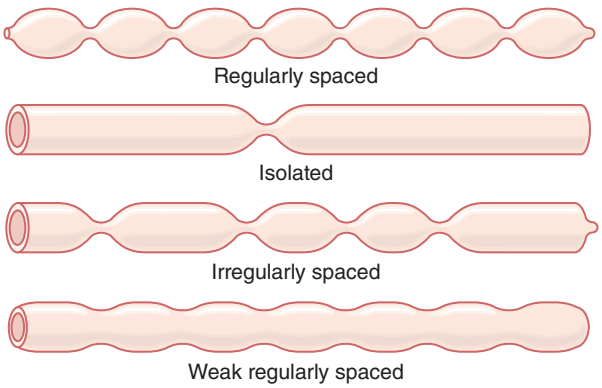

Figure 64.3 Segmentation movements of the small intestine.

occurs only under extreme conditions of stimulation. In the terminal ileum, the maximum frequency is usually 8 to 9 contractions per minute.

The segmentation contractions become exceedingly weak when the excitatory activity of the enteric nervous system is blocked by the drug atropine. Therefore, even though it is the slow waves in the smooth muscle that cause the segmentation contractions, these contractions are not effective without background excitation, mainly from the myenteric nerve plexus.

PROPULSIVE MOVEMENTS

Peristalsis in the Small Intestine. Chyme is propelled through the small intestine by *peristaltic waves*, as discussed in Chapter 63 and illustrated in Fig. 63.5. These waves can occur in any part of the small intestine and move toward the anus at a velocity of 0.5 to 2.0 cm/sec—faster in the proximal intestine and slower in the terminal intestine. They are normally weak and usually die out after traveling only 3 to 5 centimeters. The waves rarely travel farther than 10 centimeters, so forward movement of the chyme is very slow—so slow that *net* movement along the small intestine normally averages only 1 cm/min. This rate of travel means that 3 to 5 hours are required for passage of chyme from the pylorus to the ileocecal valve.

Control of Peristalsis By Nervous and Hormonal Signals. Peristaltic activity of the small intestine increases markedly after a meal. This increased activity is caused partly by the beginning of chyme entry into the duodenum, causing stretch of the duodenal wall. In addition, peristaltic activity is increased by the *gastroenteric reflex* that is initiated by distention of the stomach and conducted principally through the myenteric plexus from the stomach down along the wall of the small intestine.

In addition to the nervous signals, several hormonal factors may also affect peristalsis in the small intestine. These factors include *gastrin, CCK, insulin, motilin*, and *serotonin*, all of which enhance intestinal motility and are secreted during various phases of food processing. Conversely, *secretin, glucagon, and GLP-1* inhibit motility in the small intestine. The physiological importance of each of these hormonal factors for controlling motility of the small intestine is still uncertain.

The function of the peristaltic waves in the small intestine is not only to cause progression of chyme toward the ileocecal valve but also to spread out the chyme along the intestinal mucosa. As the chyme enters the intestines from the stomach and elicits peristalsis, the peristalsis immediately spreads the chyme along the intestine, and this process intensifies as additional chyme enters the duodenum. On reaching the ileocecal valve, the chyme is sometimes blocked for several hours until the person eats another meal; at that time, a *gastroileal reflex* intensifies peristalsis in the ileum and forces the remaining chyme through the ileocecal valve into the cecum of the large intestine.

Propulsive Effect of the Segmentation Movements. The segmentation movements, although lasting for only a few seconds at a time, often also travel 1 centimeter or so in the anal direction, and during that time they help propel the food down the intestine. The difference between the segmentation and the peristaltic movements is not as great as might be implied by their separation into these two classifications.

Powerful, Rapid Peristalsis—"Peristaltic Rush." Although peristalsis in the small intestine is normally weak, intense irritation of the intestinal mucosa, as occurs in some severe cases of infectious diarrhea, can cause both powerful and rapid peristalsis, called the *peristaltic rush*. This phenomenon is initiated partly by nervous reflexes that involve the autonomic nervous system and brain stem and partly by intrinsic enhancement of the myenteric plexus reflexes in the gut wall. The powerful peristaltic contractions travel long distances in the small intestine within minutes, sweeping the contents of the intestine into the colon and thereby relieving the small intestine of irritative chyme and excessive distention.

Movements Caused By the Muscularis Mucosae and Muscle Fibers of the Villi. The *muscularis mucosae* can cause short folds to appear in the intestinal mucosa. In addition, individual fibers from this muscle extend into the intestinal villi and cause them to contract intermittently. The mucosal folds increase the surface area exposed to the chyme, thereby increasing absorption. Also, contractions of the villi—shortening, elongating, and shortening again—"milk" the villi so that lymph flows freely from the central lacteals of the villi into the lymphatic system. These mucosal and villous contractions are initiated mainly by local nervous reflexes in the submucosal nerve plexus that occur in response to chyme in the small intestine.

THE ILEOCECAL VALVE PREVENTS BACKFLOW FROM THE COLON TO THE SMALL INTESTINE

As shown in **Fig. 64.4**, the ileocecal valve protrudes into the lumen of the cecum and therefore is forcefully closed when excess pressure builds up in the cecum and tries to push cecal contents backward against the valve lips. The valve usually can resist reverse pressure of at least 50 to 60 centimeters of water.

In addition, the wall of the ileum for several centimeters immediately upstream from the ileocecal valve has a thickened circular muscle called the *ileocecal sphincter*. This sphincter normally remains mildly constricted and slows emptying of ileal contents into the cecum. However, immediately after a meal, a gastroileal reflex (described earlier) intensifies peristalsis in the ileum, and emptying of ileal contents into the cecum proceeds.

Resistance to emptying at the ileocecal valve prolongs the stay of chyme in the ileum and thereby facilitates absorption. Normally, only 1500 to 2000 mL of chyme empty into the cecum each day.

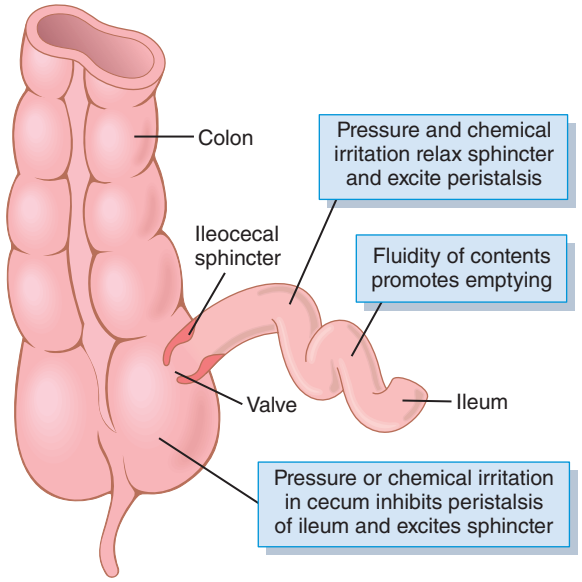

Figure 64.4 Emptying at the ileocecal valve.

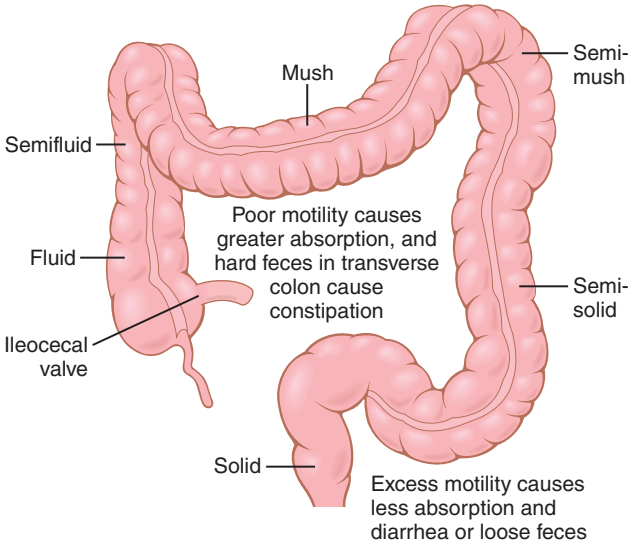

Figure 64.5 Absorptive and storage functions of the large intestine.

Feedback Control of the Ileocecal Sphincter By Reflexes From the Cecum. The degree of contraction of the ileocecal sphincter and the intensity of peristalsis in the terminal ileum are controlled significantly by reflexes from the cecum. When the cecum is distended, contraction of the ileocecal sphincter becomes intensified and ileal peristalsis is inhibited, both of which greatly delay emptying of additional chyme into the cecum from the ileum.

Also, any irritant in the cecum delays emptying. For example, when a person has an inflamed appendix, the irritation of this vestigial remnant of the cecum can cause such intense spasm of the ileocecal sphincter and partial paralysis of the ileum that these effects together block emptying of the ileum into the cecum. The reflexes from the cecum to the ileocecal sphincter and ileum are mediated via the myenteric plexus in the gut wall and of the extrinsic autonomic nerves, especially by way of the prevertebral sympathetic ganglia.

MOVEMENTS OF THE COLON

The principal functions of the colon are (1) absorption of water and electrolytes from the chyme to form solid feces and (2) storage of fecal matter until it can be expelled. The proximal half of the colon, shown in **Fig. 64.5**, is concerned principally with absorption, and the distal half with storage. Because intense colon wall movements are not required for these functions, the movements of the colon are normally sluggish. Yet, in a sluggish manner, the movements still have characteristics similar to those of the small intestine and can be divided once again into mixing movements and propulsive movements.

Mixing Movements—"Haustrations." In the same manner that segmentation movements occur in the small intestine, large circular constrictions occur in the large intestine. At each of these constrictions, about 2.5 centimeters of the circular muscle contract, sometimes constricting the lumen of the colon almost to occlusion. At the same time, the longitudinal muscle of the colon, which is aggregated into three longitudinal strips called the *teniae coli*, contracts. These combined contractions of the circular and longitudinal strips of muscle cause the unstimulated portion of the large intestine to bulge outward into baglike sacs called *haustrations*.

Each haustration usually reaches peak intensity in about 30 seconds and then disappears during the next 60 seconds. At times the haustrations also move slowly toward the anus during contraction, especially in the cecum and ascending colon, and thereby provide a minor amount of forward propulsion of the colonic contents. After another few minutes, new haustral contractions occur in other areas nearby. Therefore, the fecal material in the large intestine is slowly *dug into and rolled over* in much the same manner that one spades the earth. In this way, all the fecal material is gradually exposed to the mucosal surface of the large intestine, and fluid and dissolved substances are progressively absorbed until only 80 to 200 mL of feces are expelled each day.

Propulsive Movements—"Mass Movements." Much of the propulsion in the cecum and ascending colon results from the slow but persistent haustral contractions, requiring as many as 8 to 15 hours to move the chyme from the ileocecal valve through the colon, while the chyme becomes fecal in quality—a semisolid instead of a semifluid slush.

From the cecum to the sigmoid, *mass movements* can, for many minutes at a time, take over the propulsive role. These movements usually occur only one to three times each day, in many people for about 15 minutes during the first hour after eating breakfast.

A mass movement is a modified type of peristalsis characterized by the following sequence of events. First, a

constrictive ring occurs in response to a distended or irritated point in the colon, usually in the transverse colon. Then, rapidly, the 20 or more centimeters of colon *distal to the constrictive ring* lose their haustrations and instead contract as a unit, propelling the fecal material in this segment *en masse* farther down the colon. The contraction develops progressively more force for about 30 seconds, and relaxation occurs during the next 2 to 3 minutes. Another mass movement then occurs, this time perhaps farther along the colon.

A series of mass movements usually persists for 10 to 30 minutes. The movements then cease but return perhaps a half day later. When they have forced a mass of feces into the rectum, the need for defecation is felt.

Initiation of Mass Movements By Gastrocolic and Duodenocolic Reflexes. The appearance of mass movements after meals is facilitated by *gastrocolic* and *duodenocolic reflexes*. These reflexes result from distention of the stomach and duodenum. They occur either not at all or hardly at all when the extrinsic autonomic nerves to the colon have been removed; therefore, the reflexes almost certainly are transmitted by way of the autonomic nervous system.

Irritation in the colon can also initiate intense mass movements. For example, a person who has an ulcerated condition of the colon mucosa *(ulcerative colitis)* frequently has mass movements that persist almost all the time.

DEFECATION

Most of the time, the rectum is empty of feces, partly because a weak functional sphincter exists about 20 centimeters from the anus at the juncture between the sigmoid colon and the rectum. A sharp angulation is also present here that contributes additional resistance to filling of the rectum.

When a mass movement forces feces into the rectum, the desire for defecation occurs immediately, including reflex contraction of the rectum and relaxation of the anal sphincters.

Continual dribble of fecal matter through the anus is prevented by tonic constriction of the following: (1) an *internal anal sphincter*, which is a several-centimeters-long thickening of the circular smooth muscle that lies immediately inside the anus; and (2) an *external anal sphincter*, composed of striated voluntary muscle that both surrounds the internal sphincter and extends distal to it. The external sphincter is controlled by nerve fibers in the *pudendal nerve*, which is part of the somatic nervous system and therefore is under *voluntary, conscious*, or at least *subconscious control;* subconsciously, the external sphincter is usually kept continuously constricted unless conscious signals inhibit the constriction.

Defecation Reflexes. Ordinarily, defecation is initiated by *defecation reflexes*. One of these reflexes is an *intrinsic reflex* mediated by the local enteric nervous system in the rectal wall. When feces enter the rectum, distention of the rectal wall initiates afferent signals that spread through the *myenteric plexus* to initiate peristaltic waves in the descending colon, sigmoid, and rectum, forcing feces toward the anus. As the peristaltic wave approaches the anus, the *internal* anal sphincter is relaxed by inhibitory signals from the myenteric plexus; if the *external* anal sphincter is also consciously, voluntarily relaxed at the same time, defecation occurs.

Normally when the intrinsic myenteric defecation reflex is functioning by itself, it is relatively weak. To be effective in causing defecation, it usually must be fortified by another type of defecation reflex called a *parasympathetic defecation reflex* that involves the sacral segments of the spinal cord, shown in **Fig. 64.6**. When the nerve endings in the rectum are stimulated, signals are transmitted first into the spinal cord and then reflexly back to the descending colon, sigmoid, rectum, and anus via parasympathetic nerve fibers in the *pelvic nerves*. These parasympathetic signals greatly intensify the peristaltic waves and relax the internal anal sphincter, thus converting the intrinsic myenteric defecation reflex from a weak effort into a powerful process of defecation that is sometimes effective in emptying the large bowel all the way from the splenic flexure of the colon to the anus.

Defecation signals entering the spinal cord initiate other effects, such as taking a deep breath, closure of the glottis, and contraction of the abdominal wall muscles to force the fecal contents of the colon downward, and at the same time they cause the pelvic floor to relax downward and pull outward on the anal ring to evaginate the feces.

When it becomes convenient for the person to defecate, the defecation reflexes can purposely be activated by taking a deep breath to move the diaphragm downward

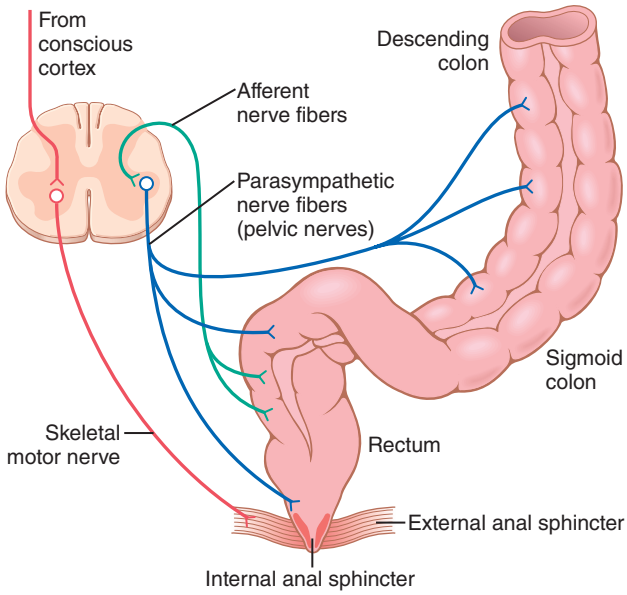

Figure 64.6 Afferent and efferent pathways of the parasympathetic mechanism for enhancing the defecation reflex.

and then contracting the abdominal muscles to increase the pressure in the abdomen, thus forcing fecal contents into the rectum to cause new reflexes. Reflexes initiated in this way are almost never as effective as those that arise naturally, and thus people who too often inhibit their natural reflexes are likely to become severely constipated.

In newborns and in some people with transected spinal cords, the defecation reflexes cause automatic emptying of the lower bowel at inconvenient times during the day because of lack of conscious control exercised through voluntary contraction or relaxation of the external anal sphincter.

OTHER AUTONOMIC REFLEXES THAT AFFECT BOWEL ACTIVITY

Aside from the duodenocolic, gastrocolic, gastroileal, enterogastric, and defecation reflexes that have been discussed in this chapter, several other important nervous reflexes also can affect the overall degree of bowel activity. They are the peritoneointestinal reflex, renointestinal reflex, and vesicointestinal reflex.

The *peritoneointestinal reflex* results from irritation of the peritoneum; it strongly inhibits the excitatory enteric nerves and thereby can cause intestinal paralysis, especially in patients with peritonitis. The *renointestinal* and *vesicointestinal reflexes* inhibit intestinal activity as a result of kidney or bladder irritation, respectively.

CHAPTER 65

Secretory Functions of the Alimentary Tract

Throughout the gastrointestinal tract, secretory glands subserve two primary functions: (1) *digestive enzymes* are secreted in most areas of the alimentary tract, from the mouth to the distal end of the ileum; and (2) mucous glands located from the mouth to the anus provide *mucus* for lubrication and protection of all parts of the alimentary tract.

Most digestive secretions are formed in response to the presence of food in the alimentary tract, and the quantity secreted in each segment of the tract is regulated to provide the amount needed for proper digestion. Furthermore, in some portions of the gastrointestinal tract, even the *types of enzymes* and other constituents of the secretions are varied in accordance with the types of food present. In this chapter we describe the different alimentary secretions, their functions, and regulation of their production.

GENERAL PRINCIPLES OF ALIMENTARY TRACT SECRETION

TYPES OF ALIMENTARY TRACT GLANDS

Several types of glands provide the different types of alimentary tract secretions. First, on the surface of the epithelium in most parts of the gastrointestinal tract are billions of *single-cell mucous glands* called simply *mucous cells* or *goblet cells* because they look like goblets. They function mainly in response to local irritation of the epithelium and extrude *mucus* directly onto the epithelial surface to act as a lubricant that also protects the surfaces from excoriation and digestion.

Second, many surface areas of the gastrointestinal tract are lined by *pits* that represent invaginations of the epithelium into the submucosa. In the small intestine, these pits, called *crypts of Lieberkühn*, are deep and contain specialized secretory cells. One of these cells is shown in **Fig. 65.1**.

Third, in the stomach and upper duodenum are large numbers of deep *tubular glands*. A typical tubular gland can be seen in **Fig. 65.4**, which shows an acid- and pepsinogen-secreting gland of the stomach *(oxyntic gland)*.

Fourth, also associated with the alimentary tract are several complex glands—the *salivary glands, pancreas*, and *liver*—that provide secretions for digestion or emulsification of food. The liver has a highly specialized structure that is discussed in Chapter 71. The salivary glands and the pancreas are compound acinous glands of the type shown in **Fig. 65.2**. These glands lie outside the walls of the alimentary tract and, in this aspect, they differ from all other alimentary glands. They contain millions of *acini* lined with secreting glandular cells; these acini feed into a system of ducts that finally empty into the alimentary tract.

BASIC MECHANISMS OF STIMULATION OF THE ALIMENTARY TRACT GLANDS

Contact of Food With Gut Epithelium Activates the Enteric Nervous System and Stimulates Secretion. The presence of food in a particular segment of the gastrointestinal tract usually stimulates the glands of that region and adjacent regions to secrete moderate to large quantities of juices. Part of this local effect, especially the secretion of mucus by mucous cells, results from direct contact stimulation of the surface glandular cells by the food.

In addition, local epithelial stimulation also activates the *enteric nervous system* of the gut wall. The types of stimuli that activate this system are (1) tactile stimulation, (2) chemical irritation, and (3) distention of the gut wall.

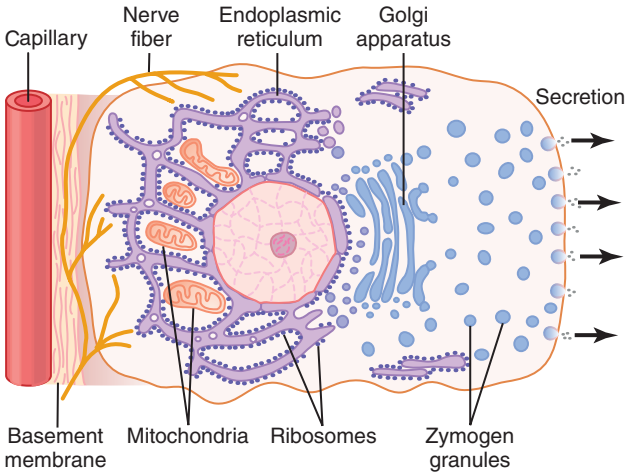

Figure 65.1 Typical function of a glandular cell for formation and secretion of enzymes and other secretory substances.

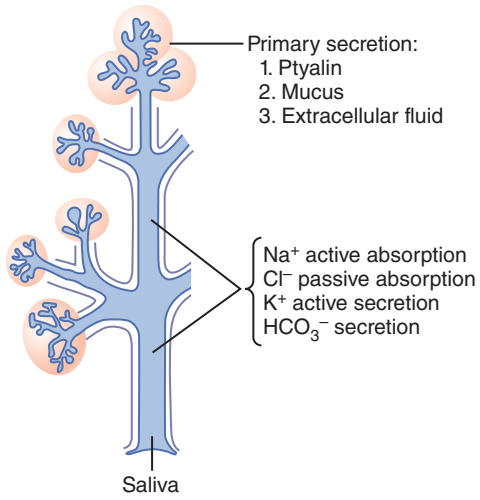

Figure 65.2 Formation and secretion of saliva by a submandibular salivary gland.

The resulting nervous reflexes stimulate the mucous cells on the gut epithelial surface and the deep glands in the gut wall to increase their secretion.

Parasympathetic Stimulation Increases Alimentary Tract Glandular Secretion Rate. Stimulation of the parasympathetic nerves to the alimentary tract almost invariably increases the rates of alimentary glandular secretion. This increased secretion rate is especially true of the glands in the upper portion of the tract (innervated by the glossopharyngeal and vagus parasympathetic nerves) such as the salivary glands, esophageal glands, gastric glands, pancreas, and Brunner glands in the duodenum. It is also true of some glands in the distal portion of the large intestine, which are innervated by pelvic parasympathetic nerves. Secretion in the remainder of the small intestine and in the first two-thirds of the large intestine occurs mainly in response to local neural and hormonal stimuli in each segment of the gut.

Sympathetic Stimulation Has a Dual Effect on Alimentary Tract Glandular Secretion Rate. Stimulation of the sympathetic nerves going to the gastrointestinal tract causes a slight to moderate increase in secretion by some of the local glands. However, sympathetic stimulation also constricts the blood vessels that supply the glands. Therefore, sympathetic stimulation can have a dual effect: (1) sympathetic stimulation alone may slightly increase secretion by some glands in the alimentary tract, and (2) if parasympathetic or hormonal stimulation is already causing copious secretion by the glands, superimposed sympathetic stimulation usually reduces secretion, sometimes significantly, mainly because of vasoconstrictive reduction of the blood supply.

Regulation of Glandular Secretion By Hormones. In the stomach and intestine, several different *gastrointestinal hormones* help regulate the volume and composition of the secretions. These hormones are liberated from the gastrointestinal mucosa in response to the presence of food in the lumen of the gut. The hormones are then absorbed into the blood and carried to the glands, where they stimulate secretion. This type of stimulation is particularly valuable to increase the output of gastric juice and pancreatic juice when food enters the stomach or duodenum.

Chemically, the gastrointestinal hormones are polypeptides or polypeptide derivatives and will be discussed in more detail later.

BASIC MECHANISM OF SECRETION BY GLANDULAR CELLS

Secretion of Organic Substances. Although all the basic mechanisms by which glandular cells function are not known, experimental evidence points to the following principles of secretion, as shown in **Fig. 65.1**.

1. The nutrient material needed for formation of the secretion must first diffuse or be actively transported by the blood in the capillaries into the base of the glandular cell.
2. Many *mitochondria* located inside the glandular cell near its base use oxidative energy to form adenosine triphosphate (ATP).
3. Energy from ATP, along with appropriate substrates provided by nutrients, is then used to synthesize the organic secretory substances; this synthesis occurs almost entirely in the *endoplasmic reticulum* and *Golgi complex* of the glandular cell. *Ribosomes* adherent to the reticulum are specifically responsible for formation of proteins that are secreted.
4. The secretory materials are transported through the tubules of the endoplasmic reticulum, passing in about 20 minutes all the way to the vesicles of the Golgi complex.
5. In the Golgi complex, the materials are modified, added to, concentrated, and discharged into the cytoplasm in the form of *secretory vesicles*, which are stored in the apical ends of the secretory cells.
6. These vesicles remain stored until nervous or hormonal control signals cause the cells to extrude the vesicular contents through the cells' surface. This action probably occurs in the following way. The hormone binds to its receptor and, through one of several possible cell signaling mechanisms, *increases the cell membrane permeability to calcium ions*. Calcium enters the cell and causes many of the vesicles to fuse with the apical cell membrane. The apical cell membrane then breaks open, thus emptying the vesicles to the exterior; this process is called *exocytosis*.

Water and Electrolyte Secretion. A second necessity for glandular secretion is secretion of sufficient water and electrolytes to go along with the organic substances. Secretion by the salivary glands, discussed in more detail later, provides an example of how nervous stimulation causes water and salts to pass through the glandular cells in great profusion,

washing the organic substances through the secretory border of the cells at the same time. Hormones acting on the cell membrane of some glandular cells also cause secretory effects similar to those caused by nervous stimulation.

Lubricating and Protective Properties of Mucus in the Gastrointestinal Tract

Mucus is a thick secretion composed mainly of water, electrolytes, and a mixture of several glycoproteins that are composed of large polysaccharides bound with much smaller quantities of protein. Mucus is slightly different in different parts of the gastrointestinal tract, but in all locations it has several important characteristics that make it both an excellent lubricant and a protectant for the gut wall:

1. Mucus has adherent qualities that make it adhere tightly to the food or other particles and to spread as a thin film over the surfaces.
2. It has sufficient *body* that it coats the wall of the gut and prevents actual contact of most food particles with the mucosa.
3. Mucus has a low resistance for slippage, so the particles can slide along the epithelium with great ease.
4. Mucus causes fecal particles to adhere to one another to form the feces that are expelled during a bowel movement.
5. Mucus is strongly resistant to digestion by the gastrointestinal enzymes.
6. The glycoproteins of mucus have *amphoteric properties*, which means that they are capable of buffering small amounts of either acids or alkalies; also, mucus often contains moderate quantities of HCO_3^-, which specifically neutralizes acids.

Thus, mucus has the ability to allow easy slippage of food along the gastrointestinal tract and to prevent excoriative or chemical damage to the epithelium. A person becomes acutely aware of the lubricating qualities of mucus when the salivary glands fail to secrete saliva, because then it is difficult to swallow solid food even when it is eaten along with large amounts of water.

SECRETION OF SALIVA

Saliva Contains a Serous Secretion and a Mucus Secretion. The principal glands of salivation are the *parotid, submandibular*, and *sublingual glands;* in addition, there are many tiny *buccal* glands. Daily secretion of saliva normally ranges between 800 and 1500 mL, with an average value of 1000 mL, as shown in **Table 65.1**.

Saliva contains two major types of protein secretion: (1) a *serous secretion* that contains *ptyalin* (an *α-amylase*), which is an enzyme for digesting starches, and (2) *mucus secretion* that contains *mucin* for lubricating and for surface protective purposes.

The parotid glands secrete almost entirely the serous type of secretion, whereas the submandibular and sublingual glands secrete both serous secretion and mucus. The buccal glands secrete only mucus. Saliva has a pH between 6.0 and 7.0, which is a favorable range for the digestive action of ptyalin.

Table 65.1 Daily Alimentary Tract Secretions

Type of Secretion	Daily Volume (mL)	pH
Saliva	1000	6.0–7.0
Gastric secretion	1500	1.0–3.5
Pancreatic secretion	1000	8.0–8.3
Bile	1000	7.8
Small intestine secretion	1800	7.5–8.0
Brunner gland secretion	200	8.0–8.9
Large intestine secretion	200	7.5–8.0
Total	**6700**	

Secretion of Ions in Saliva. Saliva contains especially large quantities of K^+ and HCO_3^-. Conversely, the concentrations of Na^+ and Cl^- are several times less in saliva than in plasma. One can understand these special concentrations of ions in saliva from the following description of the mechanism for secretion of saliva.

Fig. 65.2 shows secretion by the submandibular gland, a typical compound gland that contains *acini* and *salivary ducts*. Salivary secretion is a two-stage operation. The first stage involves the acini, and the second stage involves the salivary ducts. The acini secrete a *primary secretion* that contains ptyalin and/or mucin in a solution of ions with concentrations not greatly different from those of typical extracellular fluid. As the primary secretion flows through the ducts, two major active transport processes take place that markedly modify the ionic composition of the fluid in the saliva.

First, Na^+ is actively reabsorbed from all the salivary ducts and K^+ is actively secreted in exchange for Na^+. Therefore, Na^+ concentration of the saliva becomes greatly reduced, whereas K^+ concentration becomes increased. However, there is excess Na^+ reabsorption compared with K^+ secretion, which creates electrical negativity of about −70 millivolts in the salivary ducts; this negativity, in turn, causes Cl^- to be reabsorbed passively. Therefore, Cl^- concentration in the salivary fluid falls to a very low level, matching the ductal decrease in Na^+ concentration.

Second, HCO_3^- is secreted by the ductal epithelium into the lumen of the duct. This secretion is at least partly caused by passive exchange of bicarbonate for Cl^-, but it may also result partly from an active secretory process.

The net result of these transport processes is that *under resting conditions*, the concentrations of Na^+ and Cl^- in saliva are only about 15 mEq/L each, about one-seventh to one-tenth their concentrations in plasma. Conversely, K^+ concentration is about 30 mEq/L, seven times as great as in plasma, and HCO_3^- concentration is 50 to 70 mEq/L, about two to three times that of plasma.

During maximal salivation, the salivary ionic concentrations change considerably because the formation rate of primary secretion by the acini can increase as much as 20-fold. This acinar secretion then flows through the ducts so rapidly that the ductal reconditioning of the secretion is considerably reduced. Therefore, when copious

quantities of saliva are being secreted, the NaCl concentration is about one-half or two-thirds that of plasma, and K^+ concentration rises to only four times that of plasma.

Function of Saliva for Oral Hygiene. Under basal awake conditions, about 0.5 mL of saliva, almost entirely of the mucous type, is secreted each minute; however, during sleep, little secretion occurs. This secretion plays an exceedingly important role for maintaining healthy oral tissues. The mouth is loaded with pathogenic bacteria that can easily destroy tissues and cause dental caries. Saliva helps prevent the deteriorative processes in several ways:

1. The flow of saliva helps wash away pathogenic bacteria, as well as food particles that provide their metabolic support.
2. Saliva contains several factors that destroy bacteria. One of these is *thiocyanate ions* and another is several *proteolytic enzymes*—most important, *lysozyme*—that (a) attack the bacteria, (b) aid thiocyanate ions in entering the bacteria where these ions, in turn, become bactericidal, and (c) digest food particles, thus helping further to remove the bacterial metabolic support.
3. Saliva often contains significant amounts of antibodies that can destroy oral bacteria, including some that cause dental caries. In the absence of adequate salivation (*xerostomia*), oral tissues may become ulcerated or infected, and caries of the teeth can become rampant. Some of the most common causes of xerostomia are aging, chronic use of certain medications (e.g. antihistamines), autoimmune disorders that damage saliva-producing cells, and radiation therapy for cancers of the head and neck that damage the salivary glands.

NERVOUS REGULATION OF SALIVARY SECRETION

Fig. 65.3 shows the parasympathetic nervous pathways for regulating salivation and demonstrates that the salivary glands are controlled mainly by *parasympathetic nervous signals* all the way from the *superior* and *inferior salivatory nuclei* in the brain stem.

The salivatory nuclei are located approximately at the juncture of the medulla and pons and are excited by taste and tactile stimuli from the tongue and other areas of the mouth and pharynx. Many taste stimuli, especially the sour taste (caused by acids), elicit copious secretion of saliva—often 8 to 20 times the basal rate of secretion. Also, certain tactile stimuli, such as the presence of smooth objects in the mouth (e.g., a pebble), cause marked salivation, whereas rough objects cause less salivation and occasionally even inhibit salivation.

Salivation can also be stimulated or inhibited by nervous signals arriving in the salivatory nuclei from higher centers of the central nervous system. For example, when a person smells or eats favorite foods, salivation is greater than when food that is disliked is smelled or eaten. The *appetite area* of the brain, which partially regulates these effects, is located in proximity to the parasympathetic

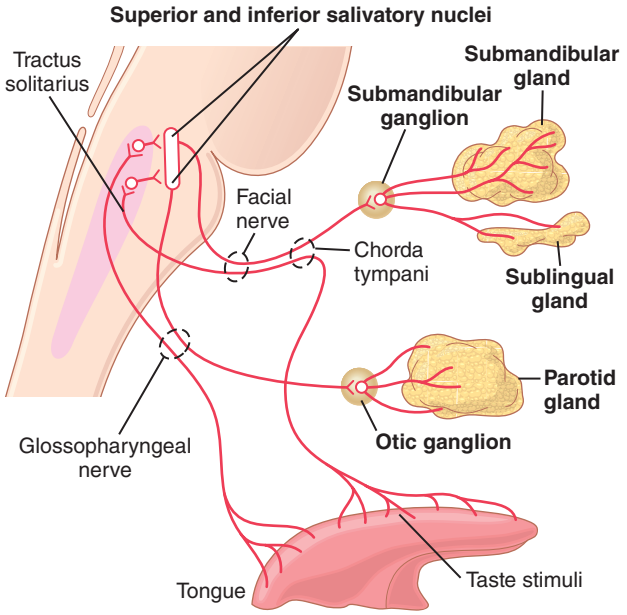

Figure 65.3 Parasympathetic nervous regulation of salivary secretion.

centers of the anterior hypothalamus, and it functions to a great extent in response to signals from the taste and smell areas of the cerebral cortex or amygdala.

Salivation also occurs in response to reflexes originating in the stomach and upper small intestines—particularly when irritating foods are swallowed or when a person is nauseated because of some gastrointestinal abnormality. The saliva, when swallowed, helps to remove the irritating factor in the gastrointestinal tract by diluting or neutralizing the irritant substances.

Sympathetic stimulation can also increase salivation a slight amount—much less so than parasympathetic stimulation. Also, the saliva formed in response to sympathetic activity is thicker compared with saliva produced during increased parasympathetic activity. The sympathetic nerves originate from the superior cervical ganglia and travel along the surfaces of the blood vessel walls to the salivary glands.

A secondary factor that also affects salivary secretion is the *blood supply to the glands* because secretion always requires adequate nutrients from the blood. The parasympathetic nerve signals that induce copious salivation also moderately dilate the blood vessels. In addition, salivation directly dilates the blood vessels, thus providing increased salivatory gland nutrition as needed by the secreting cells. Part of this additional vasodilator effect is caused by *kallikrein* secreted by the activated salivary cells, which in turn acts as an enzyme to split one of the blood proteins, an α_2-globulin, to form *bradykinin*, a strong vasodilator.

Esophageal Secretion

Esophageal secretions are entirely mucous and mainly provide lubrication for swallowing. The main body of the esophagus is lined with many *simple mucous glands*. At the

gastric end and to a lesser extent in the initial portion of the esophagus, many *compound mucous glands* can also be found. The mucus secreted by the compound glands in the upper esophagus prevents mucosal excoriation by newly entering food, whereas the compound glands located near the esophagogastric junction protect the esophageal wall from digestion by acidic gastric juices that often reflux from the stomach back into the lower esophagus. Despite this protection, a peptic ulcer at times can still occur at the gastric end of the esophagus.

GASTRIC SECRETION

In addition to mucus-secreting cells that line the entire surface of the stomach, the stomach mucosa has two important types of tubular glands—*oxyntic glands* (also called *gastric glands*) and *pyloric glands*. The oxyntic (acid-forming) glands secrete *hydrochloric acid, pepsinogen, intrinsic factor*, and *mucus*. The pyloric glands secrete mainly *mucus* for protection of the pyloric mucosa from the stomach acid. They also secrete the hormone *gastrin*.

The oxyntic glands are located on the inside surfaces of the fundus and body of the stomach—the proximal 80% of the stomach. The pyloric glands are located in the antral portion of the stomach—the distal 20% of the stomach.

Secretions From the Gastric (Oxyntic) Glands

A typical stomach oxyntic gland is illustrated in **Fig. 65.4**. It is composed of three main types of cells: (1) *mucous neck cells*, which secrete mainly *mucus;* (2) *peptic* (or *chief*) cells, which secrete large quantities of *pepsinogen;* and (3) *parietal* (or *oxyntic*) *cells*, which secrete *hydrochloric acid* and *intrinsic factor*. Oxyntic glands also contain some additional cell types, including the *enterochromaffin-like* (ECL) *cells* that secrete histamine.

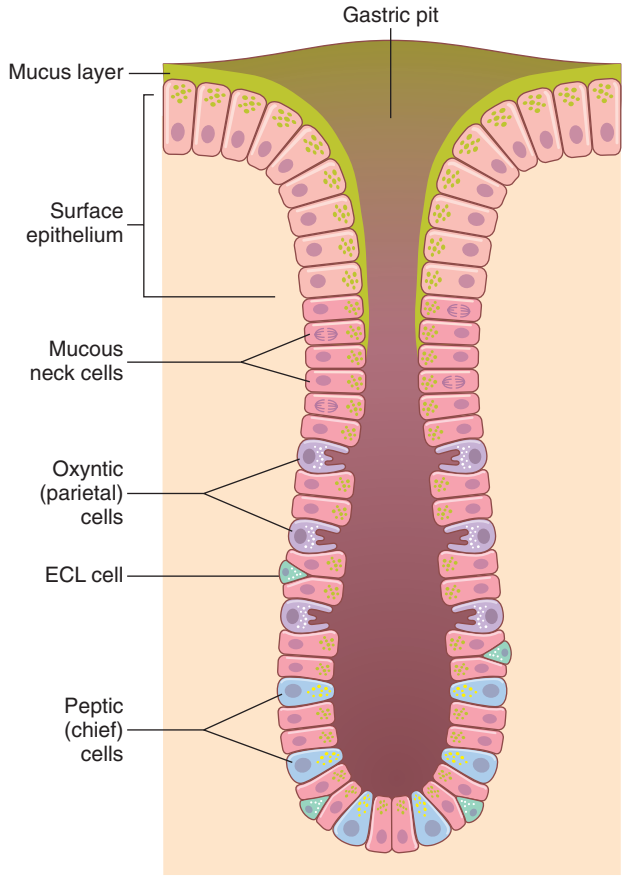

Figure 65.4 Gastric (oxyntic) gland from the body of the stomach. *ECL*, Enterochromaffin-like cells.

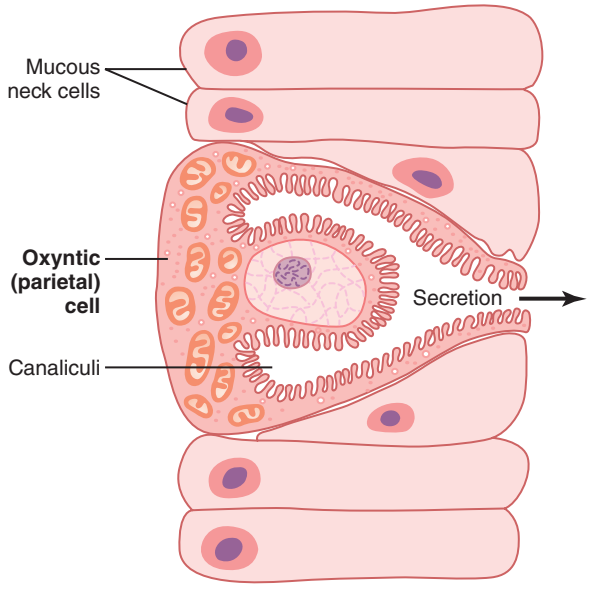

Figure 65.5 Schematic anatomy of the canaliculi in a parietal (oxyntic) cell.

Basic Mechanism of Hydrochloric Acid Secretion By Parietal (Oxyntic) Cells. When stimulated, the parietal cells secrete an acid solution that contains about 160 mmol/L of hydrochloric acid, which is nearly isotonic with the body fluids. The pH of this acid is about 0.8, demonstrating its extreme acidity. At this pH, the H^+ concentration is about 3 million times that of the arterial blood. To concentrate the H^+ this tremendous amount requires more than 1500 calories of energy/L of gastric juice. At the same time that H^+ is secreted, HCO_3^- diffuses into the blood so that gastric venous blood has a higher pH than arterial blood when the stomach is secreting acid.

Fig. 65.5 shows schematically the functional structure of a parietal cell (also called an *oxyntic cell*), demonstrating that it contains large branching intracellular *canaliculi*. The hydrochloric acid is formed at the villus-like projections inside these canaliculi and is then conducted through the canaliculi to the secretory end of the cell.

The main driving force for hydrochloric acid secretion by the parietal cells is a *hydrogen-potassium pump* (H^+-K^+ *adenosine triphosphatase* [ATPase]). The chemical mechanism of hydrochloric acid formation is shown in **Fig. 65.6** and consists of the following steps:

1. Water inside the parietal cell becomes dissociated into H^+ and hydroxide (OH^-) in the cell cytoplasm.

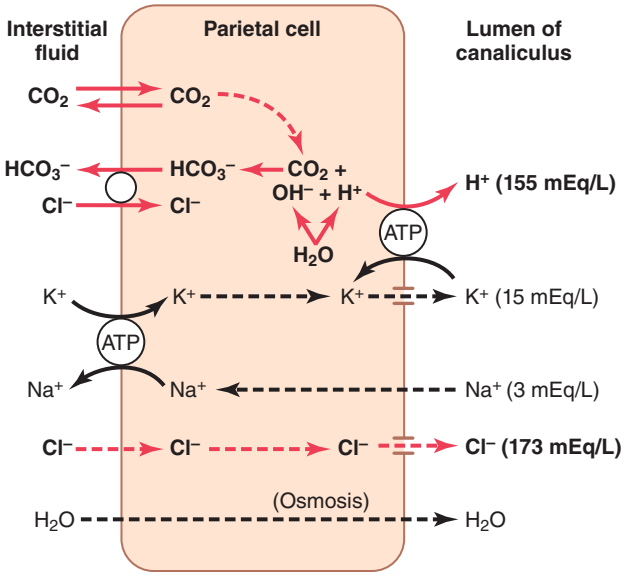

Figure 65.6 Postulated mechanism for secretion of hydrochloric acid. (The points labeled "ATP" [adenosine triphosphate] indicate active pumps, and the *dashed lines* represent free diffusion and osmosis.)

The H^+ is then actively secreted into the canaliculus in exchange for K^+, an active exchange process that is catalyzed by H^+-K^+ ATPase. Potassium ions transported into the cell by the Na^+-K^+ ATPase pump on the basolateral (extracellular) side of the membrane tend to leak into the lumen but are recycled back into the cell by the H^+-K^+ ATPase. The basolateral Na^+-K^+ ATPase creates low intracellular Na^+, which contributes to Na^+ reabsorption from the lumen of the canaliculus. Thus, most of the K^+ and Na^+ in the canaliculus is reabsorbed into the cell cytoplasm, and H^+ takes their place in the canaliculus.

2. The pumping of H^+ out of the cell by the H^+-K^+ ATPase permits OH^- to accumulate and form HCO_3^- from CO_2, either formed during metabolism in the cell or while entering the cell from the blood. This reaction is catalyzed by *carbonic anhydrase*. The HCO_3^- is then transported across the basolateral membrane into the extracellular fluid in exchange for Cl^- ions, which enter the cell and are secreted through chloride channels into the canaliculus, giving a strong solution of hydrochloric acid in the canaliculus. The hydrochloric acid is then secreted outward through the open end of the canaliculus into the lumen of the gland.
3. Water passes into the canaliculus by osmosis because of extra ions secreted into the canaliculus. Thus, the final secretion from the canaliculus contains water, hydrochloric acid at a concentration of about 150 to 160 mEq/L, potassium chloride at a concentration of 15 mEq/L, and a small amount of sodium chloride.

To produce a concentration of H^+ as great as that found in gastric juice requires minimal backleak into the mucosa of the secreted acid. A major part of the stomach's ability to prevent backleak of acid can be attributed to the *gastric barrier* due to the formation of alkaline mucus and to tight junctions between epithelial cells, as described later. If this barrier is damaged by toxic substances, such as occurs with excessive use of aspirin or alcohol, the secreted acid does leak down an electrochemical gradient into the mucosa, causing stomach mucosal damage.

Basic Factors That Stimulate Gastric Secretion Are Acetylcholine, Gastrin, and Histamine. Acetylcholine released by parasympathetic stimulation excites secretion of pepsinogen by peptic cells, hydrochloric acid by parietal cells, and mucus by mucous cells. In comparison, both gastrin and histamine strongly stimulate acid secretion by parietal cells but have little effect on the other cells.

Secretion and Activation of Pepsinogen. Several slightly different types of pepsinogen are secreted by the peptic and mucous cells of the gastric glands, but all the pepsinogens perform the same basic functions.

When pepsinogen is first secreted, it has no digestive activity. However, as soon as it comes in contact with hydrochloric acid, it is activated to form active *pepsin*. In this process, the pepsinogen molecule, having a molecular weight of about 42,500, is split to form a pepsin molecule, having a molecular weight of about 35,000.

Pepsin functions as an active proteolytic enzyme in a highly acidic medium (optimum pH, 1.8–3.5), but above a pH of about 5 it has almost no proteolytic activity and becomes completely inactivated in a short time. Hydrochloric acid is as necessary as pepsin for protein digestion in the stomach, as discussed in Chapter 66.

Secretion of Intrinsic Factor By Parietal Cells. The substance *intrinsic factor*, which is essential for vitamin B_{12} absorption in the ileum, is secreted by the *parietal cells* along with hydrochloric acid. When the acid-producing parietal cells of the stomach are destroyed, which frequently occurs in persons with chronic gastritis, not only does *achlorhydria* (lack of stomach acid secretion) develop, but *pernicious anemia* also often develops because of failure of red blood cell maturation in the absence of vitamin B_{12} stimulation of the bone marrow. This condition is discussed in Chapter 33.

PYLORIC GLANDS SECRETE MUCUS AND GASTRIN

The pyloric glands are structurally similar to the oxyntic glands but contain few peptic cells and almost no parietal cells. Instead, they contain mostly mucous cells that are identical with the mucous neck cells of the oxyntic glands. These cells secrete a small amount of pepsinogen, as discussed earlier, and an especially large amount of thin mucus that helps to lubricate food movement, as well as to protect the stomach wall from digestion by the gastric enzymes. The pyloric glands also secrete the hormone *gastrin*, which plays a key role in controlling gastric secretion, as we discuss shortly.

SURFACE MUCOUS CELLS

The entire surface of the stomach mucosa between glands has a continuous layer of a special type of mucous cells called simply "surface mucous cells." They secrete large quantities of *viscid mucus*, which coats the stomach mucosa with a gel layer of mucus (often more than 1 millimeter thick), thus providing a major shell of protection for the stomach wall and contributing to lubrication of food transport.

Another characteristic of this mucus is that *it is alkaline*. Therefore, the *normal* underlying stomach wall is not directly exposed to the highly acidic, proteolytic stomach secretions. Even the slightest contact with food or any irritation of the mucosa directly stimulates the surface mucous cells to secrete additional quantities of this thick, alkaline, viscid mucus.

STIMULATION OF GASTRIC ACID SECRETION

Parietal Cells of the Oxyntic Glands Are the Only Cells That Secrete Hydrochloric Acid. As noted earlier in the chapter, the acidity of the fluid secreted by the parietal cells of the oxyntic glands can be great, with pH as low as 0.8. However, secretion of this acid is under continuous control by endocrine and nervous signals. Furthermore, parietal cells operate in close association with another type of cell called *enterochromaffin-like cells* (*ECL cells*), the primary function of which is to secrete *histamine*.

The ECL cells lie in the deep recesses of the oxyntic glands and therefore release histamine in direct contact with the parietal cells of the glands. The formation and secretion rates of hydrochloric acid by the parietal cells are directly related to the amount of histamine secreted by the ECL cells. In turn, the ECL cells are stimulated to secrete histamine by the hormone *gastrin*, which is formed almost entirely in the antral portion of the stomach mucosa in response to proteins in the foods being digested. The ECL cells may also be stimulated by hormones secreted by the enteric nervous system of the stomach wall. We will first discuss the gastrin mechanism for control of the ECL cells and their subsequent control of parietal cell secretion of hydrochloric acid.

Gastrin Stimulates Acid Secretion. Gastrin is a hormone secreted by *gastrin cells*, also called *G cells*. These cells are located in the *pyloric glands* in the distal end of the stomach. Gastrin is a large polypeptide secreted in two forms—a large form called G-34, which contains 34 amino acids, and a smaller form, G-17, which contains 17 amino acids. Although both of these forms are important, the smaller form is more abundant.

When meats or other foods containing protein reach the antral end of the stomach, some of the proteins from these foods have a special stimulatory effect on *gastrin cells in the pyloric glands* to cause release of *gastrin* into the blood to be transported to the ECL cells of the stomach. The vigorous mixing of the gastric juices transports the gastrin rapidly to the ECL cells in the body of the stomach, causing release of *histamine directly into the deep oxyntic glands*. The histamine then acts quickly to stimulate gastric hydrochloric acid secretion.

REGULATION OF PEPSINOGEN SECRETION

Stimulation of *pepsinogen* secretion by the peptic cells in the oxyntic glands occurs in response to three main types of signals: (1) *acetylcholine* released from the *vagus nerves* or from the *gastric enteric nervous plexus*, (2) *acid* in the stomach, and (3) *secretin*, released by the duodenum, which has a moderate effect to stimulate pepsinogen secretion.

Acid probably does not stimulate the peptic cells mainly by direct effects but instead elicits additional enteric nervous reflexes that support the original nervous signals to the peptic cells. Therefore, the rate of secretion of *pepsinogen*, the precursor of the enzyme *pepsin* that causes protein digestion, is strongly influenced by the amount of acid in the stomach. In people who have lost the ability to secrete normal amounts of acid, secretion of pepsinogen is also decreased, even though the peptic cells may otherwise appear to be normal.

Phases of Gastric Secretion

Gastric secretion is said to occur in three "phases" (as shown in **Fig. 65.7**): a *cephalic phase*, a *gastric phase*, and an *intestinal phase*.

Cephalic Phase. The cephalic phase of gastric secretion occurs even before food enters the stomach, especially while it is being eaten. It results from the sight, smell, thought, or taste of food, and the greater the appetite, the more intense is the stimulation. Neurogenic signals that cause the cephalic phase of gastric secretion originate in the cerebral cortex and in the appetite centers of the amygdala and hypothalamus. They are transmitted through the dorsal motor nuclei of the vagi and thence through the vagus nerves to the stomach. This phase of secretion normally accounts for about 30% of the gastric secretion associated with eating a meal.

Gastric Phase. Once food enters the stomach, it excites the following: (1) long vagovagal reflexes from sensory afferent vagal fibers in the stomach to the brain and back to the stomach via vagal parasympathetic efferent fibers; (2) local enteric reflexes; and (3) the gastrin mechanism, all of which cause secretion of gastric juice during several hours while food remains in the stomach. The gastric phase of secretion accounts for about 60% of the total gastric secretion associated with eating a meal and therefore accounts for most of the total daily gastric secretion of about 1500 mL.

Intestinal Phase. The presence of food in the upper portion of the small intestine, particularly in the duodenum, will continue to cause stomach secretion of small amounts of gastric juice, probably partly because of small amounts of gastrin released by the duodenal mucosa. This secretion accounts for about 10% of the acid response to a meal.

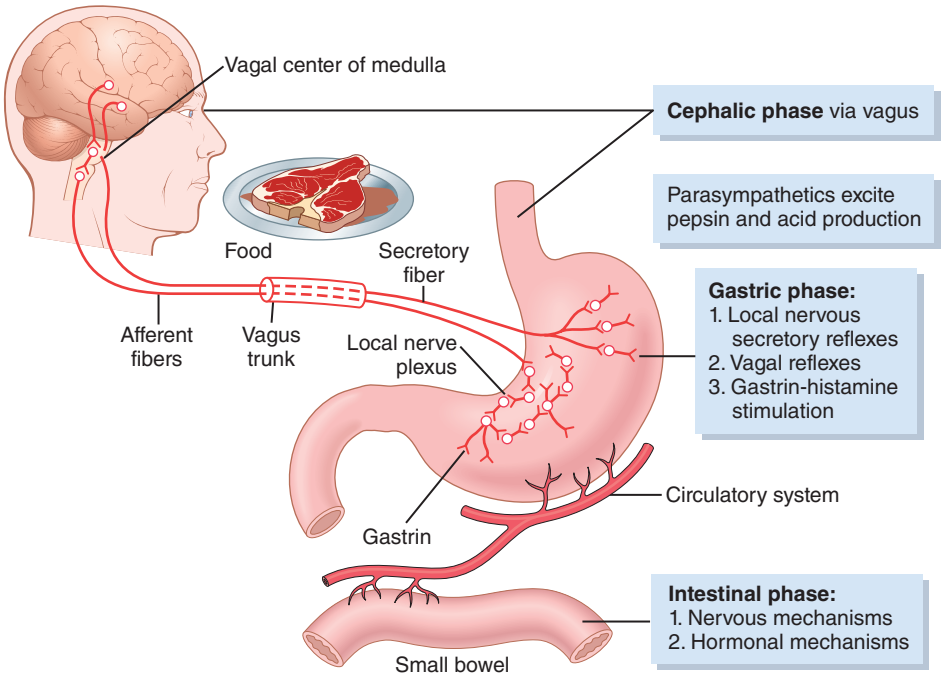

Figure 65.7 Phases of gastric secretion and their regulation.

Inhibition of Gastric Secretion By Other Intestinal Factors

Although intestinal chyme slightly stimulates gastric secretion during the early intestinal phase of stomach secretion, it paradoxically inhibits gastric secretion at other times. This inhibition results from at least two influences.

1. The presence of food in the small intestine initiates a *reverse enterogastric reflex*, transmitted through the myenteric nervous system and extrinsic sympathetic and vagus nerves, inhibiting stomach secretion. This reflex can be initiated by (a) distending the small bowel, (b) the presence of acid in the upper intestine, (c) the presence of protein breakdown products, or (d) irritation of the mucosa. This reflex is part of the complex mechanism discussed in Chapter 64 for slowing stomach emptying when the intestines are already filled.
2. The presence of acid, fat, protein breakdown products, hyperosmotic or hypo-osmotic fluids, or any irritating factor in the upper small intestine causes release of several intestinal hormones. One of these hormones is *secretin*, which is especially important for control of pancreatic secretion. However, secretin opposes stomach acid secretion by inhibiting gastrin secretion while stimulating pepsinogen secretion. Three other hormones—*glucose-dependent insulinotropic peptide (gastric inhibitory peptide), vasoactive intestinal polypeptide*, and *somatostatin*—have slight or moderate effects to inhibit gastric secretion.

The purpose of intestinal factors that inhibit gastric secretion is presumably to slow passage of chyme from the stomach when the small intestine is already filled or already overactive. In fact, the enterogastric inhibitory reflexes plus inhibitory hormones usually also reduce stomach motility at the same time that they reduce gastric acid secretion, as discussed in Chapter 64.

Gastric Secretion During the Interdigestive Period. The stomach secretes a few milliliters of gastric juice each hour during the "interdigestive period," when little or no digestion is occurring anywhere in the gut. The secretion that does occur is usually almost entirely of the nonoxyntic type, composed mainly of *mucus* but little pepsinogen and almost no acid.

Emotional stimuli may increase interdigestive gastric secretion (which is highly peptic and acidic) to 50 mL or more per hour, in much the same way that the cephalic phase of gastric secretion excites secretion at the onset of a meal. This increase of secretion in response to emotional stimuli may contribute to the development of peptic ulcers, as discussed in Chapter 67.

Chemical Composition of Gastrin and Other Gastrointestinal Hormones

Gastrin, cholecystokinin (CCK), and *secretin* are all large polypeptides with approximate molecular weights of 2000, 4200, and 3400, respectively. The terminal five amino acids in the gastrin and CCK molecular chains are the same. The functional activity of gastrin resides in the terminal four amino acids, and the activity for CCK resides in the terminal eight amino acids. All the amino acids in the secretin molecule are essential.

A synthetic gastrin, *pentagastrin*, is composed of the terminal four amino acids of natural gastrin plus the amino acid alanine; pentagastrin has all the same physiological properties as the natural gastrin.

PANCREATIC SECRETION

The pancreas, which lies parallel to and beneath the stomach (illustrated in **Fig. 65.10**), is a large compound gland, and most of its internal structure is similar to that of the salivary glands shown in **Fig. 65.2**. The pancreatic

digestive enzymes are secreted by *pancreatic acini*, and large volumes of sodium bicarbonate solution are secreted by the small ductules and larger ducts leading from the acini. The combined product of enzymes and sodium bicarbonate then flows through a long *pancreatic duct* that normally joins the common bile duct immediately before it empties into the duodenum through the *papilla of Vater*, surrounded by the *sphincter of Oddi* (see **Fig. 65.11**).

Pancreatic juice is secreted most abundantly in response to the presence of chyme in the upper portions of the small intestine, and the characteristics of pancreatic juice are determined to some extent by the types of food in the chyme. The pancreas also secretes *insulin*, but it is not secreted by the same pancreatic tissue that secretes intestinal pancreatic juice. Instead, insulin is secreted directly into the *blood*—not into the intestine—by the *islets of Langerhans* that occur in islet patches throughout the pancreas. These structures and their key role in regulating carbohydrate, fat, and protein metabolism are discussed in Chapter 79.

PANCREATIC DIGESTIVE ENZYMES

Pancreatic secretion contains multiple enzymes for digesting all of the three major types of food—proteins, carbohydrates, and fats. It also contains large quantities of HCO_3^-, which play an important role in neutralizing the acidity of the chyme emptied from the stomach into the duodenum.

The most important of the pancreatic enzymes for digesting proteins are *trypsin, chymotrypsin*, and *carboxypolypeptidase*. By far the most abundant of these is trypsin.

Trypsin and chymotrypsin split whole and partially digested proteins into peptides of various sizes but do not cause release of individual amino acids. However, carboxypolypeptidase splits some peptides into individual amino acids, thus completing digestion of some proteins all the way to the amino acid state.

The pancreatic enzyme for digesting carbohydrates is *pancreatic amylase*, which hydrolyzes starches, glycogen, and most other carbohydrates (except cellulose) to form mostly disaccharides and a few trisaccharides.

The main enzymes for fat digestion are the following: (1) *pancreatic lipase*, which is capable of hydrolyzing neutral fat into fatty acids and monoglycerides; (2) *cholesterol esterase*, which causes hydrolysis of cholesterol esters; and (3) *phospholipase*, which splits fatty acids from phospholipids.

When first synthesized in the pancreatic cells, the proteolytic digestive enzymes are in their enzymatically inactive forms—*trypsinogen, chymotrypsinogen*, and *procarboxypolypeptidase*. They become activated only after they are secreted into the intestinal tract. Trypsinogen is activated by an enzyme called *enterokinase*, which is secreted by the intestinal mucosa when chyme comes in contact with the mucosa. Trypsinogen also can be autocatalytically activated by trypsin that has already been formed from previously secreted trypsinogen. Chymotrypsinogen is activated by trypsin to form chymotrypsin, and procarboxypolypeptidase is activated in a similar manner.

Secretion of Trypsin Inhibitor Prevents Digestion of the Pancreas. It is important that the proteolytic enzymes of the pancreatic juice not become activated until after they have been secreted into the intestine because the trypsin and the other enzymes would digest the pancreas. Fortunately, the same cells that secrete proteolytic enzymes into the acini of the pancreas simultaneously secrete another substance called *trypsin inhibitor*. This substance, which is formed in the cytoplasm of the glandular cells, prevents activation of trypsin inside the secretory cells and in the acini and ducts of the pancreas. In addition, because it is trypsin that activates the other pancreatic proteolytic enzymes, trypsin inhibitor prevents activation of the other enzymes as well.

When the pancreas becomes severely damaged or when a duct becomes blocked, large quantities of pancreatic secretion sometimes become pooled in the damaged areas of the pancreas. Under these conditions, the effect of trypsin inhibitor is often overwhelmed, in which case the pancreatic secretions rapidly become activated and can literally digest the entire pancreas within a few hours, giving rise to the condition called *acute pancreatitis*. This condition is sometimes lethal because of accompanying circulatory shock; even if it is not lethal, it usually leads to a lifetime of pancreatic insufficiency.

SECRETION OF BICARBONATE IONS

Although the enzymes of the pancreatic juice are secreted entirely by the acini of the pancreatic glands, the other two important components of pancreatic juice, HCO_3^- and water, are secreted mainly by the epithelial cells of the ductules and ducts that lead from the acini. When the pancreas is stimulated to secrete copious quantities of pancreatic juice, the HCO_3^- concentration can rise to as high as 145 mEq/L, a value about five times that of HCO_3^- in the plasma. This high concentration provides a large quantity of alkali in the pancreatic juice that serves to neutralize the hydrochloric acid emptied into the duodenum from the stomach.

The basic steps in the cellular mechanism for secreting sodium bicarbonate solution into the pancreatic ductules and ducts, shown in **Fig. 65.8**, are as follows:

1. Carbon dioxide diffuses to the interior of the cell from the blood and, under the influence of carbonic anhydrase, combines with water to form carbonic acid (H_2CO_3). The carbonic acid dissociates into HCO_3^- and H^+. Additional HCO_3^- enters the cell through the basolateral membrane by co-transport with Na^+. The HCO_3^- is then exchanged for Cl^- by secondary active transport through the luminal border of the cell into the lumen of the duct. The

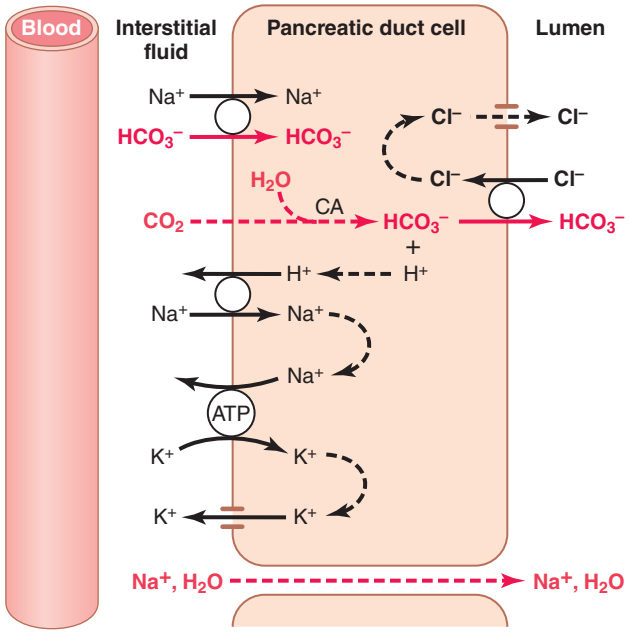

Figure 65.8 Secretion of isosmotic sodium bicarbonate solution by the pancreatic ductules and ducts. *ATP*, Adenosine triphosphate; *CA*, carbonic anhydrase.

Cl^- that enters the cell is recycled back into the lumen by special chloride channels.

2. The H^+ formed by dissociation of carbonic acid inside the cell is *exchanged for Na^+ through the basolateral membrane of the cell* by secondary active transport. Sodium ions also enter the cell by cotransport with HCO_3^- across the basolateral membrane. Sodium ions are then transported across the *luminal border* into the pancreatic duct lumen. The negative voltage of the lumen also pulls the positively charged Na^+ across the tight junctions between the cells.
3. The overall movement of Na^+ and HCO_3^- from the blood into the duct lumen creates an osmotic pressure gradient that causes osmosis of water also into the pancreatic duct, thus forming an almost completely isosmotic bicarbonate solution.

REGULATION OF PANCREATIC SECRETION

Three basic stimuli are important in causing pancreatic secretion:

1. *Acetylcholine*, which is released from the parasympathetic vagus nerve endings and from other cholinergic nerves in the enteric nervous system
2. *Cholecystokinin* (CCK), which is secreted by the duodenal and upper jejunal mucosa when food enters the small intestine
3. *Secretin*, which is also secreted by the duodenal and jejunal mucosa when highly acidic food enters the small intestine

The first two of these stimuli, acetylcholine and CCK, stimulate the acinar cells of the pancreas, causing production of large quantities of pancreatic digestive enzymes but relatively small quantities of water and electrolytes to go with the enzymes. Without the water, most of the enzymes remain temporarily stored in the acini and ducts until more fluid secretion comes along to wash them into the duodenum. Secretin, in contrast to the first two basic stimuli, stimulates secretion of large quantities of water solution of sodium bicarbonate by the pancreatic ductal epithelium.

Multiplicative Effects of Different Stimuli. When all the different stimuli of pancreatic secretion occur at once, the total secretion is far greater than the sum of the secretions caused by each one separately. Therefore, the various stimuli multiply, or potentiate, one another in stimulating pancreatic secretion. Thus, pancreatic secretion normally results from the combined effects of the multiple basic stimuli, not from one alone.

Phases of Pancreatic Secretion

Pancreatic secretion, as with gastric secretion, occurs in three phases: the *cephalic phase*, the *gastric phase*, and the *intestinal phase*. Their characteristics are described in the following sections.

Cephalic and Gastric Phases. During the cephalic phase of pancreatic secretion, the same nervous signals from the brain that cause secretion in the stomach also cause acetylcholine release by the vagal nerve endings in the pancreas. This signaling causes moderate amounts of enzymes to be secreted into the pancreatic acini, accounting for about 20% of the total secretion of pancreatic enzymes after a meal. However, little of the secretion flows immediately through the pancreatic ducts into the intestine because only small amounts of water and electrolytes are secreted along with the enzymes.

During the gastric phase, the nervous stimulation of enzyme secretion continues, accounting for another 5% to 10% of pancreatic enzymes secreted after a meal. However, again, only small amounts reach the duodenum because of continued lack of significant fluid secretion.

Intestinal Phase. After chyme leaves the stomach and enters the small intestine, pancreatic secretion becomes copious, mainly in response to the hormone *secretin*. The intestinal phase accounts for 70% to 80% of total pancreatic secretion.

Secretin Stimulates Copious Secretion of Bicarbonate Ions, Which Neutralizes Acidic Stomach Chyme. Secretin is a polypeptide containing 27 amino acids (with a molecular weight of ~3400). It is present in an inactive form, prosecretin, in the *S cells* in the mucosa of the duodenum and jejunum. When acid chyme with a pH less than 4.5 to 5.0 enters the duodenum from the stomach, it causes duodenal mucosal release and activation of secretin, which is then absorbed into the blood. The one truly potent constituent of chyme that causes secretin release is hydrochloric acid from the stomach.

Secretin in turn causes the pancreas to secrete large quantities of fluid containing a high concentration of HCO_3^- (up to 145 mEq/L) but a low concentration of Cl^-. The secretin mechanism is especially important for two reasons. First, secretin begins to be released from the mucosa of the small intestine when the pH of the duodenal contents falls below 4.5 to 5.0, and its release increases greatly as the pH falls to 3.0. This mechanism immediately causes copious secretion of pancreatic juice that contains abundant amounts of sodium bicarbonate. The net result is then the following reaction in the duodenum:

$$HCl + NaHCO_3 \rightarrow NaCl + H_2CO_3$$

The carbonic acid then immediately dissociates into CO_2 and water. The CO_2 is absorbed into the blood and expired through the lungs, thus leaving a neutral solution of sodium chloride in the duodenum. In this way, the acid contents that are emptied into the duodenum from the stomach become neutralized, and thus further peptic digestive activity by the gastric juices in the duodenum is immediately blocked. Because the mucosa of the small intestine cannot withstand the digestive action of acid gastric juice, this protective mechanism is essential to prevent the development of duodenal ulcers, as discussed in Chapter 67.

Bicarbonate ion secretion by the pancreas provides an appropriate pH for action of the pancreatic digestive enzymes, which function optimally in a slightly alkaline or neutral medium, at a pH of 7.0 to 8.0. Fortunately, the pH of the sodium bicarbonate secretion averages 8.0.

Cholecystokinin Contributes to Control of Digestive Enzyme Secretion By the Pancreas. The presence of food in the upper small intestine also causes a second hormone, CCK, a polypeptide containing 33 amino acids, to be released from yet another group of cells, the *I cells*, in the mucosa of the duodenum and upper jejunum. This release of CCK results especially from the presence of *proteoses* and *peptones* (products of partial protein digestion) and *long-chain fatty acids* in the chyme coming from the stomach.

CCK, like secretin, passes via the blood to the pancreas, but instead of causing sodium bicarbonate secretion, it mainly causes secretion of much more pancreatic digestive enzymes by the acinar cells. This effect is similar to that caused by vagal stimulation but is even more pronounced, accounting for 70% to 80% of the total secretion of the pancreatic digestive enzymes after a meal.

The differences between the pancreatic stimulatory effects of secretin and CCK are shown in **Fig. 65.9**, which demonstrates the following: (1) intense sodium bicarbonate secretion in response to acid in the duodenum, stimulated by secretin; (2) a dual effect in response to soap (a fat); and (3) intense digestive enzyme secretion (when peptones enter the duodenum) stimulated by CCK.

Fig. 65.10 summarizes the more important factors that regulate pancreatic secretion. The total amount secreted each day is about 1 liter.

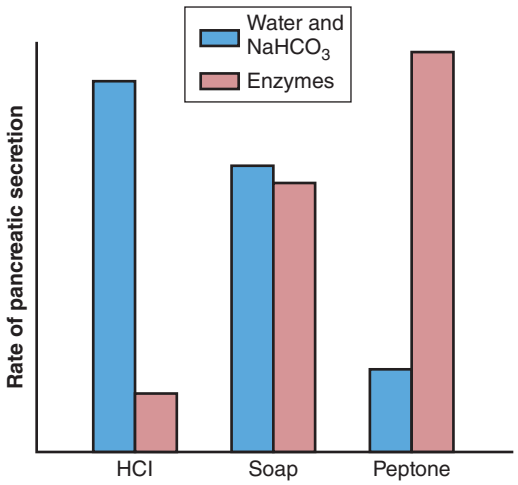

Figure 65.9 Sodium bicarbonate ($NaHCO_3$), water, and enzyme secretion by the pancreas, caused by the presence of acid (HCl), fat (soap), or peptone solutions in the duodenum.

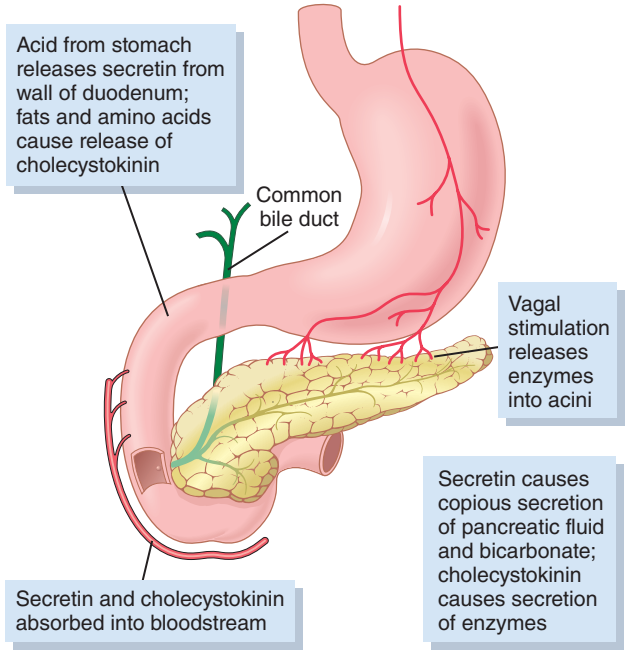

Figure 65.10 Regulation of pancreatic secretion.

BILE SECRETION BY THE LIVER

One of the many functions of the liver is to secrete *bile*, normally between 600 and 1000 mL/day. Bile serves two major functions.

First, bile plays an important role in fat digestion and absorption. *Bile acids* perform two important functions that contribute to fat digestion: (1) they help emulsify large fat particles of the food into many minute particles, the surface of which can then be attacked by lipase enzymes secreted in pancreatic juice, and (2) they aid in absorption of digested fat end products through the intestinal mucosal membrane.

Second, bile serves as a means for excretion of several important waste products from the blood. These waste

products include in particular *bilirubin*, an end product of hemoglobin destruction, and excesses of *cholesterol*.

PHYSIOLOGICAL ANATOMY OF BILIARY SECRETION

Bile is secreted in two stages by the liver:

1. The first stage is secretion by the *hepatocytes*, the principal functional cells of the liver. This initial secretion contains large amounts of bile acids, cholesterol, and other organic constituents. It is secreted into minute *bile canaliculi* that originate between the hepatic cells (see Fig. 71.1).
2. Next, the bile flows in the canaliculi toward the interlobular septa, where the canaliculi empty into *terminal bile ducts* and then into progressively larger ducts, finally reaching the *hepatic duct* and *common bile duct*. From these ducts the bile either empties directly into the duodenum or is diverted for minutes up to several hours through the *cystic duct* into the *gallbladder*, shown in **Fig. 65.11**.

In its course through the bile ducts, a second portion of liver secretion is added to the initial bile. This additional secretion is a watery solution of Na^+ and HCO_3^- secreted by epithelial cells that line the ductules and ducts. This second secretion sometimes increases the total quantity of bile by as much as 100%. The second secretion is stimulated especially by *secretin*, which causes the release of additional quantities of HCO_3^- to supplement the HCO_3^- in pancreatic secretion (for neutralizing acid that empties into the duodenum from the stomach).

The Gallbladder Stores and Concentrates Bile. Bile is secreted continually by the liver cells, but most of it is normally stored in the gallbladder until it is needed in the duodenum. The maximum volume that the gallbladder can hold is only 30 to 60 mL. Nevertheless, as much as 12 hours of bile secretion (usually ~450 mL) can be stored in the gallbladder because water, sodium, chloride, and most other small electrolytes are continually absorbed through the gallbladder mucosa, concentrating the remaining bile constituents that contain the bile salts, cholesterol, lecithin, and bilirubin.

Most of this gallbladder absorption is caused by active transport of sodium through the gallbladder epithelium, and this transport is followed by secondary absorption of Cl^-, water, and most other diffusible constituents. Bile is normally concentrated in this way about 5-fold, but it can be concentrated up to a maximum of 20-fold.

Composition of Bile. **Table 65.2** lists the composition of bile when it is first secreted by the liver and then after it has been concentrated in the gallbladder. By far the most abundant substances secreted in the bile are *bile salts*, which account for about one-half of the total solutes in the bile. Also secreted or excreted in large concentrations are *bilirubin, cholesterol, lecithin*, and the usual *electrolytes* of plasma.

In the concentrating process in the gallbladder, water and large portions of the electrolytes (except calcium ions) are reabsorbed by the gallbladder mucosa. Essentially all other constituents, especially the bile salts and the lipid substances cholesterol and lecithin, are not reabsorbed

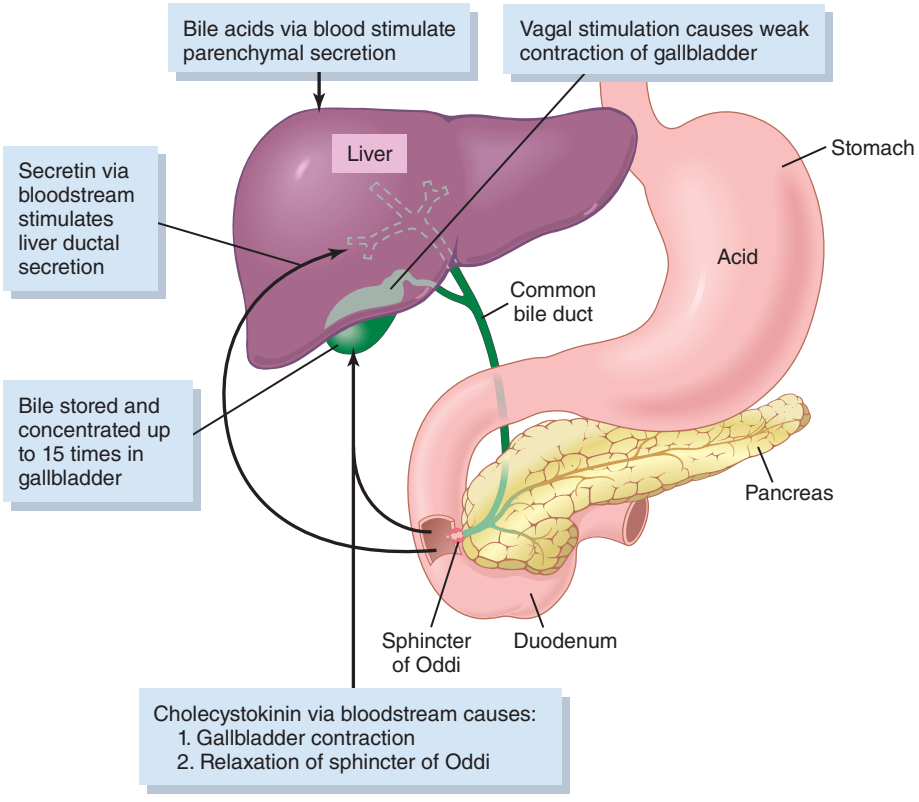

Figure 65.11 Liver secretion and gallbladder emptying.

Table 65.2 Approximate Normal Composition of Bile

Substance	Liver Bile	Gallbladder Bile
Water	97.5 g/dL	92 g/dL
Bile salts	1.1 g/dL	6 g/dL
Bilirubin	0.04 g/dL	0.3 g/dL
Cholesterol	0.1 g/dL	0.3–0.9 g/dL
Fatty acids	0.12 g/dL	0.3–1.2 g/dL
Lecithin	0.04 g/dL	0.3 g/dL
Na^+	145 mEq/L	130 mEq/L
K^+	5 mEq/L	12 mEq/L
Ca^{2+}	5 mEq/L	23 mEq/L
Cl^-	100 mEq/L	25 mEq/L
HCO_3^-	28 mEq/L	10 mEq/L

and, therefore, become highly concentrated in the gallbladder bile.

Cholecystokinin Stimulates Gallbladder Emptying. When food begins to be digested in the upper gastrointestinal tract, the gallbladder begins to empty, especially when fatty foods reach the duodenum about 30 minutes after a meal. The mechanism of gallbladder emptying is rhythmic contractions of the gallbladder wall, but effective emptying also requires simultaneous relaxation of the *sphincter of Oddi*, which guards the exit of the common bile duct into the duodenum.

By far the most potent stimulus for causing the gallbladder contractions is the hormone CCK. As discussed previously, CCK also causes increased secretion of digestive enzymes by the acinar cells of the pancreas. The stimulus for CCK entry into the blood from the duodenal mucosa is mainly the presence of fatty foods in the duodenum.

The gallbladder is also stimulated less strongly by *acetylcholine-secreting nerve fibers* from both the vagi and the intestinal enteric nervous system. They are the same nerves that promote motility and secretion in other parts of the upper gastrointestinal tract.

In summary, the gallbladder empties its store of concentrated bile into the duodenum mainly in response to the CCK stimulus that is initiated mainly by fatty foods. When fat is not in the food, the gallbladder empties poorly, but when significant quantities of fat are present, the gallbladder normally empties completely in about 1 hour. **Fig. 65.11** summarizes the secretion of bile, its storage in the gallbladder, and its ultimate release from the gallbladder to the duodenum.

FUNCTION OF BILE SALTS IN FAT DIGESTION AND ABSORPTION

The liver cells synthesize about 6 g/day of *bile salts*. The precursor of bile salts is *cholesterol*, which is either present in the diet or synthesized in liver cells during the course of fat metabolism. The cholesterol is first converted to *cholic acid* or *chenodeoxycholic acid* in about equal quantities. These acids in turn combine principally with glycine and to a lesser extent with taurine to form *glyco-conjugated* and *tauro-conjugated bile acids*. The salts of these acids, mainly sodium salts, are then secreted in the bile. The bile salts have two major actions in the intestinal tract.

First, they have a detergent action on the fat particles in the food. This action, which decreases surface tension of the particles and allows agitation in the intestinal tract to break the fat globules into minute sizes, is called the *emulsifying* or *detergent function* of bile salts.

Second, and even more important than the emulsifying function, bile salts help in the absorption of (1) fatty acids, (2) monoglycerides, (3) cholesterol, and (4) other lipids from the intestinal tract. They help in this absorption by forming small physical complexes with these lipids called *micelles*, which are semisoluble in the chyme because of the electrical charges of the bile salts. The intestinal lipids are "ferried" in this form to the intestinal mucosa, where they are then absorbed into the blood, as will be described in more detail in Chapter 66.

Without the presence of bile salts in the intestinal tract excessive amounts of fat are excreted in the feces, a condition called *steatorrhea*; up to 40% of the ingested fats may be lost into the feces in the absence of adequate bile salts in the intestine, and a metabolic deficit often develops because of this nutrient loss.

Enterohepatic Circulation of Bile Salts. About 95% of the bile salts emptied into the duodenum are reabsorbed into the blood from the small intestine. A small portion of this reabsorption (~5%) occurs by *diffusion* through the mucosa in the early portions of the small intestine and the remainder (~90%) by an *active transport* process through the intestinal mucosa in the distal ileum. The bile salts then enter the portal blood and pass back to the liver. On reaching the liver and during first passage through the venous sinusoids, these salts are absorbed almost entirely back into the hepatic cells and are then resecreted into the bile.

In this way, about 95% of all the bile salts are recirculated into the bile, so on average these salts make the entire circuit many times before being carried out in the feces. The small quantities of bile salts lost into the feces are replaced by new amounts formed continually by the liver cells. This recirculation of the bile salts is called the *enterohepatic circulation of bile salts*.

The quantity of bile secreted by the liver each day is highly dependent on the availability of bile salts—the greater the quantity of bile salts in the enterohepatic circulation (usually a total of only ~2.5 grams), the greater the rate of bile secretion. Indeed, ingestion of supplemental bile salts can increase bile secretion by several hundred milliliters per day.

If a bile fistula empties the bile salts to the exterior for several days to several weeks so that they cannot be reabsorbed from the ileum, the liver increases its production of bile salts 6- to 10-fold, which increases the rate of bile

secretion most of the way back to normal. This demonstrates that the daily rate of liver bile salt secretion is actively controlled by the availability (or lack of availability) of bile salts in the enterohepatic circulation.

Role of Secretin in Controlling Bile Secretion. In addition to the strong stimulating effect of bile acids to cause bile secretion, the hormone *secretin*—which also stimulates pancreatic secretion—increases bile secretion, sometimes more than doubling its secretion for several hours after a meal. This increase in secretion consists almost entirely of secretion of a sodium bicarbonate–rich watery solution by the epithelial cells of the bile ductules and ducts and does not represent increased secretion by the liver parenchymal cells. The bicarbonate in turn passes into the small intestine and joins the bicarbonate from the pancreas in neutralizing the hydrochloric acid from the stomach.

Thus, the secretin feedback mechanism for neutralizing duodenal acid operates not only through its effects on pancreatic secretion but also to a lesser extent through its effect on secretion by the liver ductules and ducts.

Liver Secretion of Cholesterol Into the Bile and Gallstone Formation

Bile salts are formed in the hepatic cells from cholesterol in the blood plasma. In the process of secreting bile salts, about 1 to 2 grams of cholesterol are removed from the blood plasma and secreted into the bile each day.

Cholesterol is almost completely insoluble in pure water, but the bile salts and lecithin in bile combine physically with the cholesterol to form ultramicroscopic *micelles* in the form of a colloidal solution, as explained in Chapter 66. When the bile becomes concentrated in the gallbladder, the bile salts and lecithin become concentrated along with the cholesterol, which keeps the cholesterol in solution.

Under abnormal conditions, the cholesterol may precipitate in the gallbladder, resulting in the formation of *cholesterol gallstones*, as shown in **Fig. 65.12**. The amount of cholesterol in the bile is determined partly by the quantity of fat that the person eats, because liver cells synthesize cholesterol as one of the products of fat metabolism in the body. For this reason, people who are obese and consume a high-fat diet over a period of years are prone to develop gallstones. Other risk factors for gallstones include increasing age and female sex, diabetes mellitus, and genetic susceptibility.

Inflammation of the gallbladder epithelium, often resulting from a low-grade chronic infection, may also change the absorptive characteristics of the gallbladder mucosa, sometimes allowing excessive absorption of water and bile salts but leaving behind the cholesterol in the gallbladder in progressively greater concentrations. The cholesterol then begins to precipitate, first forming many small crystals of cholesterol on the surface of the inflamed mucosa, but then progressing to large gallstones.

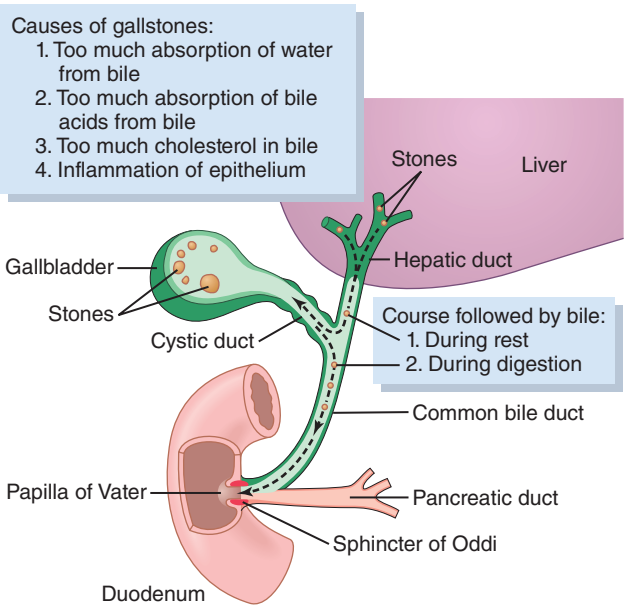

Figure 65.12 Formation of gallstones.

SECRETIONS OF THE SMALL INTESTINE

SECRETION OF MUCUS BY BRUNNER GLANDS IN THE DUODENUM

An extensive array of compound mucous glands, called *Brunner glands*, is located in the wall of the first few centimeters of the duodenum, mainly between the pylorus of the stomach and the papilla of Vater, where pancreatic secretion and bile empty into the duodenum. These glands secrete large amounts of alkaline mucus in response to the following: (1) tactile or irritating stimuli on the duodenal mucosa; (2) vagal stimulation, which causes increased Brunner gland secretion concurrently with increase in stomach secretion; and (3) gastrointestinal hormones, especially *secretin*.

The main function of the mucus secreted by Brunner glands is to protect the duodenal wall from digestion by the highly acidic gastric juice emptying from the stomach. In addition, the mucus contains a large excess of HCO_3^-, which adds to the HCO_3^- from pancreatic secretion and liver bile in neutralizing the hydrochloric acid entering the duodenum from the stomach.

Brunner glands are inhibited by sympathetic stimulation; therefore, excessive and prolonged sympathetic stimulation may leave the duodenal bulb unprotected and is perhaps one of the factors that cause this area of the gastrointestinal tract to be the site of peptic ulcers in about 50% of persons with ulcers.

SECRETION OF INTESTINAL DIGESTIVE JUICES BY THE CRYPTS OF LIEBERKÜHN

Located over the entire surface of the small intestine are small pits called *crypts of Lieberkühn*, one of which is illustrated in **Fig. 65.13**. These crypts lie between the intestinal villi. The surfaces of both the crypts and the villi are covered by an epithelium composed of two types of cells: (1) a moderate number of *goblet cells*, which secrete *mucus* that lubricates and protects the intestinal surfaces; and (2) a large number of *enterocytes*, which, in the crypts, secrete large quantities of water and electrolytes and, over

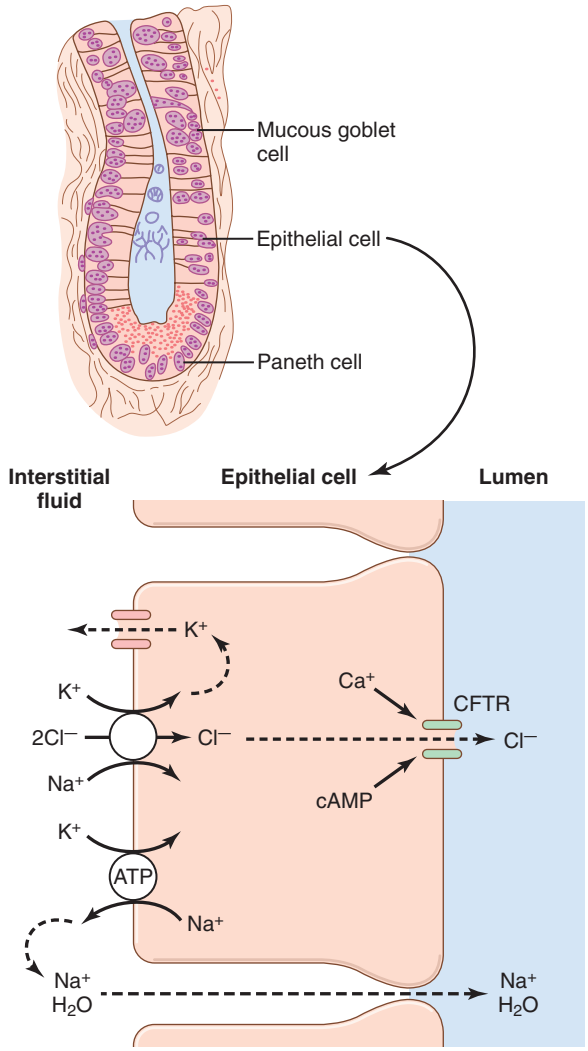

Figure 65.13 A *crypt of Lieberkühn* (upper figure), found in all parts of the small intestine between the villi, which secretes almost pure extracellular fluid. The lower figure illustrates the mechanisms for secretion of sodium, chloride, and water by the epithelial crypt cells. *CFTR*, Cystic fibrosis transmembrane conductance regulator; *cAMP*, cyclic adenosine monophosphate; *ATP*, adenosine triphosphate.

the surfaces of adjacent villi, reabsorb the water and electrolytes along with the end products of digestion.

The intestinal secretions are formed by the enterocytes of the crypts at a rate of about 1800 mL/day. These secretions are almost pure extracellular fluid and have a slightly alkaline pH in the range of 7.5 to 8.0. The secretions are also rapidly reabsorbed by the villi. This flow of fluid from the crypts into the villi supplies a watery vehicle for absorption of substances from chyme when it comes in contact with the villi. Thus, the primary function of the small intestine is to absorb nutrients and their digestive products into the blood.

Mechanism of Sodium Chloride and Fluid Secretion By the Crypts. Although the exact mechanisms that control secretion of NaCl and fluid by the crypts of Lieberkühn have not been fully elucidated, most of this secretion is believed to be driven by the processes shown in **Fig. 65.13**. The Na^+-K^+-ATPase pump on the basolateral membrane generates a low intracellular Na^+ concentration and the driving force for NaCl entry into the cell via the Na^+-K^+-$2Cl^-$ co-transporter. Potassium co-transported with Na^+ and Cl^- into the cell is recycled across the basolateral membrane through K^+ channels. The increased Cl^- concentration inside the cell and K^+ leaving the cell provide an electrochemical gradient for Cl^- exit through specific luminal membrane Cl^- channels, including *cystic fibrosis transmembrane conductance regulator (CFTR) chloride channels*. Phosphorylation and opening of the CFTR chloride channels are regulated by multiple *secretagogues* (e.g., acetylcholine, histamine, and gut peptides) that stimulate complex intracellular signaling pathways and increase Ca^{2+} and cyclic adenosine monophosphate (cAMP). Secretion of Cl^- causes electrical drag of Na^+ through the paracellular pathway of the membrane and into the secreted fluid as well. Finally, secretion of NaCl into the lumen causes osmotic movement of water into the lumen. The net effect is secretion of large amounts of NaCl and fluid by the crypts.

Digestive Enzymes in the Small Intestinal Secretion. When secretions of the small intestine are collected without cellular debris, they have almost no enzymes. The enterocytes of the mucosa, especially those that cover the villi, contain digestive enzymes that digest specific food substances *while they are being absorbed* through the epithelium. These enzymes are as follows: (1) several *peptidases* for splitting small peptides into amino acids; (2) four enzymes—*sucrase, maltase, isomaltase*, and *lactase*—for splitting disaccharides into monosaccharides; and (3) small amounts of *intestinal lipase* for splitting neutral fats into glycerol and fatty acids.

The epithelial cells deep in the crypts of Lieberkühn continually undergo mitosis, and new cells migrate along the basement membrane upward out of the crypts toward the tips of the villi, thus continually replacing the villus epithelium and also forming new digestive enzymes. As the villus cells age, they are finally shed into the intestinal secretions. The life cycle of an intestinal epithelial cell is about 5 days. This rapid growth of new cells also allows rapid repair of excoriations that occur in the mucosa.

Small Intestine Secretion Is Regulated By Local Stimuli. By far the most important means for regulating small intestine secretion are local enteric nervous reflexes, especially reflexes initiated by tactile or irritative stimuli from the chyme in the intestines.

SECRETION OF MUCUS BY THE LARGE INTESTINE

Mucus Secretion By Crypts of Lieberkühn. The mucosa of the large intestine, like that of the small intestine, has many crypts of Lieberkühn; however, unlike the small intestine, it contains no villi. The epithelial cells

secrete almost no digestive enzymes. Instead, they contain mucous cells that secrete only *mucus*. This mucus contains moderate amounts of HCO_3^- secreted by a few non–mucus-secreting epithelial cells. The rate of mucus secretion is regulated principally by direct, tactile stimulation of the epithelial cells lining the large intestine and by local nervous reflexes to the mucous cells in the crypts of Lieberkühn.

Stimulation of the *pelvic nerves* from the spinal cord, which carry *parasympathetic innervation* to the distal one-half to two-thirds of the large intestine, also can cause marked increases in mucus secretion along with increased peristaltic motility of the colon, as discussed in Chapter 64.

During extreme parasympathetic stimulation, often caused by emotional disturbances, so much mucus can occasionally be secreted into the large intestine that the person has a bowel movement of ropy mucus as often as every 30 minutes. This mucus often contains little or no fecal material.

Mucus in the large intestine protects the intestinal wall against excoriation, but it also provides an adherent medium for holding fecal matter together. Furthermore, it protects the intestinal wall from the great amount of bacterial activity that takes place inside the feces. Finally, the mucus plus the alkalinity of the secretion (a pH of 8.0 caused by large amounts of sodium bicarbonate) provides a barrier to keep acids formed in the feces from attacking the intestinal wall.

Diarrhea Caused By Excess Secretion of Water and Electrolytes in Response to Irritation. Whenever a segment of the large intestine becomes intensely irritated, as occurs when bacterial infection becomes rampant during *enteritis*, the mucosa secretes extra-large quantities of water and electrolytes in addition to the normal viscid alkaline mucus. This secretion acts to dilute the irritating factors and to cause rapid movement of the feces toward the anus. The result is *diarrhea*, with loss of large quantities of water and electrolytes. However, the diarrhea also washes away irritant factors, which promotes earlier recovery from the disease than might otherwise occur.

CHAPTER 66

Digestion and Absorption in the Gastrointestinal Tract

The major foods on which the body lives (with the exception of small quantities of substances such as vitamins and minerals) are *carbohydrates, fats*, and *proteins*. They generally cannot be absorbed in their natural forms through the gastrointestinal mucosa, and for this reason, they are useless as nutrients without preliminary digestion. This chapter discusses the processes by which carbohydrates, fats, and proteins are digested into small enough compounds for absorption and the mechanisms by which the digestive end products, as well as water, electrolytes, and other substances, are absorbed.

DIGESTION OF VARIOUS FOODS BY HYDROLYSIS

Hydrolysis of Carbohydrates. Almost all the carbohydrates of the diet are either large *polysaccharides* or *disaccharides*, which are combinations of *monosaccharides* bound to one another by *condensation*. This phenomenon means that a hydrogen ion (H^+) has been removed from one of the monosaccharides, and a hydroxyl ion (OH^-) has been removed from the next one. The two monosaccharides then combine with each other at these sites of removal, and the H^+ and OH^- then combine to form water (H_2O).

When carbohydrates are digested, this process is reversed, and the carbohydrates are converted into monosaccharides. Specific enzymes in the digestive juices of the gastrointestinal tract return the H^+ and OH^- from H_2O to the polysaccharides and thereby separate the monosaccharides from each other. This process, called *hydrolysis*, is the following (in which R′′-R′ is disaccharide):

$$R''\text{–}R' + H_2O \xrightarrow[\text{enzyme}]{\text{Digestive}} R''OH + R'H$$

Hydrolysis of Fats. Almost the entire fat portion of the diet consists of triglycerides (neutral fats), which are combinations of three *fatty acid* molecules condensed with a single *glycerol* molecule. During condensation, three molecules of water are removed.

Hydrolysis (digestion) of the triglycerides consists of the reverse process: the fat-digesting enzymes return three molecules of water to the triglyceride molecule and thereby split the fatty acid molecules away from the glycerol.

Hydrolysis of Proteins. Proteins are formed from multiple *amino acids* that are bound together by *peptide linkages*. At each linkage, a OH^- has been removed from one amino acid and a H^+ has been removed from the succeeding one; thus, the successive amino acids in the protein chain are also bound together by condensation, and digestion occurs by the reverse effect: hydrolysis. That is, the proteolytic enzymes return H^+ and OH^- from water molecules to the protein molecules to split them into their constituent amino acids.

Therefore, the chemistry of digestion is simple because, in the case of all three major types of food, the same basic process of *hydrolysis* is involved. The only difference lies in the types of enzymes required to promote the hydrolysis reactions for each type of food.

All the digestive enzymes are proteins. Their secretion by the different gastrointestinal glands was discussed in Chapter 65.

DIGESTION OF CARBOHYDRATES

Carbohydrate Foods of the Diet. Only three major sources of carbohydrates exist in the normal human diet. They are *sucrose*, which is the disaccharide known popularly as cane sugar; *lactose*, which is a disaccharide found in milk; and *starches*, which are large polysaccharides present in almost all nonanimal foods, particularly in potatoes and different types of grains. Other carbohydrates ingested to a slight extent are *amylose, glycogen, alcohol, lactic acid, pyruvic acid, pectins, dextrins*, and minor quantities of *carbohydrate derivatives in meats*.

The diet also contains a large amount of *cellulose*, which is a carbohydrate. However, enzymes capable of hydrolyzing cellulose are not secreted in the human digestive tract. Consequently, cellulose cannot be considered a food for humans.

Digestion of Carbohydrates Begins in the Mouth and Stomach. When food is chewed, it is mixed with saliva, which contains the digestive enzyme *ptyalin* (an *α-amylase*), secreted mainly by the parotid glands. This enzyme hydrolyzes starch into the disaccharide *maltose* and other small polymers of glucose that contain three to nine glucose molecules, as shown in **Fig. 66.1**. However, the food remains in the mouth only a short time,

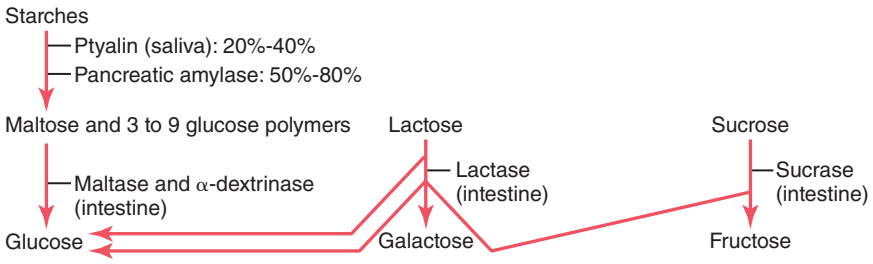

Figure 66.1 Digestion of carbohydrates.

so probably not more than 5% of all the starches become hydrolyzed by the time the food is swallowed.

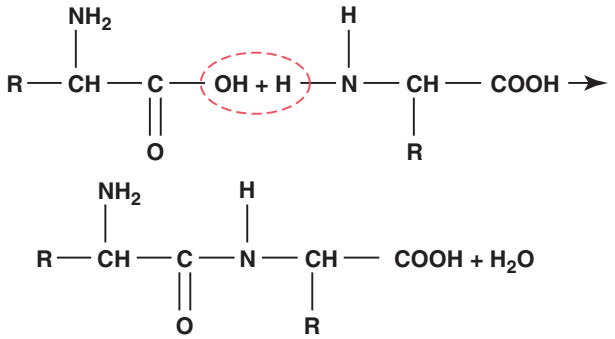
Starch digestion sometimes continues in the body and fundus of the stomach for as long as 1 hour before the food becomes mixed with the stomach secretions. Activity of the salivary amylase is then blocked by acid of the gastric secretions because the amylase is essentially inactive as an enzyme once the pH of the medium falls below about 4.0. Nevertheless, on average, before food and its accompanying saliva become completely mixed with the gastric secretions, as much as 30% to 40% of the starches will have been hydrolyzed, mainly to form *maltose*.

DIGESTION OF CARBOHYDRATES IN THE SMALL INTESTINE

Digestion By Pancreatic Amylase. Pancreatic secretion, like saliva, contains a large quantity of α-amylase that is almost identical in its function to the α-amylase of saliva but is several times as powerful. Therefore, within 15 to 30 minutes after the chyme empties from the stomach into the duodenum and mixes with pancreatic juice, virtually all the carbohydrates will have become digested.

In general, the carbohydrates are almost totally converted into *maltose* and/or *other small glucose polymers* before passing beyond the duodenum or upper jejunum.

Hydrolysis of Disaccharides and Small Glucose Polymers Into Monosaccharides By Intestinal Epithelial Enzymes. The *enterocytes* lining the villi of the small intestine contain four enzymes (*lactase*, *sucrase*, *maltase*, and *α-dextrinase*), which are capable of splitting the disaccharides lactose, sucrose, and maltose, plus other small glucose polymers, into their constituent monosaccharides. These enzymes are located *in the enterocytes* covering *the intestinal microvilli brush border*, so the disaccharides are digested as they come in contact with these enterocytes.



Lactose splits into a molecule of *galactose* and a molecule of *glucose*. Sucrose splits into a molecule of *fructose* and a molecule of *glucose*. Maltose and other small glucose polymers all split into *multiple molecules of glucose*. Thus, the final products of carbohydrate digestion are all monosaccharides. They are all water soluble and are absorbed immediately into the portal blood.

In the ordinary diet, which contains far more starches than all other carbohydrates combined, glucose represents more than 80% of the final products of carbohydrate digestion, and galactose and fructose each seldom represent more than 10%.

The major steps in carbohydrate digestion are summarized in **Fig. 66.1**.

DIGESTION OF PROTEINS

Proteins of the Diet. Dietary proteins are chemically long chains of amino acids bound together by *peptide linkages*. A typical linkage is the following:

The characteristics of each protein are determined by its amino acids and the sequential arrangements of these amino acids. The physical and chemical characteristics of different proteins important in human tissues are discussed in Chapter 70.

Digestion of Proteins in the Stomach. *Pepsin*, an important peptic enzyme of the stomach, is most active at a pH of 2.0 to 3.0 and is inactive at a pH above about 5.0. Consequently, for this enzyme to cause digestion of protein, the stomach juices must be acidic. As explained in Chapter 65, the gastric glands secrete a large quantity of hydrochloric acid. This hydrochloric acid is secreted by the parietal (oxyntic) cells in the glands at a pH of about 0.8, but by the time it is mixed with the stomach contents and with secretions from the nonoxyntic glandular cells of the stomach, the pH then averages around 2.0 to 3.0, a highly favorable range of acidity for pepsin activity.

One of the important features of pepsin digestion is its ability to digest the protein *collagen*, an albuminoid type of protein that is affected little by other digestive enzymes. Collagen is a major constituent of the intercellular connective tissue of meats; therefore, for the digestive enzymes to penetrate meats and digest the other meat proteins, it is necessary that the collagen fibers be

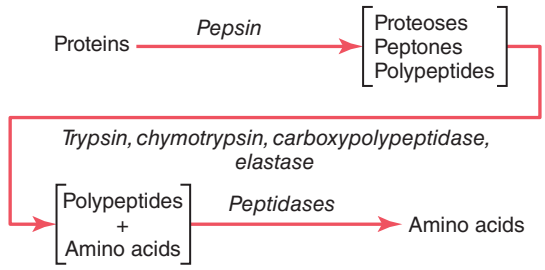


Figure 66.2 Digestion of proteins.

digested. Consequently, in people who lack pepsin in the stomach juices, the ingested meats are less well penetrated by the other digestive enzymes and, therefore, may be poorly digested.

As shown in **Fig. 66.2**, pepsin only initiates the process of protein digestion, usually providing only 10% to 20% of the total protein digestion to convert the protein to proteoses, peptones, and a few polypeptides. This splitting of proteins occurs as a result of hydrolysis at the peptide linkages between amino acids.

Most Protein Digestion Results From Actions of Pancreatic Proteolytic Enzymes. Most protein digestion occurs in the upper small intestine, in the duodenum and jejunum, under the influence of proteolytic enzymes from pancreatic secretion. Immediately upon entering the small intestine from the stomach, the partial breakdown products of the protein foods are attacked by the major proteolytic pancreatic enzymes *trypsin, chymotrypsin, carboxypolypeptidase*, and *elastase*, as shown in **Fig. 66.2**.

As discussed in Chapter 65, these pancreatic peptidases are stored in their inactive precursor forms (*zymogen* or *proenzyme*) in the pancreas and become activated only after they are secreted into the intestine. Trypsinogen is activated by *enterokinase*, a proteolytic enzyme expressed on the luminal membrane of the small intestine epithelial cells (**Fig. 66.3**). Trypsinogen also can be autocatalytically activated by trypsin that has already been formed from previously secreted trypsinogen. Chymotrypsinogen, procarboxypolypeptidases, and proelastase are also activated by trypsin to form the active proteolytic enzymes chymotrypsin, carboxypeptidases, and elastase, respectively.

Both trypsin and chymotrypsin split proteins into small polypeptides; carboxypolypeptidase then cleaves individual amino acids from the carboxyl ends of the polypeptides. *Elastase* digests elastin fibers that partially hold meats together.

Only small percentages of the proteins are digested all the way to their constituent amino acids by the pancreatic juices. Most remain as dipeptides and tripeptides.

Digestion of Peptides By Peptidases in the Enterocytes That Line the Small Intestinal Villi. The last digestive stage of proteins in the intestinal lumen is achieved by enterocytes that line the villi of the small intestine, mainly

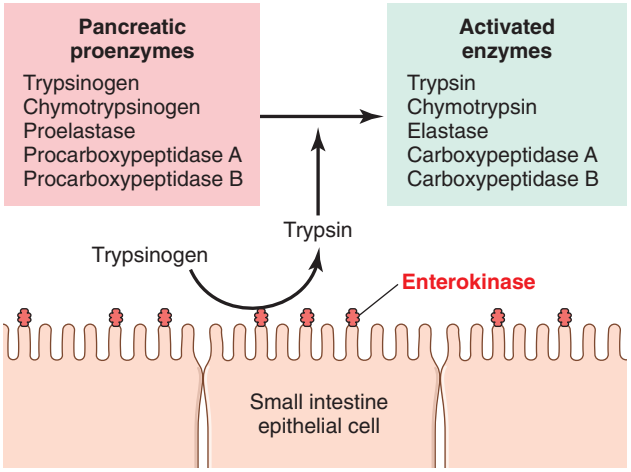

Figure 66.3 Activation of proenzymes secreted by the pancreas. Inactive trypsinogen is converted to trypsin by enterokinase on the brush border of the small intestine, and trypsin, in turn, converts the other pancreatic proenzymes to their active forms.

in the duodenum and jejunum. These cells have a *brush border* that consists of hundreds of *microvilli* projecting from the surface of each cell. In the membrane of each of these microvilli are multiple *peptidases* that protrude through the membranes to the exterior, where they come in contact with the intestinal fluids.

Two types of peptidase enzymes are especially important, *aminopolypeptidase* and several *dipeptidases*. They split the remaining larger polypeptides into tripeptides and dipeptides and a few into amino acids. The amino acids, dipeptides, and tripeptides are easily transported through the microvillar membrane to the interior of the enterocyte.

Finally, inside the cytosol of the enterocyte are multiple other peptidases that are specific for the remaining types of linkages between amino acids. Within minutes, virtually all the last dipeptides and tripeptides are digested to the final stage to form single amino acids, which then pass on through to the other side of the enterocyte and thence into the blood.

More than 99% of the final protein digestive products that are absorbed are individual amino acids, with only rare absorption of peptides and very rare absorption of whole protein molecules. Even these few absorbed molecules of whole protein can sometimes cause serious allergic or immunologic disturbances, as discussed in Chapter 35.

DIGESTION OF FATS

Fats of the Diet. By far the most abundant fats of the diet are the neutral fats, also known as *triglycerides*, each molecule of which is composed of a glycerol nucleus and three fatty acid side chains, as shown in **Fig. 66.4**. Neutral fat is a major constituent in food of animal origin but much less so in food of plant origin.

Small quantities of phospholipids, cholesterol, and cholesterol esters are also present in the usual diet. The

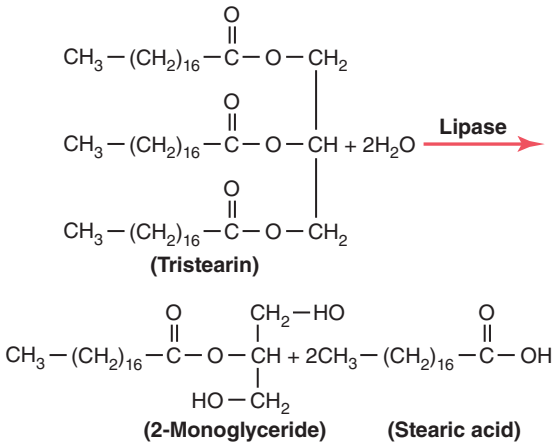

Figure 66.4 Hydrolysis of neutral fat catalyzed by lipase.

phospholipids and cholesterol esters contain fatty acid and therefore can be considered fats. Cholesterol is a sterol compound that contains no fatty acid, but it does exhibit some of the physical and chemical characteristics of fats. In addition, it is derived from fats and is metabolized similarly to fats. Therefore, cholesterol is considered, from a dietary point of view, to be a fat.

Digestion of Fats Occurs Mainly in the Small Intestine. A small amount of triglycerides is digested *in the stomach* by *lingual lipase* secreted by lingual glands in the mouth and swallowed with the saliva. This amount of digestion is less than 10% and is generally unimportant. Instead, essentially all fat digestion occurs in the small intestine, as follows.

The First Step in Fat Digestion Is Emulsification By Bile Acids and Lecithin. The first step in fat digestion is to physically break the fat globules into small sizes so that the water-soluble digestive enzymes can act on the globule surfaces. This process is called *emulsification of the fat*, and it begins by agitation in the stomach to mix the fat with the products of stomach digestion.

Most of the emulsification then occurs in the duodenum under the influence of *bile*, the liver secretion that does not contain any digestive enzymes. However, bile does contain a large quantity of *bile salts*, as well as the phospholipid *lecithin*. Both of these substances, *but especially lecithin*, are extremely important for emulsification of the fat. The polar parts (i.e., the points where ionization occurs in water) of the bile salts and lecithin molecules are highly soluble in water, whereas most of the remaining portions of their molecules are highly soluble in fat. Therefore, the fat-soluble portions of these liver secretions dissolve in the surface layer of the fat globules, with the polar portions projecting. The polar projections, in turn, are soluble in the surrounding watery fluids, which greatly decreases the interfacial tension of the fat and makes it soluble as well.

When the interfacial tension of a globule of nonmiscible fluid is low, this nonmiscible fluid, upon agitation, can be broken up into many tiny particles far more easily

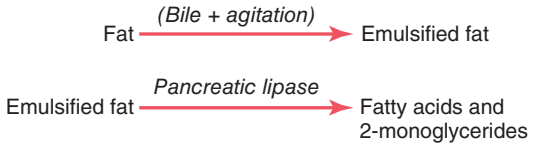

Figure 66.5 Digestion of fats.

than it can when the interfacial tension is great. Consequently, a major function of the bile salts and lecithin in the bile is to make the fat globules readily fragmentable by agitation with the water in the small bowel. This action is the same as that of many detergents that are widely used in household cleaners for removing grease.

Each time the diameters of the fat globules are significantly decreased as a result of agitation in the small intestine, the total surface area of the fat increases many-fold. Because the average diameter of the fat particles in the intestine after emulsification has occurred is less than 1 micrometer, this represents an increase of as much as 1000-fold in total surface areas of the fats caused by the emulsification process.

The lipase enzymes are water-soluble and can attack the fat globules only on their surfaces. Consequently, this detergent function of bile salts and lecithin is very important for digestion of fats.

Triglycerides Are Digested By Pancreatic Lipase. By far the most important enzyme for digestion of the triglycerides is *pancreatic lipase*, present in enormous quantities in pancreatic juice, enough to digest within 1 minute all triglycerides that it can reach. The enterocytes of the small intestine contain additional lipase, known as *enteric lipase*, but it is usually not needed.

End Products of Fat Digestion Are Free Fatty Acids. Most of the triglycerides of the diet are split by pancreatic lipase into *free fatty acids* and *2-monoglycerides*, as shown in **Fig. 66.5**.

Bile Salts Form Micelles That Accelerate Fat Digestion. The hydrolysis of triglycerides is a highly reversible process; therefore, accumulation of monoglycerides and free fatty acids in the vicinity of digesting fats quickly blocks further digestion. However, the bile salts play the additional important role of removing the monoglycerides and free fatty acids from the vicinity of the digesting fat globules almost as rapidly as these end products of digestion are formed. This process occurs in the following way.

When bile salts are of a high enough concentration in water, they have the propensity to form *micelles*, which are small spherical, cylindrical globules 3 to 6 nanometers in diameter composed of 20 to 40 molecules of bile salt. These micelles develop because each bile salt molecule is composed of a sterol nucleus that is highly fat-soluble and a polar group that is highly water-soluble. The sterol nucleus encompasses the fat digestate, forming a small fat globule in the middle of a resulting micelle, with polar groups of bile salts projecting outward to cover the surface

of the micelle. Because these polar groups are negatively charged, they allow the entire micelle globule to dissolve in the water of the digestive fluids and to remain in stable solution until the fat is absorbed into the blood.

The bile salt micelles also act as a transport medium to carry the monoglycerides and free fatty acids, both of which would otherwise be relatively insoluble, to the brush borders of the intestinal epithelial cells. There the monoglycerides and free fatty acids are absorbed into the blood, as discussed later, but the bile salts are released back into the chyme to be used again and again for this "ferrying" process.

Digestion of Cholesterol Esters and Phospholipids. Most cholesterol in the diet is in the form of cholesterol esters, which are combinations of free cholesterol and one molecule of fatty acid. Phospholipids also contain fatty acid within their molecules. The cholesterol esters and the phospholipids are hydrolyzed by two other lipases in the pancreatic secretion that free the fatty acids—the enzyme *cholesterol ester hydrolase* to hydrolyze the cholesterol ester, and *phospholipase* A_2 to hydrolyze the phospholipid.

The bile salt micelles play the same role in "ferrying" free cholesterol and phospholipid molecule digestates that they play in ferrying monoglycerides and free fatty acids. Indeed, essentially no cholesterol is absorbed without this function of the micelles.

BASIC PRINCIPLES OF GASTROINTESTINAL ABSORPTION

We suggest that the reader review the basic principles of cell membrane transport of substances discussed in Chapter 4. The following paragraphs present specialized applications of these transport processes during gastrointestinal absorption.

ANATOMICAL BASIS OF ABSORPTION

The total quantity of fluid that must be absorbed each day by the intestines is approximately equal to the ingested fluid (~1.5 liters) plus that secreted in the various gastrointestinal secretions (~7 liters), which comes to a total of 8 to 9 liters. All but about 1.5 liters of this fluid is absorbed in the small intestine, leaving only 1.5 liters to pass through the ileocecal valve into the colon each day.

The stomach is a poor absorptive area of the gastrointestinal tract because it lacks the typical villus type of absorptive membrane and because the junctions between the epithelial cells are tight junctions. Only a few highly lipid-soluble substances, such as alcohol and some drugs (e.g., aspirin), can be absorbed in small quantities by the stomach.

Folds of Kerckring, Villi, and Microvilli Increase the Small Intestine Mucosal Absorptive Area By Nearly 1000-Fold. **Fig. 66.6** demonstrates the absorptive surface of the small intestinal mucosa, showing many folds called *valvulae conniventes* (or *folds of Kerckring*), which increase the surface area of the absorptive mucosa about 3-fold. These folds extend circularly most of the way around the intestine and are especially well developed in the duodenum and jejunum, where they often protrude up to 8 millimeters into the lumen.

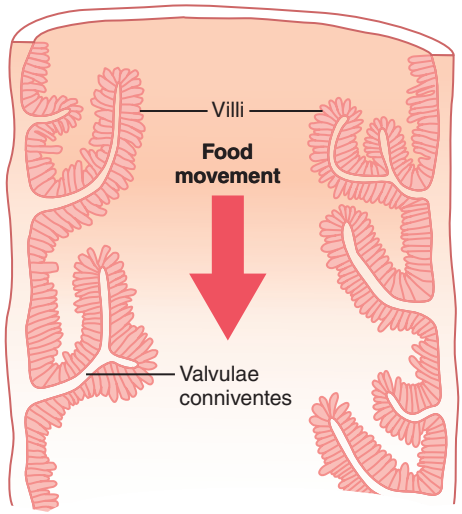

Figure 66.6 Longitudinal section of the small intestine, showing the valvulae conniventes *(Kerckring folds)* covered by villi.

Also located on the epithelial surface of the small intestine all the way down to the ileocecal valve are millions of small *villi*. These villi project about 1 millimeter from the surface of the mucosa, as shown on the surfaces of the valvulae conniventes in **Fig. 66.6** and in individual detail in **Fig. 66.7**. The villi lie so close to one another in the upper small intestine that they touch in most areas, but their distribution is less profuse in the distal small intestine. The presence of villi on the mucosal surface enhances the total absorptive area another 10-fold.

Finally, each intestinal epithelial cell on each villus is characterized by a *brush border*, consisting of as many as 1000 *microvilli* that are 1 micrometer in length and 0.1 micrometer in diameter and protrude into the intestinal chyme. These microvilli are shown in the electron micrograph in **Fig. 66.8**. This brush border increases the surface area exposed to the intestinal materials at least another 20-fold.

Thus, the combination of the folds of Kerckring, the villi, and the microvilli increases the total absorptive area of the mucosa perhaps 1000-fold, making a tremendous total area of 250 or more square meters for the entire small intestine—about the surface area of a tennis court.

Fig. 66.7A shows in longitudinal section the general organization of the villus, emphasizing (1) the advantageous arrangement of the vascular system for absorption of fluid and dissolved material into the portal blood and (2) the arrangement of the "*central lacteal*" lymph vessel for absorption into the lymph. **Fig. 66.7B** shows a cross section of the villus, and **Fig. 66.8** shows many small *pinocytic vesicles*, which are pinched-off portions of infolded

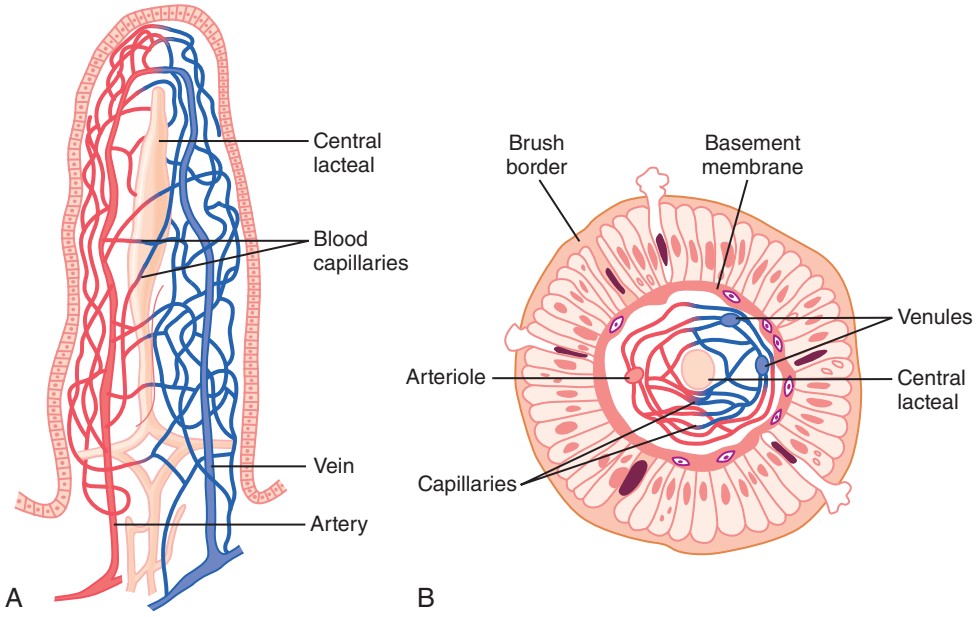

Figure 66.7 Functional organization of the villus. (A) Longitudinal section. (B) Cross section showing a basement membrane beneath the epithelial cells and a brush border at the other ends of these cells.

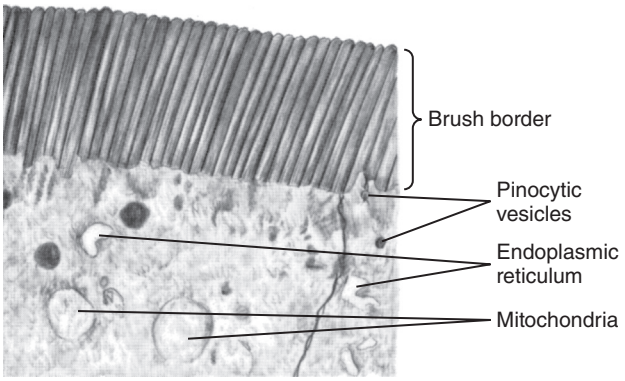

Figure 66.8 Brush border of a gastrointestinal epithelial cell, also showing absorbed pinocytic vesicles, mitochondria, and endoplasmic reticulum lying immediately beneath the brush border. *(Courtesy Dr. William Lockwood.)*

enterocyte membrane forming vesicles of absorbed fluids that have been entrapped. Small amounts of substances are absorbed by this physical process of *pinocytosis*.

Extending from the epithelial cell body into each microvillus of the brush border are multiple *actin filaments* that contract rhythmically to cause continual movement of the microvilli, keeping them constantly exposed to new quantities of intestinal fluid.

ABSORPTION IN THE SMALL INTESTINE

Absorption from the small intestine each day consists of several hundred grams of carbohydrates, 100 or more grams of fat, 50 to 100 grams of amino acids, 50 to 100 grams of ions, and 7 to 8 liters of water. The absorptive *capacity* of the normal small intestine is far greater than this; each day as much as several kilograms of carbohydrates, 500 grams of fat, 500 to 700 grams of proteins, and 20 or more liters of water can be absorbed. The *large* intestine can absorb still more water and ions, although it can absorb very few nutrients.

ISOSMOTIC ABSORPTION OF WATER

Water is transported through the intestinal membrane entirely by *diffusion*. Furthermore, this diffusion obeys the usual laws of osmosis. Therefore, when the chyme is dilute enough, water is absorbed through the intestinal mucosa into the blood of the villi almost entirely by osmosis.

Conversely, water can also be transported in the opposite direction—from plasma into the chyme. This type of transport occurs especially when hyperosmotic solutions are discharged from the stomach into the duodenum. Within minutes, sufficient water usually will be transferred by osmosis to make the chyme isosmotic with the plasma.

ABSORPTION OF IONS

Sodium Is Actively Transported Through the Intestinal Membrane. Twenty to 30 grams of sodium are secreted in the intestinal secretions each day. In addition, the average person eats 5 to 8 grams of sodium each day. Therefore, to prevent net loss of sodium into the feces, the intestines must absorb 25 to 35 grams of sodium each day, which is equal to about one-seventh of all the sodium present in the body.

Whenever significant amounts of intestinal secretions are lost to the exterior, as in extreme diarrhea, the sodium reserves of the body can sometimes be depleted to lethal levels within hours. Normally, however, less than 0.5% of the intestinal sodium is lost in the feces each day because

it is rapidly absorbed through the intestinal mucosa. Sodium also plays an important role in helping to absorb sugars and amino acids, as subsequent discussions reveal.

The basic mechanism of sodium absorption from the intestine is shown in **Fig. 66.9**. The principles of this mechanism, discussed in Chapter 4, are also essentially the same as for absorption of sodium from the gallbladder and renal tubules, as discussed in Chapter 28.

Sodium absorption is powered by active transport of Na^+ from inside the epithelial cells through the basal and lateral walls of these cells into paracellular spaces. This active transport obeys the usual laws of active transport. It requires energy, and the energy process is catalyzed by adenosine triphosphatase (ATPase) enzyme in the cell membrane (see Chapter 4). Part of the Na^+ is absorbed along with Cl^-; in fact, the negatively charged Cl^- is mainly passively "dragged" by the positive electrical charges of the Na^+.

Active transport of Na^+ through the basolateral membranes of the cell reduces the Na^+ concentration inside the cell to a low value (~50 mEq/L). Because the Na^+ concentration in the chyme is normally about 142 mEq/L (i.e., about equal to that in plasma), Na^+ moves down this steep electrochemical gradient from the chyme through the brush border of the epithelial cell into the epithelial cell cytoplasm. Sodium is also co-transported through the brush border membrane by several specific carrier proteins, including the following: (1) the sodium-glucose co-transporter 1 (SGLT1); (2) sodium–amino acid co-transporters; and (3) the sodium-hydrogen exchanger. These transporters function similarly as in the renal tubules, described in Chapter 28, and provide still more

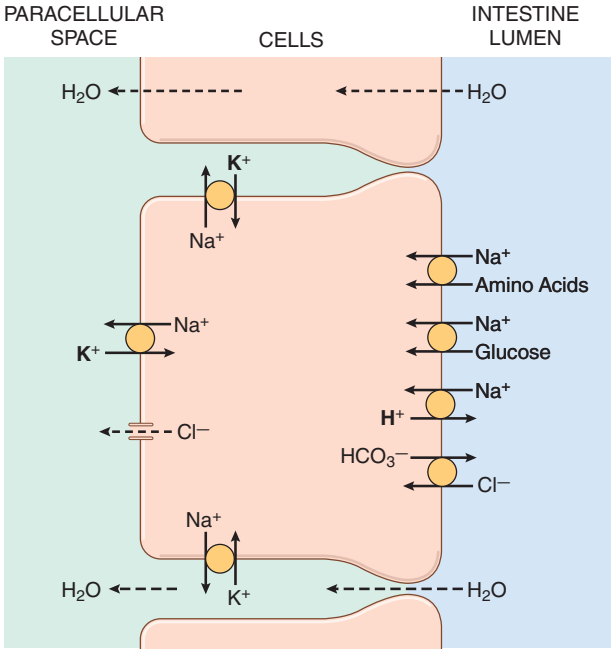

Figure 66.9 Absorption of sodium, chloride, glucose, and amino acids through the intestinal epithelium. Note also osmotic absorption of water (i.e., water "follows" sodium through the epithelial membrane).

Na^+ to be transported by the epithelial cells into the interstitial fluid and paracellular spaces. At the same time, they also provide secondary active absorption of glucose and amino acids, powered by the active sodium-potassium (Na^+-K^+) ATPase pump on the basolateral membrane.

Osmosis of Water Through Transcellular and Paracellular Pathways. The next step in the transport process is osmosis of water by transcellular and paracellular pathways. This osmosis occurs because a large osmotic gradient is created by the elevated concentration of ions in the paracellular space. Much of this osmosis occurs through the tight junctions between the apical borders of the epithelial cells (the paracellular pathway), but much also occurs through the transcellular pathway via *aquaporins* (water channels) in the cell membranes. Osmotic movement of water creates flow of fluid into and through the cell membrane aquaporins and paracellular spaces and, finally, into the circulating blood of the villus.

Aldosterone Greatly Enhances Sodium Absorption. When a person becomes dehydrated, large amounts of aldosterone are secreted by the cortices of the adrenal glands. Within 1 to 3 hours this aldosterone causes increased activation of the enzyme and transport mechanisms for Na^+ absorption by the intestinal epithelium. The increased Na^+ absorption in turn causes secondary increases in absorption of Cl^-, water, and some other substances.

This effect of aldosterone is especially important in the colon because it allows virtually no loss of sodium chloride in the feces and also little water loss. Thus, the function of aldosterone in the intestinal tract is the same as that for aldosterone in the renal tubules, which also serves to conserve sodium chloride and water in the body when a person becomes depleted of sodium chloride and dehydrated.

Absorption of Chloride Ions in the Small Intestine. In the upper part of the small intestine, Cl^- absorption is rapid and occurs mainly by diffusion (i.e., absorption of Na^+ through the epithelium creates electronegativity in the chyme and electropositivity in the paracellular spaces between the epithelial cells). Cl^- then moves along this electrical gradient to "follow" the Na^+. Chloride is also absorbed across the brush border membrane of parts of the ileum and large intestine by a brush border membrane chloride-bicarbonate exchanger (see **Fig. 66.9**). Chloride exits the cell on the basolateral membrane through chloride channels.

Absorption of Bicarbonate Ions in the Duodenum and Jejunum. Often large quantities of bicarbonate ions (HCO_3^-) must be reabsorbed from the upper small intestine because large amounts of HCO_3^- have been secreted into the duodenum in pancreatic secretion and bile. The HCO_3^- is absorbed in an indirect way as follows: When Na^+ is absorbed, H^+ is secreted into the lumen of the gut in exchange for some of the Na^+. These H^+, in turn,

combine with the HCO_3^- to form carbonic acid (H_2CO_3), which then dissociates to form water and carbon dioxide (CO_2). The water remains as part of the chyme in the intestines, but the CO_2 is readily absorbed into the blood and subsequently expired through the lungs. This process is the so-called "active" absorption of HCO_3^-. It is the same mechanism that occurs in the tubules of the kidneys (see Chapter 31).

Secretion of Bicarbonate and Absorption of Chloride Ions in the Ileum and Large Intestine. The epithelial cells on the surfaces of the villi in the ileum, as well as on all surfaces of the large intestine, have a special capability of secreting HCO_3^- in exchange for absorption of Cl^- (see **Fig. 66.9**). This capability is important because it provides alkaline HCO_3^- that neutralizes acid products formed by bacteria in the large intestine.

Extreme Secretion of Chloride Ions, Sodium Ions, and Water From the Large Intestine Epithelium in Some Types of Diarrhea. Immature epithelial cells that continually divide to form new epithelial cells are found deep in the spaces between the intestinal epithelial folds. These new epithelial cells spread outward over the luminal surfaces of the intestines. While still in the deep folds, the epithelial cells secrete sodium chloride and water into the intestinal lumen. This secretion, in turn, is reabsorbed by the older epithelial cells outside the folds, thus providing flow of water for absorbing intestinal digestates.

The *toxins of cholera* and of some other types of diarrheal bacteria can stimulate the epithelial fold secretion so greatly that this secretion often becomes much greater than can be reabsorbed, thus sometimes causing a loss of 5 to 10 liters of water and sodium chloride as *diarrhea* each day. Within 1 to 5 days, some severely affected patients may die of this loss of fluid alone.

Extreme diarrheal secretion is initiated by entry of a subunit of cholera toxin into the epithelial cells. This subunit stimulates formation of excess cyclic adenosine monophosphate (cAMP), which opens tremendous numbers of the *cystic fibrosis transmembrane conductance regulator (CFTR)* Cl^- channels (see **Fig. 65.13**), allowing Cl^- to flow rapidly from inside the cell into the intestinal crypts. In turn, increased secretion of Cl^- causes electrical drag of Na^+ through the paracellular pathway of the membrane and into the secreted fluid. Cholera toxins may also inhibit active Na^+ reabsorption. All this extra NaCl in the lumen of the intestine causes extreme osmosis of water from the extracellular fluid, thus providing rapid flow of fluid along with the NaCl. This excess fluid washes away most of the bacteria and is of value in combating the disease, but too much of a good thing can be lethal because of serious dehydration of the whole body that might ensue. In most instances, the life of a person with cholera can be saved by the administration of tremendous amounts of NaCl solution to make up for the loss.

Active Absorption of Calcium, Iron, Potassium, Magnesium, and Phosphate. *Calcium ions* are actively absorbed into the blood, especially from the duodenum, and the amount of calcium ion absorption is exactly controlled to supply the daily need of the body for calcium. One important factor controlling calcium absorption is *parathyroid hormone* secreted by the parathyroid glands, and another is *vitamin D*. Parathyroid hormone activates vitamin D, and the activated vitamin D in turn greatly enhances calcium absorption. These effects are discussed in Chapter 80.

Iron ions are also actively absorbed from the small intestine. The basic principles of iron absorption and regulation of its absorption in proportion to the body's need for iron, especially for the formation of hemoglobin, are discussed in Chapter 33.

Potassium, magnesium, phosphate, and probably *still other ions* can also be actively absorbed through the intestinal mucosa. In general, the monovalent ions are absorbed with ease and in great quantities. Bivalent ions are normally absorbed in smaller amounts; for example, maximum absorption of calcium ions is only one-fiftieth as great as the normal absorption of Na^+. Fortunately, only small quantities of the bivalent ions are normally required daily by the body.

ABSORPTION OF NUTRIENTS

Carbohydrates Are Mainly Absorbed as Monosaccharides

Essentially all the carbohydrates in food are absorbed in the form of monosaccharides; only a small fraction is absorbed as disaccharides and almost none is absorbed as larger carbohydrate compounds. By far the most abundant of the absorbed monosaccharides is *glucose*, which usually accounts for more than 80% of the carbohydrate calories absorbed. The reason for this high percentage is that glucose is the final digestion product of our most abundant carbohydrate food, the starches. The remaining 20% of absorbed monosaccharides is composed almost entirely of *galactose* and *fructose*—the galactose derived from milk and the fructose as one of the monosaccharides digested from cane sugar.

Virtually all the monosaccharides are absorbed by a secondary active transport process. We will first discuss the absorption of glucose.

Glucose Is Transported By a Sodium Co-Transport Mechanism. In the absence of Na^+ transport through the intestinal membrane, virtually no glucose can be absorbed because glucose absorption occurs in a co-transport mode with active transport of Na^+ (**Fig. 66.10**).

The transport of Na^+ and glucose through the intestinal membrane occurs in two stages. First, Na^+ is actively transported through the basolateral membranes of the intestinal epithelial cells into the interstitial fluid, thereby depleting Na^+ inside the epithelial cells. Second, a decrease of Na^+ inside the cells causes Na^+ from the intestinal lumen to move through the brush border of the epithelial cells to the cell interior by a process of *secondary active transport*. That is, a Na^+ combines with a transport

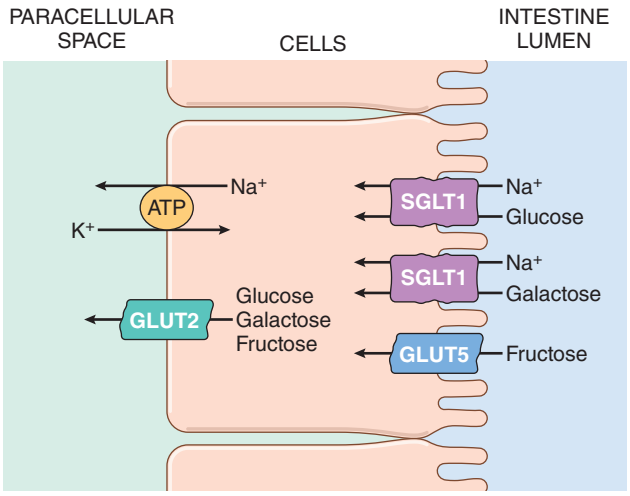

Figure 66.10 Absorption of glucose, galactose, and fructose through the intestinal epithelium. *ATP*, Adenosine triphosphate; *GLUT2*, glucose transporter 2; *GLUT5*, glucose transporter 5; *SGLT1*, sodium-glucose co-transporter 1.

protein, SGLT1, which will not transport Na^+ to the cell interior until SGLT1 also combines with glucose. Intestinal glucose also combines simultaneously with SGLT1, and both the Na^+ and glucose molecule are then transported together to the interior of the cell. Once inside the epithelial cell, another transport protein, glucose transporter 2 (GLUT2) facilitates glucose diffusion through the cell's basolateral membrane into the paracellular space and from there into the blood (see **Fig. 66.10**).

To summarize, it is the initial active transport of Na^+ through the basolateral membranes of the intestinal epithelial cells that provides the eventual force for moving glucose through the membranes as well.

Absorption of Other Monosaccharides—Galactose and Fructose. Galactose is transported by almost exactly the same mechanism as glucose, using the SGLT1 and GLUT2 transporters to cross the luminal and basolateral membranes, respectively (see **Fig. 66.10**). Fructose transport does not occur by the Na^+ co-transport mechanism. Instead, fructose is transported by facilitated diffusion all the way through the intestinal epithelium and is not coupled with Na^+ transport. Transport of fructose from the intestinal lumen to the cell interior is facilitated by GLUT5, and exit of fructose from the cell to the paracellular space is facilitated by GLUT2 (see **Fig. 66.10**).

Some of the fructose, upon entering the cell, becomes phosphorylated. It is then converted to glucose and finally transported in the form of glucose the rest of the way into the blood. Because fructose is not co-transported with Na^+, its overall rate of transport is only about one-half that of glucose or galactose.

Absorption of Proteins as Dipeptides, Tripeptides, or Amino Acids

As explained earlier, most proteins, after digestion, are absorbed through the luminal membranes of the intestinal epithelial cells in the form of dipeptides, tripeptides, and a few free amino acids. The energy for most of this transport is supplied by a Na^+ co-transport mechanism in the same way that Na^+ co-transport of glucose occurs. That is, most peptide or amino acid molecules bind in the cell's microvillus membrane with a specific transport protein that requires Na^+ binding before transport can occur. After binding, the Na^+ then moves down its electrochemical gradient to the interior of the cell and pulls the amino acid or peptide along with it. This process is called *co-transport* (or *secondary active transport*) *of the amino acids and peptides* (see **Fig. 66.9**). A few amino acids do not require this Na^+ co-transport mechanism but instead are transported by special membrane transport proteins in the same way that fructose is transported, by facilitated diffusion.

At least 10 different types of transport proteins for amino acids and peptides have been found in the intestinal epithelial cells. This multiplicity of transport proteins is required because of the diverse binding properties of different amino acids and peptides.

Absorption of Fats

Earlier in this chapter, we pointed out that when fats are digested to form monoglycerides and free fatty acids, both of these digestive end products first become dissolved in the central lipid portions of *bile micelles*. Because the molecular dimensions of these micelles are only 3 to 6 nanometers in diameter, and because of their highly charged exterior, they are soluble in chyme. In this form, the monoglycerides and free fatty acids are carried to the surfaces of the microvilli of the intestinal cell brush border and then penetrate into the recesses among the moving, agitating microvilli. Here, both the monoglycerides and fatty acids diffuse immediately out of the micelles and into the interior of the epithelial cells, which is possible because the lipids are also soluble in the epithelial cell membrane. This process leaves the bile micelles still in the chyme, where they function again and again to help absorb still more monoglycerides and fatty acids.

Thus, the micelles perform a "ferrying" function that is highly important for fat absorption. In the presence of an abundance of bile micelles, about 97% of the fat is absorbed; in the absence of the bile micelles, only 40% to 50% can be absorbed.

After entering the epithelial cell, the fatty acids and monoglycerides are taken up by the cell's smooth endoplasmic reticulum. Here, they are mainly used to form new triglycerides that are subsequently released in the form of *chylomicrons* through the base of the epithelial cell, to flow upward through the thoracic lymph duct and empty into the circulating blood.

Direct Absorption of Fatty Acids Into the Portal Blood. Small quantities of short- and medium-chain fatty acids, such as those from butterfat, are absorbed directly into the portal blood rather than being converted into triglycerides and absorbed by way of the lymphatics.

The cause of this difference between short- and long-chain fatty acid absorption is that the short-chain fatty acids are more water soluble and mostly are not reconverted into triglycerides by the endoplasmic reticulum. This phenomenon allows diffusion of these short-chain fatty acids from the intestinal epithelial cells directly into the capillary blood of the intestinal villi.

ABSORPTION IN THE LARGE INTESTINE AND FORMATION OF FECES

About 1500 mL of chyme normally pass through the ileocecal valve into the large intestine each day. Most of the water and electrolytes in this chyme are absorbed in the colon, usually leaving less than 100 mL of fluid to be excreted in the feces. Also, essentially all the ions are absorbed, leaving only 1 to 5 mEq each of Na^+ and Cl^- to be lost in the feces.

Most of the absorption in the large intestine occurs in the proximal half of the colon, giving this portion the name *absorbing colon*, whereas the distal colon functions principally for feces storage until a propitious time for feces excretion and is therefore called the *storage colon*.

Absorption and Secretion of Electrolytes and Water. The mucosa of the large intestine, like that of the small intestine, has a high capability for active absorption of Na^+, and the electrical potential gradient created by Na^+ absorption causes chloride absorption as well. The junctions between the epithelial cells of the large intestinal epithelium are much tighter than those of the small intestine. These tight junctions prevent significant amounts of back-diffusion of ions into the lumen, thus allowing the large intestinal mucosa to absorb Na^+ far more completely—that is, against a much higher concentration gradient—than can occur in the small intestine. This is especially true when large quantities of aldosterone are available because aldosterone greatly enhances Na^+ transport capability.

In addition, as occurs in the distal portion of the small intestine, the mucosa of *the large intestine secretes HCO_3^-* while it simultaneously absorbs an equal number of Cl^- in the exchange transport process previously described. The HCO_3^- helps neutralize the acidic end products of bacterial action in the large intestine.

Absorption of Na^+ and Cl^- creates an osmotic gradient across the large intestinal mucosa, which in turn causes absorption of water.

Maximum Absorption Capacity of the Large Intestine. The large intestine can absorb a maximum of 5 to 8 liters of fluid and electrolytes each day. When the total quantity entering the large intestine through the ileocecal valve or by way of large intestine secretion exceeds this amount, the excess appears in the feces as diarrhea. As noted earlier, toxins from cholera or certain other bacterial infections often cause the crypts in the terminal ileum and large intestine to secrete 10 or more liters of fluid each day, leading to severe and sometimes lethal diarrhea.

Bacterial Action in the Colon. *Numerous bacteria, especially colon bacilli, are present even normally in the absorbing colon.* They are capable of digesting small amounts of cellulose, in this way providing a few calories of extra nutrition for the body. In herbivorous animals, this source of energy is significant, although it is of negligible importance in human beings.

Other substances formed as a result of bacterial activity are vitamin K, vitamin B_{12}, thiamine, riboflavin, and various gases that contribute to *flatus* in the colon, especially CO_2, hydrogen gas, and methane. The bacteria-formed vitamin K is especially important because the amount of this vitamin in the daily ingested foods is normally insufficient to maintain adequate blood coagulation.

Composition of the Feces. The feces normally are about three-fourths *water* and one-fourth *solid matter* that is composed of about 30% *dead bacteria*, 10% to 20% *fat*, 10% to 20% *inorganic matter*, 2% to 3% *protein*, and 30% *undigested roughage* from the food and dried constituents of digestive juices, such as bile pigment and sloughed epithelial cells. The brown color of feces is caused by *stercobilin* and *urobilin*, derivatives of bilirubin. The odor is caused principally by products of bacterial action; these products vary from one person to another, depending on each person's colonic bacterial flora and on the type of food eaten. The actual odoriferous products include *indole, skatole, mercaptans*, and *hydrogen sulfide*.

Physiology of Gastrointestinal Disorders

Effective therapy for most gastrointestinal disorders depends on a basic knowledge of gastrointestinal physiology. The purpose of this chapter is to discuss a few representative types of gastrointestinal malfunction that have special physiological bases or consequences.

Disorders of Swallowing and the Esophagus

Paralysis of the Swallowing Mechanism. Damage to the fifth, ninth, or tenth cerebral nerve can cause paralysis of significant portions of the swallowing mechanism. In addition, a few diseases, such as *poliomyelitis* or *encephalitis*, can prevent normal swallowing by damaging the swallowing center in the brain stem. Paralysis of the swallowing muscles, as occurs in persons with *muscle dystrophy* or as a result of failure of neuromuscular transmission in persons with *myasthenia gravis* or *botulism*, can also prevent normal swallowing.

When the swallowing mechanism is partially or totally paralyzed, the abnormalities that can occur include the following: (1) complete abrogation of the swallowing act so that swallowing cannot occur, (2) failure of the glottis to close so that food passes into the lungs instead of the esophagus, and (3) failure of the soft palate and uvula to close the posterior nares so that food refluxes into the nose during swallowing.

One of the most serious instances of paralysis of the swallowing mechanism occurs when patients are in a state of *deep anesthesia*. While on the operating table, they sometimes vomit materials from the stomach into the pharynx; then, instead of swallowing the materials again, they may suck them into the trachea because the anesthetic has blocked the reflex mechanism of swallowing. As a result, such patients may choke to death on their own vomitus.

Achalasia and Megaesophagus. *Achalasia* is a condition in which the lower esophageal sphincter fails to relax during swallowing. As a result, food swallowed into the esophagus fails to pass from the esophagus into the stomach. Pathophysiological studies in patients with achalasia have shown damage in the neural network of the myenteric plexus in the lower two-thirds of the esophagus. As a result, the musculature of the lower esophagus remains spastically contracted, and the myenteric plexus has lost its ability to transmit a signal to cause "receptive relaxation" of the gastroesophageal sphincter as food approaches this sphincter during swallowing.

When achalasia becomes severe, the esophagus often cannot empty the swallowed food into the stomach for many hours, instead of the few seconds that is the normal time. Over months and years, the esophagus becomes tremendously enlarged until it often can hold as much as 1 liter of food, which often becomes putridly infected during the long periods of esophageal stasis. The infection may also cause ulceration of the esophageal mucosa, sometimes leading to severe substernal pain or even rupture and death. Considerable benefit can be achieved by stretching the lower end of the esophagus with a balloon inflated on the end of a swallowed esophageal tube. Antispasmodic drugs (i.e., drugs that relax smooth muscle) can also be helpful.

Disorders of the Stomach

Gastritis—Inflammation of the Gastric Mucosa

Mild to moderate chronic gastritis is especially common in the middle to later years of adult life. The inflammation of gastritis may be only superficial and therefore not very harmful, or it can penetrate deeply into the gastric mucosa, causing almost complete atrophy of the gastric mucosa in many long-standing cases. In a few cases, gastritis can be acute and severe, with ulcerative excoriation of the stomach mucosa by the stomach's own peptic secretions.

Gastritis often is caused by chronic bacterial infection of the gastric mucosa. In many cases, this condition can be treated successfully with an intensive regimen of antibacterial therapy.

Certain ingested irritant substances can also be damaging to the protective gastric mucosal barrier—that is, to the mucous glands and to the tight epithelial junctions between the gastric lining cells—often leading to severe acute or chronic gastritis. Two of the most common of these substances are excesses of *alcohol* or *aspirin*.

Increased Permeability of the Gastric Barrier in Gastritis. Absorption of food from the stomach directly into the blood is normally slight. This low level of absorption is mainly due to two specific features of the gastric mucosa: (1) it is lined with highly resistant mucous cells that secrete viscid and adherent mucus, and (2) it has tight junctions between the adjacent epithelial cells. These two features together plus other impediments to gastric absorption are called the "gastric barrier."

The gastric barrier normally is resistant enough to diffusion so that even the highly concentrated hydrogen ions of the gastric juice, averaging about 100,000 times

the concentration of hydrogen ions in plasma, seldom diffuse even to the slightest extent through the lining mucus as far as the epithelial membrane. In gastritis, the permeability of the barrier is greatly increased. The hydrogen ions then diffuse into the stomach epithelium, creating additional havoc and leading to a vicious circle of progressive stomach mucosal damage and atrophy. It also makes the mucosa susceptible to digestion by the peptic digestive enzymes, thus frequently resulting in a *gastric ulcer.*

Chronic Gastritis Can Lead to Gastric Atrophy and Loss of Stomach Secretions

In many people who have chronic gastritis, the mucosa gradually becomes more and more atrophic until little or no gastric gland digestive secretion remains. In some people, autoimmunity develops against the gastric mucosa, which also leads eventually to gastric atrophy. Loss of the stomach secretions in gastric atrophy leads to *achlorhydria* and, occasionally, to *pernicious anemia.*

Achlorhydria and Hypochlorhydria. *Achlorhydria* means that the stomach fails to secrete hydrochloric acid; it is diagnosed when the pH of the gastric secretions fails to decrease below 6.5 after maximal stimulation. *Hypochlorhydria* means diminished acid secretion. When acid is not secreted, pepsin also usually is not secreted. Even when it is secreted, the lack of acid prevents it from functioning because pepsin requires an acid medium for activity.

Gastric Atrophy May Cause Pernicious Anemia. Pernicious anemia commonly accompanies gastric atrophy and achlorhydria. Normal gastric secretions contain a glycoprotein called *intrinsic factor*, secreted by the same parietal cells that secrete hydrochloric acid. Intrinsic factor must be present for adequate absorption of vitamin B_{12} from the ileum. Intrinsic factor combines with vitamin B_{12} in the stomach and protects it from being digested and destroyed as it passes into the small intestine. Then, when the intrinsic factor–vitamin B_{12} complex reaches the terminal ileum, intrinsic factor binds with its receptors on the ileal epithelial surface, which in turn makes it possible for the vitamin B_{12} to be absorbed.

In the absence of intrinsic factor, only about one-fiftieth of the vitamin B_{12} is absorbed. In addition, without intrinsic factor, an adequate amount of vitamin B_{12} is not made available from the foods to cause young, newly forming red blood cells to mature in the bone marrow. The result is *pernicious anemia*. This is discussed in more detail in Chapter 33.

Peptic Ulcer

A peptic ulcer is an excoriated area of stomach or intestinal mucosa caused principally by the digestive action of gastric juice or upper small intestinal secretions. **Fig. 67.1** shows the points in the gastrointestinal tract at which peptic ulcers most frequently occur, demonstrating that the most frequent sites are within a few centimeters of the pylorus. In addition, peptic ulcers frequently occur along the lesser curvature of the antral end of the stomach or, more rarely, in the lower end of the esophagus where stomach juices frequently reflux. A type of peptic ulcer called a *marginal ulcer* also often occurs wherever a surgical opening such as a gastrojejunostomy has been made between the stomach and the jejunum of the small intestine.

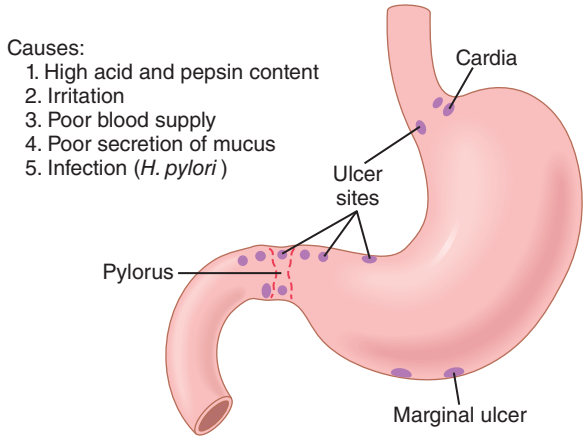

Figure 67.1 Causes and most frequent locations of peptic ulcer. *H. pylori, Helicobacter pylori*.

Basic Cause of Peptic Ulceration. Peptic ulceration is usually associated with an *imbalance* between the rate of gastric juice secretion and the degree of protection afforded by (1) the gastroduodenal mucosal barrier and (2) the neutralization of the gastric acid by duodenal juices. All areas normally exposed to gastric juice are well supplied with mucous glands, beginning with compound mucous glands in the lower esophagus plus the mucous cell coating of the stomach mucosa, the mucous neck cells of the gastric glands, the deep pyloric glands that secrete mainly mucus, and, finally, the glands of Brunner of the upper duodenum, which secrete a highly alkaline mucus.

In addition to the mucus protection of the mucosa, the duodenum is protected by the *alkalinity of the small intestinal secretions*. Especially important is *pancreatic secretion*, which contains large quantities of sodium bicarbonate that neutralize the hydrochloric acid of the gastric juice, thus also inactivating pepsin and preventing digestion of the mucosa. In addition, large amounts of bicarbonate ions are provided in (1) the secretions of the large Brunner glands in the first few centimeters of the duodenal wall and (2) bile coming from the liver.

Finally, two feedback control mechanisms normally ensure that this neutralization of gastric juices is complete, as follows:

1. When excess acid enters the duodenum, it inhibits gastric secretion and peristalsis in the stomach by nervous reflexes and by hormonal feedback from the duodenum, thereby decreasing the rate of gastric emptying.
2. The presence of acid in the small intestine liberates *secretin* from the intestinal mucosa, which then passes by way of the blood to the pancreas to promote rapid secretion of pancreatic juice. This juice also contains a high concentration of sodium bicarbonate, thus making additional sodium bicarbonate available for neutralization of the acid.

Therefore, a peptic ulcer can be caused in either of two ways: (1) excess secretion of acid and pepsin by the gastric mucosa or (2) diminished ability of the gastroduodenal mucosal barrier to protect against the digestive properties of the stomach acid–pepsin secretion.

Specific Causes of Peptic Ulcer

Bacterial Infection By *Helicobacter pylori* Breaks Down the Gastroduodenal Mucosal Barrier and Stimulates Gastric Acid Secretion. At least 75% of persons with peptic ulcers have been found to have chronic infection of the terminal portions of the gastric mucosa and initial portions of the duodenal mucosa, most often caused by the bacterium *Helicobacter pylori*. Once this infection begins, it can last a lifetime unless it is eradicated by antibacterial therapy. Furthermore, the bacterium is capable of penetrating the mucosal barrier by virtue of its physical capability to burrow through the barrier and by releasing ammonium that liquefies the barrier and stimulates secretion of hydrochloric acid. As a result, the strong acidic digestive juices of the stomach secretions can then penetrate into the underlying epithelium and literally digest the gastrointestinal wall, thus leading to peptic ulceration.

Other Causes of Ulceration. In many people who have peptic ulcers in the initial portion of the duodenum, the rate of gastric acid secretion is greater than normal—sometimes as much as twice normal. Although part of this increased secretion may be stimulated by bacterial infection, studies in both animals and human beings have shown that excess secretion of gastric juices for any reason (e.g., even in psychic disturbances) may cause peptic ulceration.

Other factors that predispose to ulcers include the following: (1) *smoking*, presumably because of increased nervous stimulation of the stomach secretory glands; (2) excess consumption of *alcohol*, because it tends to break down the mucosal barrier; and (3) excess consumption of *aspirin* and other nonsteroidal antiinflammatory drugs that also have a strong propensity for breaking down this barrier.

Treatment of Peptic Ulcers. Since the discovery that much peptic ulceration has a bacterial infectious basis, therapy has changed immensely. Almost all patients with peptic ulceration can be treated effectively by two measures: (1) use of *antibiotics* along with other agents to kill infectious bacteria; and (2) administration of drugs that suppress acid secretion. One acid-suppressant drug, *ranitidine*, is an antihistaminic agent that blocks the stimulatory effect of histamine on gastric gland histamine$_2$ receptors, thus reducing gastric acid secretion by 70% to 80%. *Proton pump inhibitors* can also be used to *block hydrogen-potassium ATPase enzymes* and decrease acid secretion by the parietal cells. In recent years, *potassium-competitive acid blockers* (e.g. *vonoprazan*), which bind to the potassium-binding region of the proton pump, have also been used to suppress acid secretion.

These physiological approaches to therapy have proven to be effective in most patients. In a few cases, however, the patient's condition is so severe, including massive bleeding from the ulcer, that heroic operative procedures must be used; these procedures include removal of part of the stomach or cutting the two vagus nerves that supply parasympathetic stimulation to the gastric glands.

Disorders of the Small Intestine

Abnormal Digestion of Food in the Small Intestine—Pancreatic Failure

Failure of the pancreas to secrete pancreatic juice into the small intestine is a serious cause of abnormal digestion. Lack of pancreatic secretion frequently occurs (1) in persons with *pancreatitis* (discussed later), (2) when the *pancreatic duct is blocked* by a gallstone at the papilla of Vater, or (3) after the *head of the pancreas has been removed* because of malignancy.

Loss of pancreatic juice means loss of trypsin, chymotrypsin, carboxypolypeptidase, pancreatic amylase, pancreatic lipase, and a few other digestive enzymes. Without these enzymes, up to 60% of the fat entering the small intestine may not be absorbed, along with one-third to one-half of the proteins and carbohydrates. As a result, large portions of the ingested food cannot be used for nutrition, and copious, fatty feces are excreted.

Pancreatitis—Inflammation of the Pancreas. Pancreatitis can occur in the form of either *acute pancreatitis* or *chronic pancreatitis*.

Gallstones are the most common cause of acute pancreatitis, accounting for 40% to 60% of cases. When a gallstone blocks the papilla of Vater, the main secretory duct from the pancreas and the common bile duct are blocked. The pancreatic enzymes are then dammed up in the ducts and acini of the pancreas. Eventually, so much trypsinogen accumulates that it *overcomes the trypsin inhibitor* in the secretions, and a small quantity of trypsinogen becomes activated to form trypsin. Once this happens, the trypsin activates additional trypsinogen, as well as chymotrypsinogen and carboxypolypeptidase, resulting in a vicious circle until most of the proteolytic enzymes in the pancreatic ducts and acini become activated. These enzymes rapidly digest large portions of the pancreas, sometimes completely and permanently destroying the ability of the pancreas to secrete digestive enzymes.

Excess alcohol consumption is the second most common cause of acute pancreatitis and accounts for approximately 30% of cases. In most of these cases, chronic pancreatitis has already developed and the acute clinical presentation represents a flare-up superimposed on chronic pancreatitis. The mechanisms by which excess alcohol consumption causes acute or chronic pancreatitis are complex and include direct toxic effects on the pancreas, as well as immunologic mechanisms that ultimately lead to inflammation and damage to the pancreas.

Chronic pancreatitis is an ongoing inflammatory and fibrotic condition of the pancreas that may result from relapsing bouts of acute pancreatitis associated with gallstones or excessive alcohol consumption. Other factors than can contribute to chronic pancreatitis include smoking, high levels of triglycerides, or autoimmune-mediated inflammation.

Malabsorption By the Small Intestinal Mucosa—Sprue

Occasionally, nutrients are not adequately absorbed from the small intestine even though the food has been well digested. Several diseases can cause decreased absorption by the mucosa; they are often classified together under the

general term *sprue*. Malabsorption also can occur when large portions of the small intestine have been removed.

Celiac Disease (Nontropical Sprue) Caused By an Autoimmune Response to Gluten. One type of sprue, called variously *celiac disease, nontropical sprue, idiopathic sprue*, or *gluten-sensitive enteropathy*, is an autoimmune-mediated enteropathy triggered by ingestion of *gluten*, a protein present in certain types of grains, especially wheat and rye. Celiac disease is more common in women than in men. In those who are susceptible, gluten elicits an autoimmune reaction (and accompanying inflammation) that has a destructive effect on intestinal enterocytes. In milder forms of the disease, only the microvilli of the absorbing enterocytes on the villi are destroyed, thus decreasing the absorptive surface area as much as 2-fold. In the more severe forms, the villi become blunted or disappear altogether, thus still further reducing the absorptive area of the gut. Removal of wheat and rye flour from the diet frequently results in a cure within weeks, especially in children with this disease.

Tropical Sprue. A different type of sprue called *tropical sprue* frequently occurs in the tropics and can often be treated with antibacterial agents. Although the exact cause of tropical sprue is often unknown, intestinal bacterial infections that cause inflammation of the intestinal mucosa are believed to be the initiating insult in most cases.

Malabsorption in Sprue. In the early stages of sprue, intestinal absorption of fat is more impaired than is absorption of other digestive products. The fat that appears in the stools is almost entirely in the form of salts of fatty acids rather than undigested fat, demonstrating that the problem is one of absorption, not of digestion. In fact, the condition is frequently called *steatorrhea*, which means simply excess fats in the stools.

In severe cases of sprue, impaired absorption of proteins, carbohydrates, calcium, vitamin K, folic acid, and vitamin B_{12} also occurs, in addition to malabsorption of fats. As a result, the person experiences the following: (1) severe nutritional deficiency, which often results in wasting of the body; (2) osteomalacia (i.e., demineralization of the bones because of lack of calcium); (3) inadequate blood coagulation caused by lack of vitamin K; and (4) macrocytic anemia of the pernicious anemia type, resulting from diminished vitamin B_{12} and folic acid absorption.

Disorders of the Large Intestine

Constipation

Constipation means *slow movement of feces through the large intestine*. Constipation is often associated with large quantities of dry, hard feces in the descending colon that accumulate because of excess absorption of fluid or insufficient fluid intake. Any pathology of the intestines that obstructs movement of intestinal contents, such as tumors, adhesions that constrict the intestines, or ulcers, can also cause constipation.

Infants are seldom constipated, but part of their training in the early years of life requires that they learn to control defecation; this control is effected by inhibiting the natural defecation reflexes. Clinical experience shows that if one does not allow defecation to occur when the defecation reflexes are excited or if one overuses laxatives to take the place of natural bowel function, the reflexes become progressively weaker over months or years, and the colon becomes *atonic*.

Constipation can also result from spasm of a small segment of the sigmoid colon. Motility normally is weak in the large intestine, so even a slight degree of spasm may cause serious constipation. After the constipation has continued for several days and excess feces have accumulated above a spastic sigmoid colon, excessive colonic secretions often then lead to a day or so of diarrhea. After this, the cycle begins again, with repeated bouts of alternating constipation and diarrhea.

Megacolon and Hirschsprung Disease. Occasionally, constipation is so severe that bowel movements occur only once every several days or sometimes only once a week. This phenomenon allows tremendous quantities of fecal matter to accumulate in the colon, causing the colon sometimes to distend to a diameter of 3 to 4 inches. The condition is called *megacolon*.

One cause of megacolon is *Hirschsprung disease*, a congenital disorder due to lack of or deficiency of *ganglion cells in the myenteric plexus in a segment of the sigmoid colon*. As a consequence, neither defecation reflexes nor strong peristaltic motility can occur in this area of the large intestine. The sigmoid becomes small and almost spastic while feces accumulate proximal to this area, causing megacolon in the ascending, transverse, and descending colons. About 1 in 5000 newborns has Hirschsprung disease, which is about three to four times more common in boys than in girls.

Diarrhea

Diarrhea results from rapid movement of fecal matter through the large intestine. Several causes of diarrhea with important physiological sequelae are the following.

Enteritis—Inflammation of the Intestinal Tract. Enteritis means inflammation in the intestinal tract, usually caused either by viruses or bacteria. In usual *infectious diarrhea*, the infection is most extensive in the large intestine and the distal end of the ileum. Everywhere the infection is present, the mucosa becomes irritated, and its rate of secretion becomes greatly enhanced. In addition, motility of the intestinal wall usually increases markedly. As a result, large quantities of fluid are made available for washing the infectious agent toward the anus, and at the same time strong propulsive movements propel this fluid forward. This mechanism is important for ridding the intestinal tract of a debilitating infection.

Of special interest is diarrhea caused by *cholera* (and less often by other bacteria, such as some pathogenic colon bacilli). As explained in Chapter 66, cholera toxin directly stimulates excessive secretion of electrolytes and fluid from the crypts of Lieberkühn in the distal ileum and colon. The amount can be 10 to 12 liters per day, although the colon can usually reabsorb a maximum of only 6 to 8 liters per day. Therefore, loss of fluid and electrolytes can be so debilitating within several days that death can ensue.

The most important physiological basis of therapy in cholera is to replace the fluid and electrolytes as rapidly as they are lost, mainly by giving the patient intravenous solutions. With proper therapy, along with the use of antibiotics,

almost no persons with cholera die, but without therapy, up to 50% of patients die. Also, administering antibiotics may reduce the duration and volume of diarrhea.

Psychogenic Diarrhea. Most people are familiar with the diarrhea that accompanies periods of nervous tension, such as during examination time or when a soldier is about to go into battle. This type of diarrhea, called *psychogenic* emotional diarrhea, is caused by excessive stimulation of the parasympathetic nervous system, which greatly excites both (1) motility and (2) excess secretion of mucus in the distal colon. These two effects added together can cause marked diarrhea.

Inflammatory Bowel Disease—Ulcerative Colitis and Crohn Disease. Inflammatory bowel disease (IBD) includes two major disorders of the gastrointestinal tract: *ulcerative colitis* and *Crohn disease*. Ulcerative colitis affects the colon and is characterized by diffuse inflammation and ulcers of the mucosal layer. Crohn disease is characterized by discrete, intermittent areas of inflammation, often including deeper layers, as well as the mucosal layer, and may involve any portion of the gastrointestinal tract.

Although ulcerative colitis and Crohn disease differ in their clinical presentation and disease location (see **Table 67.1**), both forms of IBD are associated with genetic and environmental factors that interact to trigger overactive mucosal immune responses to intestinal microbiota. One potential explanation for IBD is that in susceptible individuals the inability of the innate immune system to effectively clear pathogenic microbial antigens in the gut, when combined with increased intestinal epithelia permeability to antigens, leads to an overactive adaptive immune system, inflammation, and eventually damage to the gut.

Ulcerative colitis is associated with inflammation and ulceration of extensive areas of the walls of the large intestine. The motility of the ulcerated colon is often so great that *mass movements* occur much of the day rather than for the usual 10 to 30 minutes. Also, the colon's secretions are greatly enhanced. As a result, the patient has repeated diarrheal bowel movements that are often bloody. Once the condition has progressed too far, the ulcers seldom heal until an ileostomy is performed to allow the small intestinal contents to drain to the exterior rather than to pass through the colon. Even then the ulcers sometimes fail to heal, and the only solution might be surgical removal of the entire colon.

Table 67.1 Clinical Features of Ulcerative Colitis and Crohn Disease

	Ulcerative Colitis	Crohn Disease
Site of disease	Colon	Any area of gastrointestinal tract, from esophagus to anus
Pattern	Continuous inflammation, ulcers in mucosal layer of colon	Discrete, focal inflammation, ulcers in deeper layers of intestines
Fistula	No	Yes, may occur
Diarrhea	Bloody	Not usually bloody
Severe abdominal pain	Rare	Frequent

Patients with Crohn disease initially develop discrete superficial mucosal ulcers, but as the disease progresses, the ulceration becomes deeper and may occur anywhere in the gut, from the esophagus to the anus, in an intermittent pattern. A major goal of therapy for IBD, including Crohn disease, is to reduce the inflammation. Antiinflammatory medications for IBD may include aminosalicylates, corticosteroids, drugs that modulate the immune system, and monoclonal antibodies that target inflammatory cytokines (e.g., tumor necrosis factor alpha [TNF-α]).

Paralysis of Defecation in Persons With Spinal Cord Injuries

As discussed in Chapter 64, defecation is normally initiated by accumulating feces in the rectum, which causes a spinal cord–mediated *defecation reflex* passing from the rectum to the *conus medullaris* of the spinal cord and then back to the descending colon, sigmoid, rectum, and anus.

When the spinal cord is injured somewhere between the conus medullaris and the brain, the voluntary portion of the defecation act is blocked while the basic cord reflex for defecation is still intact. Nevertheless, loss of the voluntary aid to defecation—that is, loss of the increased abdominal pressure and relaxation of the voluntary anal sphincter—often makes defecation a difficult process in the person with this type of upper cord injury. However, because the cord defecation reflex can still occur, a small enema to excite action of this cord reflex, usually given shortly after a meal, can often cause adequate defecation. In this way, people with spinal cord injuries that do not destroy the conus medullaris of the spinal cord can usually control their bowel movements each day.

General Disorders of the Gastrointestinal Tract

Vomiting

Vomiting is the means by which the upper gastrointestinal tract rids itself of its contents when almost any part of the upper tract becomes excessively irritated, overdistended, or even overexcitable. Excessive distention or irritation of the duodenum provides an especially strong stimulus for vomiting.

The sensory signals that initiate vomiting originate mainly from the pharynx, esophagus, stomach, and upper portions of the small intestines. As shown in **Fig. 67.2**, the nerve impulses are transmitted by vagal and sympathetic afferent nerve fibers to multiple distributed nuclei in the brain stem, especially the *area postrema*, that all together are called the "vomiting center." From here, *motor impulses* that cause the actual vomiting are transmitted from the vomiting center by way of the fifth, seventh, ninth, tenth, and twelfth cranial nerves to the upper gastrointestinal tract, through vagal and sympathetic nerves to the lower tract, and through spinal nerves to the diaphragm and abdominal muscles.

Antiperistalsis, the Prelude to Vomiting. In the early stages of excessive gastrointestinal irritation or overdistention, *antiperistalsis* begins to occur, often many minutes before vomiting appears. Antiperistalsis means peristalsis *up* the digestive tract rather than downward. Antiperistalsis may begin as far down in the intestinal tract as the

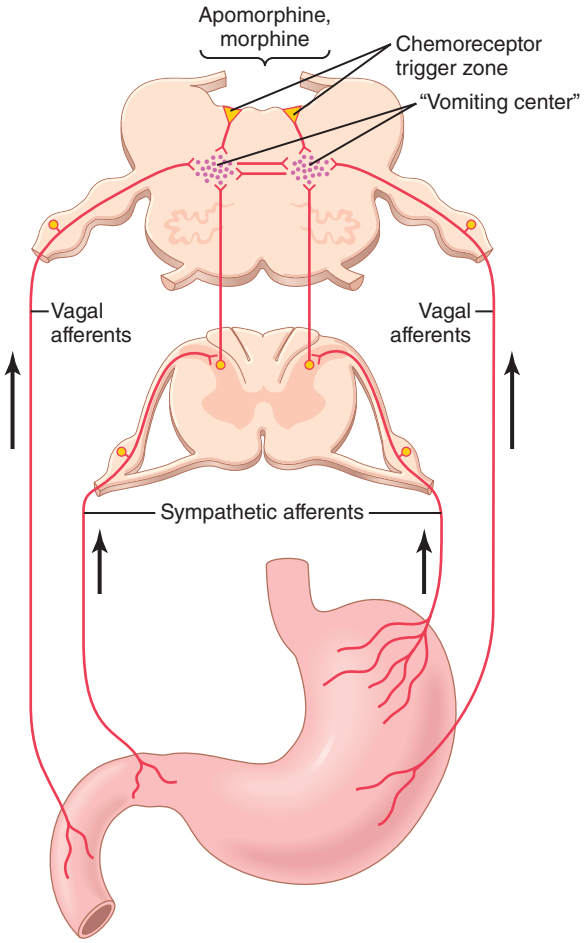

Figure 67.2 Neutral connections of the "vomiting center." This so-called vomiting center includes multiple sensory, motor, and control nuclei mainly in the medullary and pontile reticular formation but also extending into the spinal cord.

ileum, and the antiperistaltic wave travels backward up the intestine at a rate of 2 to 3 cm/sec; this process can actually push a large share of the lower small intestine contents all the way back to the duodenum and stomach within 3 to 5 minutes. Then, as these upper portions of the gastrointestinal tract, especially the duodenum, become overly distended, this distention becomes the exciting factor that initiates the actual vomiting act.

At the onset of vomiting, strong intrinsic contractions occur in both the duodenum and the stomach, along with partial relaxation of the esophageal-stomach sphincter, thus allowing vomitus to begin moving from the stomach into the esophagus. From here, a specific vomiting act involving the abdominal muscles takes over and expels the vomitus to the exterior, as explained below.

Vomiting Act. Once the vomiting center has been sufficiently stimulated and the vomiting act has been initiated, the first effects are the following: (1) a deep breath, (2) raising of the hyoid bone and larynx to pull the upper esophageal sphincter open, (3) closing of the glottis to prevent vomitus flow into the lungs, and (4) lifting of the soft palate to close the posterior nares. Next comes a strong downward contraction of the diaphragm along with simultaneous contraction of all the abdominal wall muscles, which squeezes the stomach between the diaphragm and the abdominal muscles, building the intragastric pressure to a high level. Finally, the lower esophageal sphincter relaxes completely, allowing expulsion of the gastric contents upward through the esophagus.

Thus, the vomiting act results from a squeezing action of the muscles of the abdomen associated with simultaneous contraction of the stomach wall and opening of the esophageal sphincters so that the gastric contents can be expelled.

Chemoreceptor "Trigger Zone" in the Brain Medulla for Initiation of Vomiting By Drugs or By Motion Sickness. Aside from the vomiting initiated by irritative stimuli in the gastrointestinal tract, vomiting can also be caused by nervous signals arising in areas of the brain. This mechanism is particularly true for a small area called the *chemoreceptor trigger zone for vomiting*, located in the *area postrema* on the lateral walls of the fourth ventricle. Electrical stimulation of this area can initiate vomiting, but more importantly, administration of certain drugs, including apomorphine, morphine, and some digitalis derivatives, can directly stimulate this chemoreceptor trigger zone and initiate vomiting. Destruction of this area blocks this type of vomiting but does not block vomiting resulting from irritative stimuli in the gastrointestinal tract.

Furthermore, it is well known that rapidly changing direction or rhythm of motion of the body can cause some people to vomit. The mechanism for this phenomenon is the following: The motion stimulates receptors in the vestibular labyrinth of the inner ear, and from here impulses are transmitted mainly via the brain stem *vestibular nuclei into the cerebellum*, then to the *chemoreceptor trigger zone*, and finally to the *vomiting center* to cause vomiting.

Nausea

The sensation of nausea is often a prodrome of vomiting. Nausea is the conscious recognition of subconscious excitation in an area of the medulla closely associated with or part of the vomiting center. It can be caused by (1) irritative impulses coming from the gastrointestinal tract, (2) impulses that originate in the lower brain associated with motion sickness, or (3) impulses from the cerebral cortex to initiate vomiting. Vomiting occasionally occurs without the prodromal sensation of nausea, which indicates that only certain portions of the vomiting center are associated with the sensation of nausea.

Gastrointestinal Obstruction

The gastrointestinal tract can become obstructed at almost any point along its course, as shown in **Fig. 67.3**. Some common causes of obstruction are the following: (1) *cancer*, (2) *fibrotic constriction resulting from ulceration or from peritoneal adhesions*, (3) *spasm of a gut segment*, and (4) *paralysis of a gut segment*.

The abnormal consequences of obstruction depend on the point in the gastrointestinal tract that becomes obstructed. If the obstruction occurs at the pylorus, which often results from fibrotic constriction after peptic

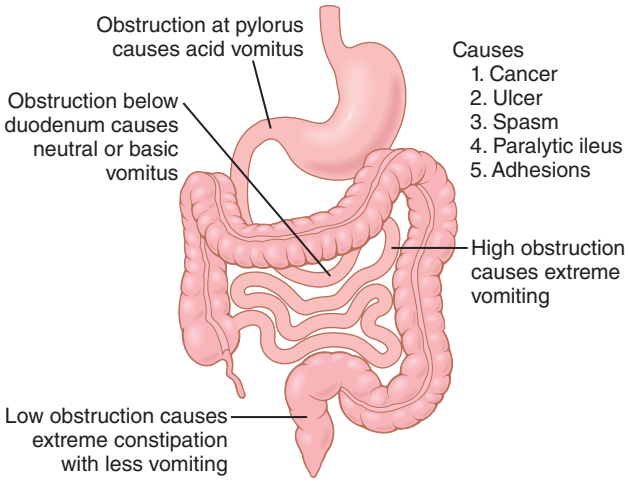

Figure 67.3 Obstruction in different parts of the gastrointestinal tract.

ulceration, persistent vomiting of stomach contents occurs. This vomiting depresses bodily nutrition; it also causes excessive loss of hydrogen ions from the stomach and can result in various degrees of *whole-body metabolic alkalosis*.

If the obstruction is beyond the stomach, antiperistaltic reflux from the small intestine causes intestinal juices to flow backward into the stomach, and these juices are vomited along with the stomach secretions. In this case, the person loses large amounts of water and electrolytes and becomes severely dehydrated, but the loss of acid from the stomach and base from the small intestine may be approximately equal, so little change in acid–base balance occurs.

If the obstruction is near the distal end of the large intestine, feces can accumulate in the colon for a week or more. The patient develops an intense feeling of constipation, but at first vomiting is not severe. After the large intestine has become completely filled and it becomes impossible for additional chyme to move from the small intestine into the large intestine, severe vomiting then occurs. Prolonged obstruction of the large intestine can eventually cause rupture of the intestine or dehydration and circulatory shock resulting from the severe vomiting.

Gases in the Gastrointestinal Tract (Flatus)

Gases, called *flatus*, can enter the gastrointestinal tract from three sources: (1) swallowed air, (2) gases formed in the gut as a result of bacterial action, or (3) gases that diffuse from the blood into the gastrointestinal tract. Most gases in the stomach are mixtures of nitrogen and oxygen derived from swallowed air. These gases are usually expelled by belching. Only small amounts of gas normally occur in the small intestine, and much of this gas is air that passes from the stomach into the intestinal tract.

In the large intestine, bacterial action generates most of the gases, including especially *carbon dioxide, methane*, and *hydrogen*. When methane and hydrogen become suitably mixed with oxygen, an actual explosive mixture is sometimes formed. Use of the electric cautery during sigmoidoscopy has been known to cause a mild explosion.

Certain foods are known to cause greater expulsion of flatus through the anus than others—beans, cabbage, onion, cauliflower, corn, and certain irritant foods such as vinegar. Some of these foods serve as a suitable medium for gas-forming bacteria, especially unabsorbed fermentable types of carbohydrates. For example, beans contain an indigestible carbohydrate that passes into the colon and becomes a superior food for colonic bacteria. But in other cases, excess expulsion of gas results from irritation of the large intestine, which promotes rapid peristaltic expulsion of gases through the anus before they can be absorbed.

The amount of gases entering or forming in the large intestine each day averages 7 to 10 liters, whereas the average amount expelled through the anus is usually only about 0.6 liter. The remainder is normally absorbed into the blood through the intestinal mucosa and expelled through the lungs.

CHAPTER 68

Metabolism of Carbohydrates and Formation of Adenosine Triphosphate

The next few chapters deal with metabolism in the body—the chemical processes that make it possible for the cells to continue living. We do not discuss the chemical details of all the various cellular reactions, which lie in the discipline of biochemistry. Instead, these chapters are devoted to (1) a review of the principal chemical processes of the cell and (2) an analysis of their physiological implications, especially the manner in which they fit into overall body homeostasis.

Release of Energy From Foods and "Free Energy"

Many of the chemical reactions in the cells are aimed at making energy in foods available to the various physiological systems of the cell. For example, energy is required for muscle activity, secretion by the glands, maintenance of membrane potentials by the nerve and muscle fibers, synthesis of substances in the cells, absorption of foods from the gastrointestinal tract, and many other functions.

Coupled Reactions. All the energy foods—carbohydrates, fats, and proteins—can be oxidized in the cells, and during this process, large amounts of energy are released. These same foods can also be burned with pure oxygen outside the body in an actual fire, releasing large amounts of energy, but the energy is released suddenly, all in the form of heat. The energy needed by the physiological processes of the cells is not heat but energy to cause mechanical movement in the case of muscle function, to concentrate solutes in the case of glandular secretion, and to effect many other cell functions. To provide this energy, the chemical reactions must be "coupled" with the systems responsible for these physiological functions. This coupling is accomplished by special cellular enzymes and energy transfer systems, some of which are explained in this and subsequent chapters.

Free Energy. The amount of energy liberated by complete oxidation of a food is called the *free energy of food oxidation* and is generally represented by the symbol ΔG. Free energy is usually expressed in terms of calories per mole of substance. For example, the amount of free energy liberated by complete oxidation of 1 mole (180 grams) of glucose is 686,000 calories.

Adenosine Triphosphate Is the "Energy Currency" of the Body

Adenosine triphosphate (ATP) is an essential link between energy-utilizing and energy-producing functions of the body (**Fig. 68.1**). For this reason, ATP has been called the "energy currency" of the body, and it can be gained and spent repeatedly.

Energy derived from the oxidation of carbohydrates, proteins, and fats is used to convert adenosine diphosphate (ADP) to ATP, which is then consumed by the various reactions of the body that are necessary to maintain and propagate life.

ATP is a labile chemical compound that is present in all cells. ATP is a combination of adenine, ribose, and three phosphate radicals, as shown in **Fig. 68.2**. The last two phosphate radicals are connected with the remainder of the molecule by high-energy bonds, which are indicated by the symbol ~.

The amount of free energy in each of these high-energy bonds per mole of ATP is about 7300 calories under standard conditions and about 12,000 calories under the usual conditions of temperature and concentrations of the reactants in the body. Therefore, in the body, removal of each of the last two phosphate radicals liberates about 12,000 calories of energy. After loss of one phosphate radical from ATP, the compound becomes ADP, and after loss of the second phosphate radical, it becomes *adenosine monophosphate* (AMP). The interconversions among ATP, ADP, and AMP are the following:

$$\text{ATP} \underset{+12{,}000\ \text{cal}}{\overset{-12{,}000\ \text{cal}}{\rightleftharpoons}} \left\{\begin{matrix}\text{ADP}\\+\\\text{PO}_3\end{matrix}\right\} \underset{+12{,}000\ \text{cal}}{\overset{-12{,}000\ \text{cal}}{\rightleftharpoons}} \left\{\begin{matrix}\text{AMP}\\+\\2\text{PO}_3\end{matrix}\right\}$$

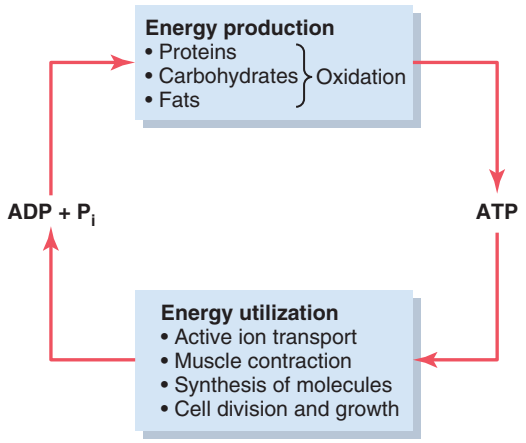

Figure 68.1 Adenosine triphosphate as the central link between energy-producing and energy-utilizing systems of the body. *ADP*, Adenosine diphosphate; P_i, inorganic phosphate.

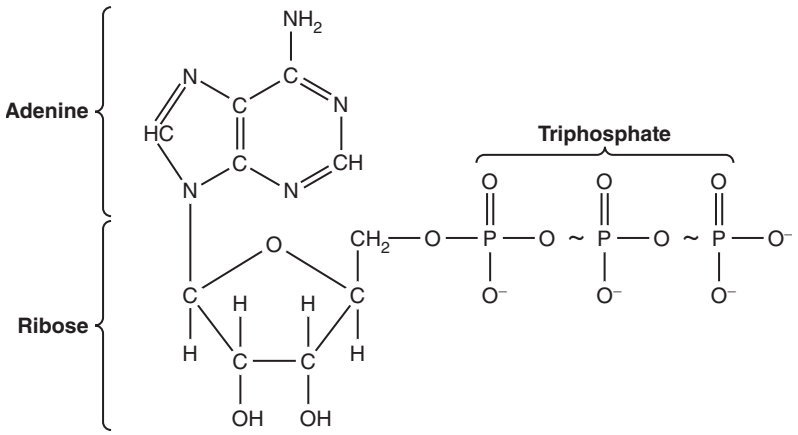

Figure 68.2 Chemical structure of adenosine triphosphate.

ATP is present everywhere in the cytoplasm and nucleoplasm of all cells, and essentially all the physiological mechanisms that require energy for operation obtain it directly from ATP (or another similar high-energy compound, guanosine triphosphate). In turn, the food in the cells is gradually oxidized, and the released energy is used to form new ATP, thus always maintaining a supply of this substance. All these energy transfers take place via coupled reactions.

The principal purpose of this chapter is to explain how the energy from carbohydrates can be used to form ATP in the cells. Normally, 90% or more of all the carbohydrates utilized by the body are for this purpose.

Central Role of Glucose in Carbohydrate Metabolism

As explained in Chapter 66, the final products of carbohydrate digestion in the alimentary tract are almost entirely glucose, fructose, and galactose—with glucose representing, on average, about 80% of these products. After absorption from the intestinal tract, much of the fructose and almost all the galactose are rapidly converted into glucose in the liver. Therefore, little fructose and galactose are present in the circulating blood. *Glucose thus becomes the final common pathway for transport of almost all carbohydrates to the tissue cells.*

In liver cells, appropriate enzymes are available to promote interconversions among the monosaccharides—glucose, fructose, and galactose—as shown in **Fig. 68.3**. Furthermore, the dynamics of the reactions are such that when the liver releases monosaccharides back into the blood, the final product is almost entirely glucose. The reason for this is that liver cells contain large amounts of *glucose phosphatase*. Therefore, glucose-6-phosphate can be degraded to glucose and phosphate, and the glucose can then be transported through the liver cell membrane back into the blood.

Once again, it should be emphasized that more than 95% of all the monosaccharides that circulate in the blood are normally the final conversion product, glucose.

Glucose Transport Through Cell Membranes

Before glucose can be used by the body's tissue cells, it must be transported through the cell membrane into the cellular cytoplasm. However, glucose *cannot easily diffuse through the pores* of the cell membrane because the maximum molecular weight of particles that can diffuse readily is about 100, and glucose has a molecular weight of 180. Yet glucose does pass to the interior of the cells with a reasonable degree of freedom by *facilitated diffusion*. The principles of this type of transport are discussed in Chapter 4.

Penetrating through the lipid matrix of the cell membrane are large numbers of protein *carrier* molecules that can bind with glucose. In this bound form, the glucose can be transported by the carrier from one side of the membrane to the other side and then released. Therefore, if the concentration of glucose is greater on one side of the membrane than on the other side, more glucose will be transported from the high-concentration area to the low-concentration area than in the opposite direction.

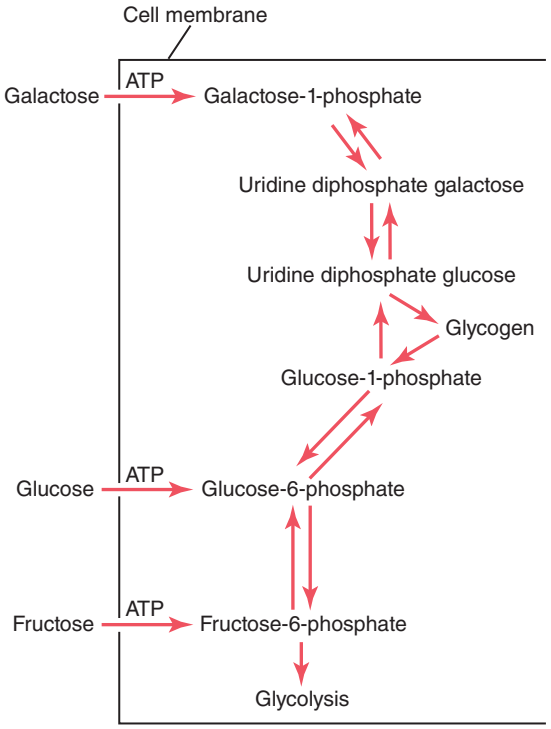

Figure 68.3 Interconversions of the three major monosaccharides—glucose, fructose, and galactose—in liver cells. *ATP*, Adenosine triphosphate.

Transport of glucose through the membranes of most tissue cells is quite different from that which occurs through the gastrointestinal membrane or through the epithelium of the renal tubules. In these cases, the glucose is transported by the mechanism of *active sodium-glucose co-transport*, in which active transport of sodium provides energy for absorbing glucose *against a concentration difference*. This sodium-glucose co-transport mechanism functions only in certain special cells, especially those epithelial cells that are specifically adapted for active absorption of glucose. At other cell membranes, glucose is transported only from higher concentration toward lower concentration by *facilitated diffusion*, made possible by the special binding properties of membrane *glucose carrier protein*. The details of *facilitated diffusion* for cell membrane transport are presented in Chapter 4.

Insulin Increases Facilitated Diffusion of Glucose

The rate of glucose transport, as well as transport of some other monosaccharides, is greatly increased in most cells by insulin. When large amounts of insulin are secreted by the pancreas, the rate of glucose transport into most cells increases to 10 or more times the rate of transport when no insulin is secreted. Conversely, the amounts of glucose that can diffuse to the insides of most cells of the body in the absence of insulin, with the exception of liver and brain cells, are far too little to supply the amount of glucose normally required for energy metabolism.

In effect, the rate of carbohydrate utilization by most cells is controlled by the rate of insulin secretion from the pancreas and the sensitivity of the various tissues to insulin's effects on glucose transport. The functions of insulin and its control of carbohydrate metabolism are discussed in detail in Chapter 79.

Phosphorylation of Glucose

Immediately upon entry into the cells, glucose combines with a phosphate radical in accordance with the following reaction:

$$\text{Glucose} \xrightarrow[+\text{ATP}]{\text{Glucokinase or hexokinase}} \text{Glucose-6-phosphate}$$

This phosphorylation is promoted mainly by the enzyme *glucokinase* in the liver and by *hexokinase* in most other cells. The phosphorylation of glucose is almost completely irreversible except in liver cells, renal tubular epithelial cells, and intestinal epithelial cells; in these cells, another enzyme, *glucose phosphatase*, is also available, and when activated, it can reverse the reaction. In most tissues of the body, phosphorylation serves to *capture* the glucose in the cell. That is, because of its almost instantaneous binding with phosphate, the glucose will not diffuse back out, except from those special cells, especially liver cells, that have phosphatase.

Glycogen Is Stored in the Liver and Muscle

After absorption into a cell, glucose can be used immediately for release of energy to the cell, or it can be stored in the form of *glycogen*, which is a large polymer of glucose.

Almost all cells of the body are capable of storing at least some glycogen, but certain cells can store large amounts. For example, *liver cells* can store up to 5% to 8% of their weight as glycogen, and *muscle cells* can store up to 1% to 3% glycogen. The glycogen molecules can be polymerized to almost any molecular weight, with the average molecular weight being 5 million or greater; most of the glycogen precipitates in the form of solid granules.

This conversion of monosaccharides into a high-molecular-weight precipitated compound (glycogen) makes it possible to store large quantities of carbohydrates without significantly altering the osmotic pressure of the intracellular fluids. High concentrations of low-molecular-weight soluble monosaccharides would play havoc with the osmotic relations between intracellular and extracellular fluids.

Glycogenesis—Formation of Glycogen

The chemical reactions for glycogenesis are illustrated in **Fig. 68.4**, which shows that *glucose-6-phosphate* can become *glucose-1-phosphate*; this substance is converted to *uridine diphosphate glucose*, which is finally converted into glycogen. Several specific enzymes are required to cause these conversions, and any monosaccharide that can be converted into glucose can enter into the reactions. Certain smaller compounds, including *lactic acid, glycerol, pyruvic acid*, and some *deaminated amino acids*, can also be converted into glucose or closely allied compounds and then converted into glycogen.

Glycogenolysis—Breakdown of Stored Glycogen

Glycogenolysis means the breakdown of the cell's stored glycogen to re-form glucose in the cells. The glucose can then be used to provide energy. Glycogenolysis does not occur by reversal of the same chemical reactions that form glycogen; instead, each succeeding glucose molecule on each branch of the glycogen polymer is split away by *phosphorylation*, catalyzed by the enzyme *phosphorylase*.

Under resting conditions, the phosphorylase is in an inactive form, and thus glycogen remains stored. When it is necessary to re-form glucose from glycogen, the phosphorylase must first be activated. This activation can be accomplished in several ways, including activation by epinephrine or by glucagon, as described in the next section.

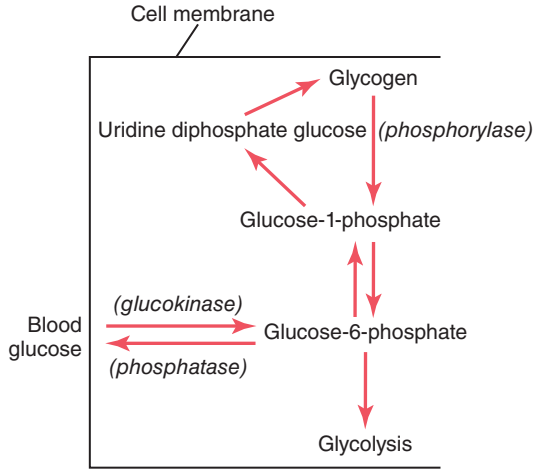

Figure 68.4 Chemical reactions of glycogenesis and glycogenolysis, also showing interconversions between blood glucose and liver glycogen. (The phosphatase required for the release of glucose from the cell is present in liver cells but not in most other cells.)

Activation of Phosphorylase By Epinephrine or By Glucagon. Two hormones, *epinephrine* and *glucagon*, can activate phosphorylase and thereby cause rapid glycogenolysis. The initial effect of each of these hormones, after binding to their cell membrane receptors, is to promote formation of *cyclic AMP* in the cells, which then initiates a cascade of chemical reactions that activates the phosphorylase. This process is discussed in detail in Chapter 79.

Epinephrine is released by the adrenal medullae when the sympathetic nervous system is stimulated. Therefore, one of the functions of the sympathetic nervous system is to increase the availability of glucose for rapid energy metabolism. This function of epinephrine occurs markedly in liver cells and muscle, thereby contributing (along with other effects of sympathetic stimulation) to preparation of the body for action, as discussed in Chapter 61.

Glucagon is a hormone secreted by the *alpha cells* of the pancreas when the blood glucose concentration falls too low. It stimulates formation of cyclic AMP mainly in the liver cells, promoting conversion of liver glycogen into glucose and its release into the blood, thereby elevating the blood glucose concentration. The function of glucagon in blood glucose regulation is discussed in Chapter 79.

Release of Energy From Glucose By the Glycolytic Pathway

Because complete oxidation of 1 gram-mole of glucose releases 686,000 calories of energy and only 12,000 calories of energy are required to form 1 gram-mole of ATP, energy would be wasted if glucose were decomposed all at once into water and carbon dioxide while forming only a single ATP molecule. Fortunately, cells of the body contain special enzymes that cause the glucose molecule to split a little at a time in many successive steps so that its energy is released in small packets to form one molecule of ATP at a time. Theoretically, 38 moles of ATP are formed for each mole of glucose metabolized by the cells, although the net gain of ATP is usually 30 to 32 moles.

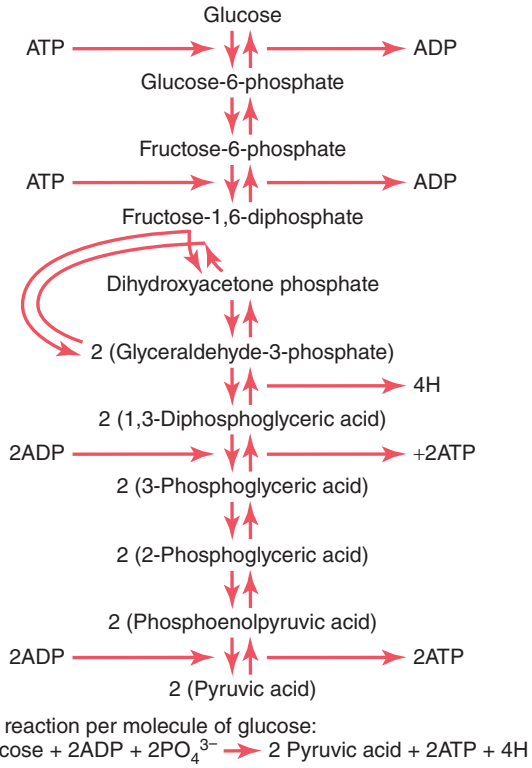
In the next sections we describe the basic principles of the processes by which the glucose molecule is progressively dissected and its energy released to form ATP.

Glycolysis—Splitting Glucose to Form Pyruvic Acid

By far the most important means of releasing energy from glucose is initiated by *glycolysis*. The end products of glycolysis are then oxidized to provide energy. Glycolysis means splitting of the glucose molecule to form *two molecules of pyruvic acid*.

Glycolysis occurs by 10 successive chemical reactions, shown in **Fig. 68.5**. Each step is catalyzed by at least one specific protein enzyme. Note that glucose is first converted into fructose-1,6-diphosphate and then split into two three-carbon-atom molecules, glyceraldehyde-3-phosphate, each of which is then converted through five additional steps into pyruvic acid.

Formation of ATP During Glycolysis. Despite the many chemical reactions in the glycolytic series, only a small portion of the free energy in the glucose molecule is released at most steps. However, between the 1,3-diphosphoglyceric acid and the 3-phosphoglyceric acid stages, and again between the phosphoenolpyruvic acid and the pyruvic acid stages, the packets of energy released are greater than 12,000 calories per mole, the amount required to form ATP, and the reactions are coupled in such a way that ATP is formed. Thus, a total of 4 moles of ATP are formed for each mole of fructose-1,6-diphosphate that is split into pyruvic acid.



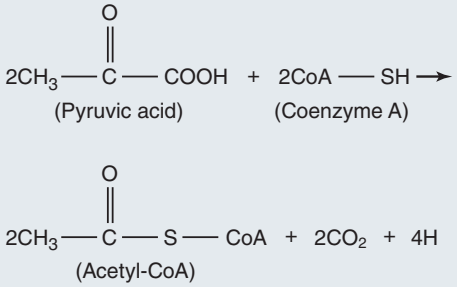


Figure 68.5 Sequence of chemical reactions responsible for glycolysis.

Yet, 2 moles of ATP are required to phosphorylate the original glucose to form fructose-1,6-diphosphate before glycolysis can begin. Therefore, *the net gain in ATP molecules by the entire glycolytic process is only 2 moles for each mole of glucose utilized*. This amounts to 24,000 calories of energy that becomes transferred to ATP, but during glycolysis, a total of 56,000 calories of energy were lost from the original glucose, giving an overall *efficiency* for ATP formation of only 43%. The remaining 57% of the energy is lost in the form of heat.

Conversion of Pyruvic Acid to Acetyl Coenzyme A

The next stage in the degradation of glucose is transport of pyruvic acid/pyruvate into the mitochondria and then a two-step conversion of the two pyruvic acid molecules (shown in **Fig. 68.5**) into two molecules of *acetylcoenzyme A* (acetyl-CoA), in accordance with the following reaction:

Two carbon dioxide molecules and four hydrogen atoms are released from this reaction, while the remaining portions of the two pyruvic acid molecules combine with coenzyme A, a derivative of the vitamin pantothenic acid, to form two molecules of acetyl-CoA. In this conversion, no ATP is formed, but up to six molecules of ATP are formed when the four released hydrogen atoms are later oxidized, as discussed later.

Citric Acid Cycle (Krebs Cycle)

The next stage in the degradation of the glucose molecule is called the *citric acid cycle* (also called the *tricarboxylic acid cycle* or the *Krebs cycle* in honor of Hans Krebs for his discovery of this cycle). The citric acid cycle is a sequence of chemical reactions in which the acetyl portion of acetyl-CoA is degraded to carbon dioxide and hydrogen atoms. These reactions all occur in the *matrix of mitochondria*. The released hydrogen atoms add to the number of these atoms that will subsequently be oxidized (as discussed later), releasing tremendous amounts of energy to form ATP.

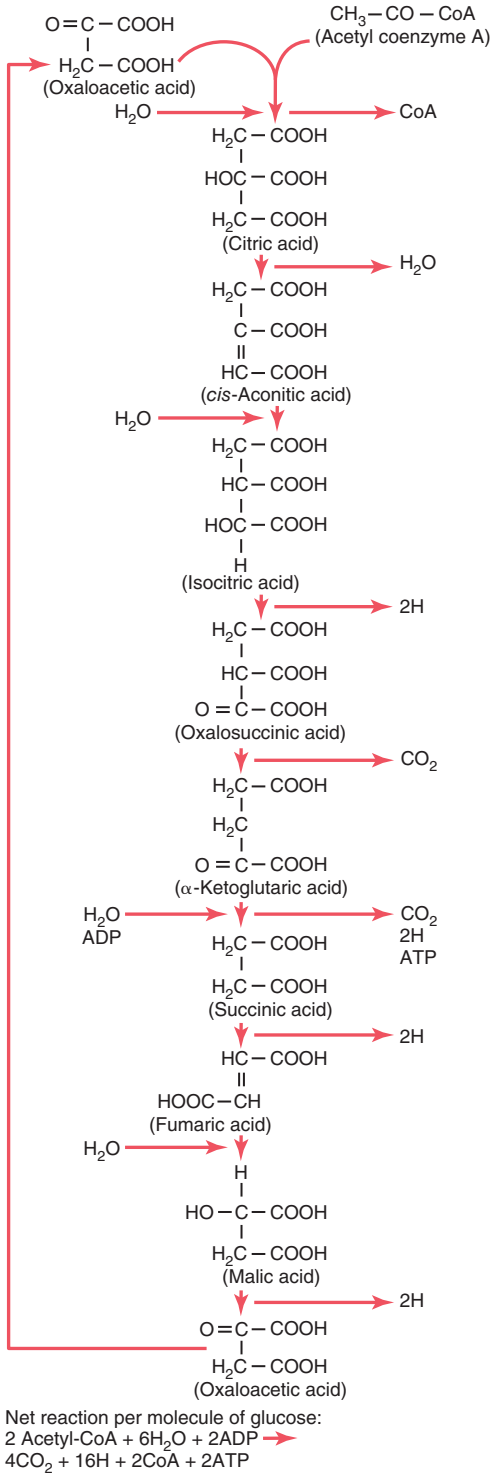
Fig. 68.6 shows the different stages of the chemical reactions in the citric acid cycle. The substances to the left are added during the chemical reactions, and the products of the chemical reactions are shown to the right. Note at the top of the column that the cycle begins with *oxaloacetic acid*, and at the bottom of the chain of reactions, *oxaloacetic acid* is formed again. Thus, the cycle can continue repeatedly.

In the initial stage of the citric acid cycle, *acetyl-CoA* combines with *oxaloacetic acid* to form *citric acid*. The coenzyme A portion of the acetyl-CoA is released and can be used repeatedly to form additional quantities of acetyl-CoA from pyruvic acid. The acetyl portion, however, becomes an integral part of the citric acid molecule. During the successive stages of the citric acid cycle, several molecules of water are added, as shown on the left in **Fig. 68.6**, and *carbon dioxide* and *hydrogen atoms* are released at other stages in the cycle, as shown on the right in the figure.

The net results of the entire citric acid cycle are provided in the explanation at the bottom of **Fig. 68.6**, demonstrating that for each molecule of glucose originally metabolized, 2 acetyl-CoA molecules enter into the citric acid cycle, along with 6 molecules of water. These molecules are then degraded into 4 carbon dioxide molecules, 16 hydrogen atoms, and 2 molecules of coenzyme A. Two molecules of ATP are formed, as follows.

Formation of ATP in the Citric Acid Cycle. The citric acid cycle itself does not cause a great amount of energy to be released; a molecule of ATP is formed in only one of the chemical reactions—during the change from α-ketoglutaric acid to succinic acid. Thus, for each molecule of glucose metabolized, two acetyl-CoA molecules pass through the citric acid cycle, each forming a molecule of ATP, or a total of two molecules of ATP formed.

Function of Dehydrogenases and Nicotinamide Adenine Dinucleotide in Causing Release of Hydrogen Atoms in the Citric Acid Cycle. As noted previously, hydrogen atoms are released during different chemical reactions of the citric acid cycle—4 hydrogen atoms during glycolysis, 4 during formation of acetyl-CoA from pyruvic acid, and 16



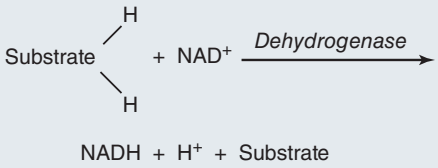


Figure 68.6 Chemical reactions of the citric acid cycle, showing the release of carbon dioxide and a number of hydrogen atoms during the cycle. *ADP*, Adenosine diphosphate; *ATP*, adenosine triphosphate.

in the citric acid cycle; *thus a total of 24 hydrogen atoms are released for each original molecule of glucose.* However, the hydrogen atoms are not simply turned loose in the intracellular fluid. Instead, they are released in packets of two, and in each case, the release is catalyzed by a specific protein enzyme called a *dehydrogenase*. Twenty of the 24 hydrogen

atoms immediately combine with nicotinamide adenine dinucleotide (NAD^+), a derivative of the vitamin niacin, in accordance with the following reaction:

$$NADH + H^+ + Substrate$$

This reaction will not occur without intermediation of the specific dehydrogenase or without the availability of NAD^+ to act as a hydrogen carrier. Both the free hydrogen ion and the hydrogen bound with NAD^+ subsequently enter into multiple oxidative chemical reactions that form large quantities of ATP, as discussed later.

The remaining 4 hydrogen atoms released during the breakdown of glucose—the 4 released during the citric acid cycle between the succinic and fumaric acid stages—combine with a specific dehydrogenase but are not subsequently released to NAD^+. Instead, they pass directly from the dehydrogenase into the oxidative process.

Function of Decarboxylases in Causing Release of Carbon Dioxide. Referring again to the chemical reactions of the citric acid cycle, as well as to those for the formation of acetyl-CoA from pyruvic acid, we find that there are three stages in which carbon dioxide is released. To cause the release of carbon dioxide, other specific protein enzymes, called *decarboxylases*, split the carbon dioxide away from the substrate. The carbon dioxide is then dissolved in the body fluids and transported to the lungs, where it is expired from the body (see Chapter 41).

Formation of Large Quantities of ATP By Oxidation of Hydrogen—The Process of Oxidative Phosphorylation

Despite all the complexities of (1) glycolysis, (2) the citric acid cycle, (3) dehydrogenation, and (4) decarboxylation, pitifully small amounts of ATP are formed during all these processes—only 2 ATP molecules in the glycolysis scheme and another 2 in the citric acid cycle for each molecule of glucose metabolized. Instead, almost 90% of the total ATP created through glucose metabolism is formed during subsequent oxidation of the hydrogen atoms that were released at early stages of glucose degradation. Indeed, the principal function of all these earlier stages is to make the hydrogen of the glucose molecule available in forms that can be oxidized.

Oxidation of hydrogen is accomplished, as illustrated in **Fig. 68.7**, by a series of enzymatically catalyzed reactions *in the mitochondria*. These reactions (1) split each hydrogen atom into a hydrogen ion and an electron and (2) use the electrons eventually to combine dissolved oxygen of the fluids with water molecules to form hydroxyl ions. Then the hydrogen and hydroxyl ions combine with each other to form water. During this sequence of oxidative reactions, tremendous quantities of energy are released to form ATP. Formation of ATP in this manner is called *oxidative phosphorylation*, which occurs entirely in the mitochondria by a highly specialized process called the *chemiosmotic mechanism*.

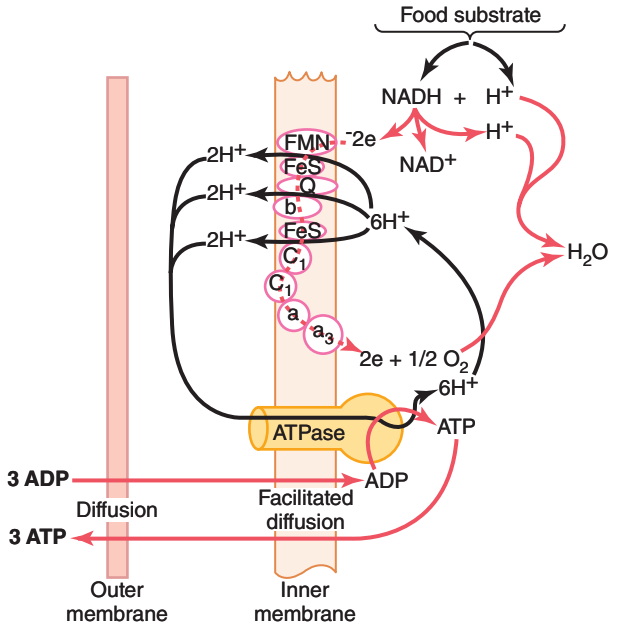

Figure 68.7 Mitochondrial chemiosmotic mechanism of oxidative phosphorylation for forming large quantities of adenosine triphosphate (ATP). This figure shows the relationship of the oxidative and phosphorylation steps at the outer and inner membranes of the mitochondrion. *ADP*, Adenosine diphosphate; *FeS*, iron sulfide protein; *FMN*, flavin mononucleotide; *NAD*$^+$, nicotinamide adenine dinucleotide; *NADH*, reduced nicotinamide adenine dinucleotide; *Q*, ubiquinone.

Chemiosmotic Mechanism of the Mitochondria to Form ATP

Ionization of Hydrogen, the Electron Transport Chain, and Water Formation. The first step in oxidative phosphorylation in the mitochondria is to ionize the hydrogen atoms that have been removed from the food substrates. As described earlier, these hydrogen atoms are removed in pairs: one immediately becomes a hydrogen ion (H^+) and the other combines with NAD^+ to form reduced nicotinamide adenine dinucleotide (NADH). The upper portion of **Fig. 68.7** shows the subsequent fate of the NADH and H^+. The initial effect is to release the other hydrogen atom from the NADH to form another H^+; this process also reconstitutes NAD^+ that will be reused repeatedly.

The electrons that are removed from the hydrogen atoms to cause the hydrogen ionization immediately enter an *electron transport chain of electron acceptors* that are an integral part of the inner membrane (the shelf membrane) of the mitochondrion. The electron acceptors can be reversibly reduced or oxidized by accepting or giving up electrons. The important members of this electron transport chain include *flavoprotein* (flavin mononucleotide), several *iron sulfide proteins, ubiquinone*, and *cytochromes B, C1, C, A*, and *A3*. Each electron is shuttled from one of these acceptors to the next until it finally reaches cytochrome A3, which is called *cytochrome oxidase* because it is capable of giving up 2 electrons and thus reducing elemental oxygen to form ionic oxygen, which then combines with hydrogen ions to form water.

Thus, **Fig. 68.7** shows the transport of electrons through the electron chain and then their ultimate use by cytochrome oxidase to cause the formation of water molecules. During the transport of these electrons through the electron transport chain, energy is released that is used to cause the synthesis of ATP, as follows.

Electron Transport Chain Releases Energy Used to Pump Hydrogen Ions Into the Outer Chamber of the Mitochondrion. As the electrons pass through the electron transport chain, large amounts of energy are released. This energy is used to pump hydrogen ions from the inner matrix of the mitochondrion (to the right in **Fig. 68.7**) into the outer chamber between the inner and outer mitochondrial membranes (to the left). This process creates a high concentration of positively charged hydrogen ions in this chamber; it also creates a strong negative electrical potential in the inner matrix.

Formation of ATP. The next step in oxidative phosphorylation is to convert ADP into ATP. This conversion occurs in conjunction with a large protein molecule that protrudes all the way through the inner mitochondrial membrane and projects with a knoblike head into the inner mitochondrial matrix. This molecule is an ATPase called *ATP synthetase*, the physical nature of which is shown in **Fig. 68.7**.

The high concentration of positively charged hydrogen ions in the outer chamber and the large electrical potential difference across the inner membrane cause the hydrogen ions to flow into the inner mitochondrial matrix *through the substance of the ATPase molecule*. In doing so, energy derived from this hydrogen ion flow is used by ATPase to convert ADP into ATP by combining ADP with a free ionic phosphate radical (P_i), thus adding another high-energy phosphate bond to the molecule.

The final step in the process is transfer of ATP from the inside of the mitochondrion back to the cell cytoplasm. This step occurs by facilitated diffusion outward through the inner membrane and then by simple diffusion through the permeable outer mitochondrial membrane. In turn, ADP is continually transferred in the other direction for continual conversion into ATP. *For each two electrons that pass through the entire electron transport chain (representing the ionization of two hydrogen atoms), up to three ATP molecules are synthesized.*

Summary of ATP Formation During the Breakdown of Glucose

We can now determine the total number of ATP molecules that, under optimal conditions, can be formed by the energy from one molecule of glucose.

1. During glycolysis, 4 molecules of ATP are formed and 2 are expended to cause the initial phosphorylation of glucose to get the process going, giving a net gain of *2 molecules of ATP*.
2. During each revolution of the citric acid cycle, 1 molecule of ATP is formed. However, because each glucose molecule splits into 2 pyruvic acid molecules, there are 2 revolutions of the cycle for each molecule of glucose metabolized, giving a net production of *2 more molecules of ATP*.
3. During the entire schema of glucose breakdown, a total of 24 hydrogen atoms are released during glycolysis and during the citric acid cycle. Twenty of these atoms are oxidized in conjunction with the chemiosmotic mechanism shown in **Fig. 68.7**, with the release of 3 ATP molecules per 2 atoms of hydrogen metabolized. This process gives an additional *30 ATP molecules*.
4. The remaining 4 hydrogen atoms are released by their dehydrogenase into the chemiosmotic oxidative schema in the mitochondrion beyond the first stage of **Fig. 68.7**. Two ATP molecules are usually released for every 2 hydrogen atoms oxidized, thus giving a total of *4 more ATP molecules*.

Now, adding all the ATP molecules formed, we find a maximum of *38 ATP molecules* formed for each molecule of glucose degraded to carbon dioxide and water. However, the net gain of ATP is usually 30 to 32 moles due to energy losses in the overall process. Thus, a maximum of 360,000 to 456,000 calories of energy can be stored in the form of ATP, whereas 686,000 calories are released during the complete oxidation of each gram-molecule of glucose. This outcome represents an overall maximum *efficiency* of energy transfer of 52% to 66%. The remaining energy becomes heat and, therefore, cannot be used by the cells to perform specific functions.

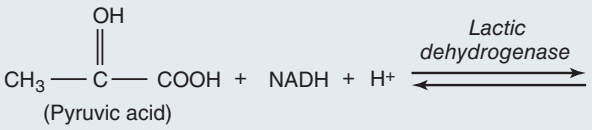
Effect of ATP and ADP Cell Concentrations in Controlling Glycolysis and Glucose Oxidation

Continual release of energy from glucose when the cells do not need energy would be an extremely wasteful process. Instead, glycolysis and the subsequent oxidation of hydrogen atoms are continually controlled in accordance with the need of the cells for ATP. This control is accomplished by multiple feedback control mechanisms within the chemical schemata. Among the more important of these mechanisms are the effects of cell concentrations of both ADP and ATP in controlling the rates of chemical reactions in the energy metabolism sequence.

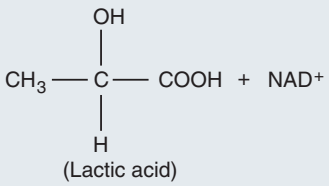
One important way in which ATP helps control energy metabolism is to inhibit the enzyme *phosphofructokinase*. Because this enzyme promotes the formation of fructose-1,6-diphosphate, one of the initial steps in the glycolytic series of reactions, the net effect of excess cellular ATP is to slow or even stop glycolysis, which in turn stops most carbohydrate metabolism. Conversely, ADP (and AMP as well) causes the opposite change in this enzyme, greatly increasing its activity. Whenever ATP is used by the tissues for energizing a major fraction of almost all intracellular chemical reactions, this action reduces the ATP inhibition of the enzyme phosphofructokinase and at the same time increases its activity as a result of the excess ADP formed. Thus, the glycolytic process is set in motion, and the total cellular store of ATP is replenished.

Another control linkage is the *citrate ion* formed in the citric acid cycle. An excess of this ion also *strongly inhibits phosphofructokinase*, thus preventing the glycolytic process from getting ahead of the citric acid cycle's ability to use the pyruvic acid formed during glycolysis.

A third way by which the ATP-ADP-AMP system controls carbohydrate metabolism, as well as controlling energy release from fats and proteins, is the following: Referring to the various chemical reactions for energy release, we see that if all the ADP in the cell has already



been converted into ATP, additional ATP simply cannot be formed. As a result, the entire sequence involved in the use of foodstuffs—glucose, fats, and proteins—to form ATP is stopped. Then, when ATP is used by the cell to energize the different physiological functions in the cell, the newly formed ADP and AMP turn on the energy processes again, and ADP and AMP are almost instantly returned to the ATP state. In this way, essentially a full store of ATP is automatically maintained, except during extreme cellular activity, such as very strenuous exercise, or when the supply of oxygen and nutrients to the tissues is greatly reduced.



Anaerobic Release of Energy—Anaerobic Glycolysis

Occasionally, oxygen becomes either unavailable or insufficient, so oxidative phosphorylation cannot take place. Yet even under these conditions, a small amount of energy can still be released to the cells by the glycolysis stage of carbohydrate degradation, because the chemical reactions for the breakdown of glucose to pyruvic acid do not require oxygen.

This process is extremely wasteful of glucose because only 24,000 calories of energy are used to form ATP for each molecule of glucose metabolized, which represents only a little over 3% of the total energy in the glucose molecule. Nevertheless, this release of glycolytic energy to the cells, which is called *anaerobic energy*, can be a lifesaving measure for up to a few minutes when oxygen becomes unavailable.

Formation of Lactic Acid During Anaerobic Glycolysis Allows Release of Extra Anaerobic Energy. The *law of mass action* states that as the end products of a chemical reaction build up in a reacting medium, the rate of the reaction decreases, approaching zero. The two end products of the glycolytic reactions (see **Fig. 68.5**) are (1) pyruvic acid and (2) hydrogen atoms combined with NAD^+ to form NADH and H^+. The buildup of either or both of these substances would stop the glycolytic process and prevent further formation of ATP. When their quantities begin to be excessive, these two end products react with each other to form lactic acid, in accordance with the following equation:

Thus, under anaerobic conditions, the major portion of the pyruvic acid is converted into lactic acid, which diffuses readily out of the cells into the extracellular fluids and even into the intracellular fluids of other less active cells. Therefore, lactic acid represents a type of "sinkhole" into which the glycolytic end products can disappear, thus allowing glycolysis to proceed far longer than would otherwise be possible. Indeed, glycolysis could proceed for only a few seconds without this conversion. Instead, it can proceed for several minutes, supplying the body with considerable extra quantities of ATP, even in the absence of respiratory oxygen.

Reconversion of Lactic Acid to Pyruvic Acid When Oxygen Becomes Available Again. When adequate oxygen becomes available to the tissues again after a period of anaerobic metabolism, the lactic acid is rapidly reconverted to pyruvic acid and NADH plus H^+. Large portions of these substances are immediately oxidized to form large quantities of ATP. This excess ATP then causes as much as 75% of the remaining excess pyruvic acid to be converted back into glucose.

Thus, the large amount of lactic acid that forms during anaerobic glycolysis is not lost from the body because, when oxygen is available again, the lactic acid can be either reconverted to glucose or used directly for energy. By far the greatest portion of this reconversion occurs in the liver, but a small amount can also occur in other tissues.

Use of Lactic Acid By the Heart for Energy. Heart muscle is especially capable of converting lactic acid to pyruvic acid and then using the pyruvic acid for energy. This process occurs to a great extent during heavy exercise, when large amounts of lactic acid are released into the blood from the skeletal muscles and consumed as an extra energy source by the heart.

Release of Energy From Glucose By the Pentose Phosphate Pathway

In almost all the body's muscles, essentially all the carbohydrates utilized for energy are degraded to pyruvic acid by glycolysis and then oxidized. However, this glycolytic scheme is not the only means by which glucose can be degraded and used to provide energy. A second important mechanism for breakdown and oxidation of glucose is called the *pentose phosphate pathway* (or *phosphogluconate pathway*), which is responsible for *as much as 30% of the glucose breakdown in the liver and even more than this in fat cells.*

This pathway is especially important because it can provide energy independently of all the enzymes of the citric acid cycle and therefore is an alternative pathway for energy metabolism when certain enzymatic abnormalities occur in cells. It has a special capacity for providing energy to multiple cellular synthetic processes.

Release of Carbon Dioxide and Hydrogen By the Pentose Phosphate Pathway. **Fig. 68.8** shows most of the basic chemical reactions in the pentose phosphate pathway. It demonstrates that glucose, during several stages of conversion, can release one molecule of carbon dioxide and four atoms of hydrogen, with the resultant formation of a five-carbon sugar, D-ribulose. This substance can change progressively into several other five-, four-, seven-, and three-carbon sugars. Finally, various combinations of these sugars can resynthesize glucose. However, *only five molecules of glucose are resynthesized for every six molecules of glucose that initially enter into the reactions.* That is, the pentose phosphate pathway is a cyclical process in which one molecule of glucose is metabolized for each revolution

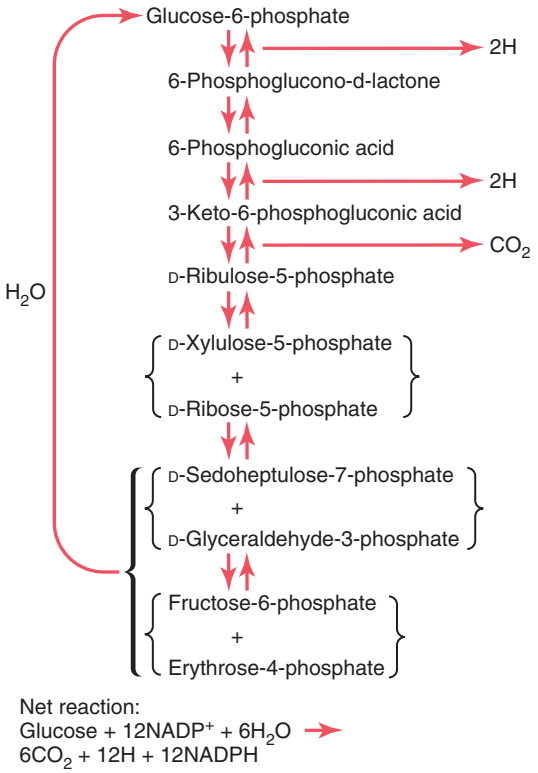


Figure 68.8 Pentose phosphate pathway for glucose metabolism. See text for details.

of the cycle. Thus, by repeating the cycle again and again, all the glucose can eventually be converted into carbon dioxide and hydrogen, and the hydrogen can enter the oxidative phosphorylation pathway to form ATP; more often, however, it is used for the synthesis of fat or other substances, as follows.

Use of Hydrogen to Synthesize Fat; the Function of Nicotinamide Adenine Dinucleotide Phosphate. The hydrogen released during the pentose phosphate cycle does not combine with NAD^+ as in the glycolytic pathway but combines with *nicotinamide adenine dinucleotide phosphate (NADP$^+$),* which is almost identical to NAD^+ except for an extra phosphate radical, P. This difference is extremely significant because only hydrogen bound with $NADP^+$ in the form of NADPH can be used for the synthesis of fats from carbohydrates (as discussed in Chapter 69) and for the synthesis of some other substances.

When the glycolytic pathway for using glucose becomes slowed because of cellular inactivity, the pentose phosphate pathway remains operative (mainly in the liver) to break down any excess glucose that continues to be transported into the cells, and NADPH becomes abundant to help convert acetyl-CoA, also derived from glucose, into long fatty acid chains. This is another way in which energy in the glucose molecule is used other than for the formation of ATP—in this case, *for the formation and storage of fat in the body.*

Glucose Conversion to Glycogen or Fat

When glucose is not immediately required for energy, the extra glucose that continually enters the cells is either stored as glycogen or converted into fat. Glucose is preferentially stored as glycogen until the cells have stored as much glycogen as they can—an amount sufficient to supply the energy needs of the body for only 12 to 24 hours.

When the glycogen-storing cells (primarily liver and muscle cells) approach saturation with glycogen, the additional glucose is converted into fat in liver and fat cells and is stored as fat in the fat cells. Other steps in the chemistry of this conversion are discussed in Chapter 69.

Gluconeogenesis—Formation of Carbohydrates From Proteins and Fats

When the body's stores of carbohydrates decrease below normal, moderate quantities of glucose can be formed from *amino acids* and the *glycerol* portion of fat. This process is called *gluconeogenesis*.

Gluconeogenesis is especially important in preventing excessive reductions in blood glucose concentration during fasting. Glucose is the primary substrate for energy in tissues such as the brain and the red blood cells, and adequate amounts of glucose must be present in the blood for several hours between meals. The liver plays a key role in maintaining blood glucose levels during fasting by converting its stored glycogen to glucose (glycogenolysis) and by synthesizing glucose, mainly from lactate and amino acids (gluconeogenesis). Approximately 25% of the liver's glucose production during fasting is from gluconeogenesis, helping to provide a steady supply of glucose to the brain. During prolonged fasting, the kidneys also synthesize considerable amounts of glucose from amino acids and other precursors.

About 60% of the amino acids in the body proteins can be converted easily into carbohydrates; the remaining 40% have chemical configurations that make this conversion difficult or impossible. Each amino acid is converted into glucose by a slightly different chemical process. For example, alanine can be converted directly into pyruvic acid simply by deamination; the pyruvic acid is then converted into glucose or stored glycogen. Several of the more complicated amino acids can be converted into different sugars that contain three, four, five, or seven carbon atoms. They can then enter the phosphogluconate pathway and eventually form glucose. Thus, by means of deamination plus several simple interconversions, many of the amino acids can become glucose. Similar interconversions can change glycerol into glucose or glycogen.

Regulation of Gluconeogenesis

Diminished carbohydrates in the cells and decreased blood sugar are the basic stimuli that increase the rate of gluconeogenesis. Diminished carbohydrates can directly reverse many of the glycolytic and phosphogluconate reactions, thus allowing conversion of deaminated amino acids and glycerol into carbohydrates. In addition, the hormone *cortisol* is especially important in this regulation, as described in the following section.

Effect of Adrenocorticotropic Hormone and Glucocorticoids on Gluconeogenesis. When normal quantities of carbohydrates are not available to the cells, the adenohypophysis, for reasons not completely understood, secretes increased quantities of the hormone *adrenocorticotropic*

hormone (ACTH), also called *corticotropin* or *adrenocorticotropin*. This secretion stimulates the adrenal cortex to produce large quantities of *glucocorticoid hormones*, especially *cortisol*. In turn, cortisol mobilizes proteins from essentially all cells of the body, making these proteins available in the form of amino acids in the body fluids. A high proportion of these amino acids immediately becomes deaminated in the liver and provides ideal substrates for conversion into glucose. Thus, one of the most important means by which gluconeogenesis is promoted is through the release of glucocorticoids from the adrenal cortex.

Blood Glucose

The normal blood glucose concentration in a person who has not eaten a meal within the past 3 to 4 hours is about 90 mg/dL. After a meal containing large amounts of carbohydrates, this level seldom rises above 140 mg/dL unless the person has diabetes mellitus, which is discussed in Chapter 79.

The regulation of blood glucose concentration is intimately related to the pancreatic hormones insulin and glucagon; this subject is discussed in detail in Chapter 79 in relation to the functions of these hormones.

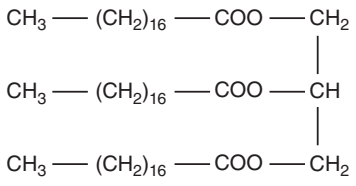
CHAPTER 69

Lipid Metabolism



Several chemical compounds in food and in the body are classified as *lipids*, including the following: (1) *neutral fat*, also known as *triglycerides;* (2) *phospholipids;* (3) *cholesterol;* and (4) a few others of less prominence. Chemically, the basic lipid moiety of triglycerides and phospholipids is *fatty acids*, which are long-chain hydrocarbon organic acids. A typical fatty acid, palmitic acid, is the following: $CH_3(CH_2)_{14}COOH$.

Although cholesterol does not contain fatty acid, its sterol nucleus is synthesized from portions of fatty acid molecules, thus giving it many of the physical and chemical properties of other lipids.

The triglycerides are used in the body mainly to provide energy for the different metabolic processes, a function they share almost equally with carbohydrates. However, some lipids, especially cholesterol, phospholipids, and small amounts of triglycerides, are used to form the membranes of all cells of the body and to perform other essential cellular functions.

BASIC CHEMICAL STRUCTURE OF TRIGLYCERIDES (NEUTRAL FAT)

Because most of this chapter deals with utilization of triglycerides for energy, the following typical structure of the triglyceride molecule should be understood:

Tristearin

Note that three long-chain fatty acid molecules are bound with one molecule of glycerol. The three fatty acids most commonly present in the triglycerides of the human body are as follows: (1) *stearic acid* (shown in the tristearin example), which has an 18-carbon chain and is fully saturated with hydrogen atoms; (2) *oleic acid*, which also has an 18-carbon chain but has one double bond in the middle of the chain; and (3) *palmitic acid*, which has 16 carbon atoms and is fully saturated.

TRANSPORT OF LIPIDS IN THE BODY FLUIDS

Transport of Triglycerides and Other Lipids From the Gastrointestinal Tract By Lymph—the Chylomicrons

As explained in Chapter 66, almost all the fats in the diet, with the principal exception of a few short-chain fatty acids, are absorbed from the intestines into the intestinal lymph. During digestion, most triglycerides are split into monoglycerides and fatty acids. Then, while passing through the intestinal epithelial cells, the monoglycerides and fatty acids are resynthesized into new molecules of triglycerides that enter the lymph as minute, dispersed droplets called *chylomicrons* (**Fig. 69.1**), whose diameters are between 0.08 and 0.6 micron. A small amount of *apolipoprotein*, mainly *apolipoprotein B*, is adsorbed to the outer surfaces of the chylomicrons. The remainder of the protein molecules project into the surrounding water and thereby increase the suspension stability of the chylomicrons in the lymph fluid and prevent their adherence to the lymphatic vessel walls.

Most of the cholesterol and phospholipids absorbed from the gastrointestinal tract enter the chylomicrons. Thus, although the chylomicrons are composed principally of triglycerides, they also contain about 9% phospholipids, 3% cholesterol, and 1% apolipoproteins. The chylomicrons are then transported upward through the thoracic duct and emptied into the circulating venous blood at the juncture of the jugular and subclavian veins.

Removal of the Chylomicrons From the Blood

About 1 hour after a meal containing large quantities of fat, the chylomicron concentration in the plasma may rise to 1% to 2% of the total plasma, and because of the large size of the chylomicrons, the plasma appears turbid and sometimes yellow. However, the chylomicrons have a half-life of less than 1 hour, so the plasma becomes clear again within a few hours. The fat of the chylomicrons is removed mainly in the following way.

Chylomicron Triglycerides Are Hydrolyzed By Lipoprotein Lipase, and Fat Is Stored in Adipose Tissue. Most of the chylomicrons are removed from the circulating blood

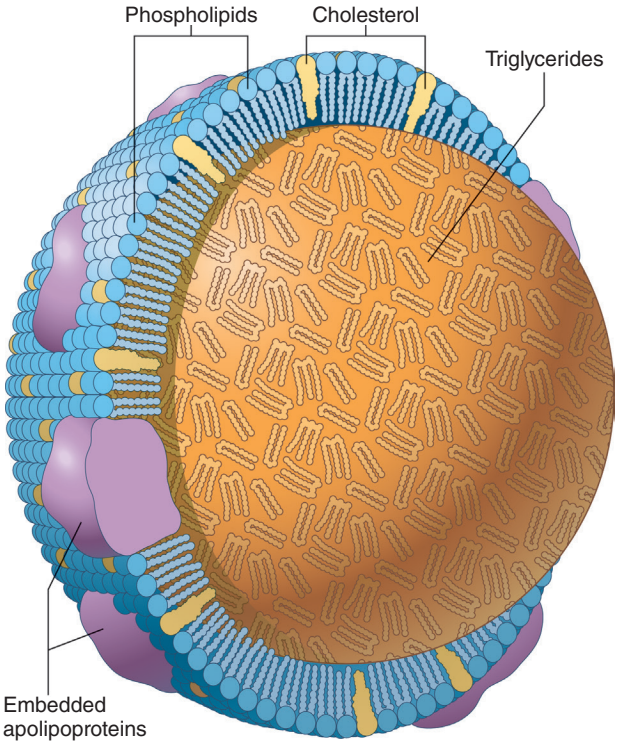


Figure 69.1 Chylomicrons are lipoprotein particles that consist of phospholipids and apolipoproteins on the outer surface and triglycerides and cholesterol inside.

as they pass through the capillaries of various tissues, especially adipose tissue, skeletal muscle, and heart. These tissues synthesize the enzyme *lipoprotein lipase*, which is transported to the surface of capillary endothelial cells, where it hydrolyzes the triglycerides of chylomicrons as they come in contact with the endothelial wall, thus releasing fatty acids and glycerol (**Fig. 69.2**).

The fatty acids released from the chylomicrons, being highly miscible with the membranes of the cells, diffuse into the fat cells of the adipose tissue and muscle cells. Once inside these cells, the fatty acids can be used for fuel or again synthesized into triglycerides, with new glycerol being supplied by the metabolic processes of the storage cells, as discussed later in the chapter. The lipase also causes hydrolysis of phospholipids, which also releases fatty acids to be stored in the cells in the same way.

After the triglycerides are removed from the chylomicrons, the cholesterol-enriched *chylomicron remnants* are rapidly cleared from the plasma. The chylomicron remnants bind to receptors on endothelial cells in the liver sinusoids. *Apolipoprotein-E* on the surface of the chylomicron remnants and secreted by liver cells also plays an important role in initiating clearance of these plasma lipoproteins.

"Free Fatty Acids" Are Transported in the Blood in Combination With Albumin

When fat that has been stored in the adipose tissue is to be used elsewhere in the body to provide energy, it must first be transported from the adipose tissue to the other tissue. It is transported mainly in the form of free fatty acids. This transport is achieved by hydrolysis of the triglycerides back into fatty acids and glycerol.

At least two classes of stimuli play important roles in promoting this hydrolysis. First, when the amount of glucose available to the fat cell is inadequate, one of the glucose breakdown products, α-glycerophosphate, is also available in insufficient quantities. Because this substance is required to maintain the glycerol portion of triglycerides, the result is hydrolysis of triglycerides. Second, a hormone-sensitive cellular lipase can be activated by several hormones from the endocrine glands, and this also promotes rapid hydrolysis of triglycerides. This topic is discussed later in the chapter.

Upon leaving fat cells, fatty acids ionize strongly in the plasma, and the ionic portion combines immediately with albumin molecules of the plasma proteins. Fatty acids bound in this manner are called *free fatty acids* or *nonesterified fatty acids*, to distinguish them from other fatty acids in the plasma that exist in the form of (1) esters of glycerol, (2) cholesterol, or (3) other substances.

The concentration of free fatty acids in the plasma under resting conditions is about 15 mg/dL, which is a total of only 0.45 gram of fatty acids in the entire circulatory system. Even this small amount accounts for almost all the transport of fatty acids from one part of the body to another for the following reasons:

1. Despite the minute amount of free fatty acids in the blood, their "turnover" rate is extremely rapid: *half the plasma fatty acids are replaced by new fatty acids every 2 to 3 minutes*. One can calculate that at this rate, almost all the normal energy requirements of the body can be provided by the oxidation of transported free fatty acids, without using any carbohydrates or proteins for energy.
2. Conditions that increase the rate of utilization of fat for cellular energy also increase the free fatty acid concentration in the blood. In fact, the concentration sometimes increases 5-fold to 8-fold. Such a large increase occurs especially in cases of *starvation* and in *diabetes mellitus;* in both these conditions, the person derives little or no metabolic energy from carbohydrates.

Under normal conditions, only about 3 molecules of fatty acid combine with each molecule of albumin, but as many as 30 fatty acid molecules can combine with a single albumin molecule when the need for fatty acid transport is extreme. This shows how variable the rate of lipid transport can be under different physiological conditions.

Lipoproteins—Their Special Function in Transporting Cholesterol and Phospholipids

In the postabsorptive state, after all the chylomicrons have been removed from the blood, more than 95% of all the lipids in the plasma are in the form of *lipoprotein*. These lipids are small particles—much smaller than chylomicrons, but qualitatively similar in composition—containing *triglycerides, cholesterol, phospholipids*, and *protein*. The total concentration of lipoproteins in the plasma averages about 700 mg per 100 mL of plasma—that is, 700 mg/dL—and can be broken down into the following individual lipoprotein constituents:

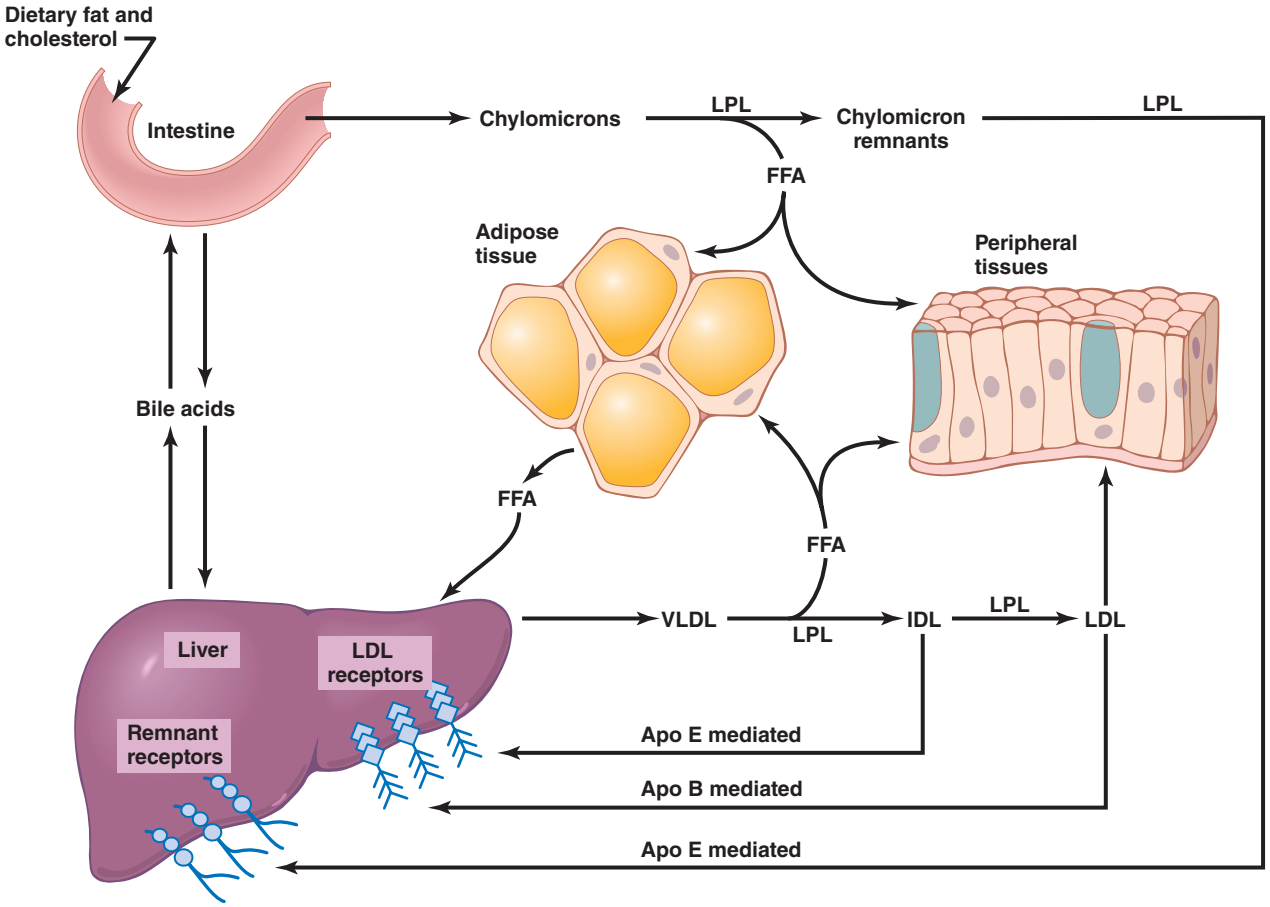

Figure 69.2 Summary of major pathways for metabolism of chylomicrons synthesized in the intestine and very low density lipoprotein (VLDL) synthesized in the liver. *Apo B*, Apolipoprotein B; *Apo E*, apolipoprotein E; *FFA*, free fatty acids; *IDL*, intermediate-density lipoprotein; *LDL*, low-density lipoprotein; *LPL*, lipoprotein lipase.

	mg/dL of Plasma
Cholesterol	180
Phospholipids	160
Triglycerides	160
Protein	200

Types of Lipoproteins. Aside from the chylomicrons, which are very large lipoproteins, there are four major types of lipoproteins, classified by their densities as measured in the ultracentrifuge: (1) *very low density lipoproteins* (VLDLs), which contain high concentrations of triglycerides and moderate concentrations of both cholesterol and phospholipids; (2) *intermediate-density lipoproteins* (IDLs), which are VLDLs from which a share of the triglycerides has been removed, so the concentrations of cholesterol and phospholipids are increased; (3) *low-density lipoproteins* (LDLs), which are derived from IDLs by removal of almost all the triglycerides, leaving an especially high concentration of cholesterol and a moderately high concentration of phospholipids; and (4) *high-density lipoproteins* (HDLs), which contain a high concentration of protein (~50%) but much smaller concentrations of cholesterol and phospholipids.

Formation and Function of Lipoproteins. Almost all the lipoproteins are formed in the liver, which is also where most of the plasma cholesterol, phospholipids, and triglycerides are synthesized. In addition, small quantities of HDLs are synthesized in the intestinal epithelium during absorption of fatty acids from the intestines.

The primary function of the lipoproteins is to transport their lipid components in the blood. The VLDLs transport triglycerides synthesized in the liver mainly to the adipose tissue. The other lipoproteins are especially important in different stages of phospholipid and cholesterol transport from the liver to the peripheral tissues or from the tissues back to the liver. Later in the chapter, we discuss in more detail special problems of cholesterol transport in relation to the disease *atherosclerosis*, which is associated with the development of fatty lesions on the insides of arterial walls.

Fat Deposits

Large quantities of fat are stored in two major tissues of the body, the *adipose tissue* and the *liver*. The adipose tissue is usually called *fat deposits*, or simply tissue fat.

Adipose Tissue

A major function of adipose tissue is storage of triglycerides until they are needed to provide energy elsewhere in the body. Additional functions are to provide *heat insulation* for the body, as discussed in Chapter 74, and *secretion*

of hormones such as *leptin* and *adiponectin*, which affect multiple body functions, including appetite and energy expenditure, as discussed in Chapter 72.

Fat Cells (Adipocytes) Store Triglycerides. The fat cells (adipocytes) of adipose tissue are modified fibroblasts that store almost pure triglycerides in quantities as great as 80% to 95% of the entire cell volume. Triglycerides inside the fat cells are generally in a liquid form. When the tissues are exposed to prolonged cold, the fatty acid chains of the cell triglycerides, over a period of weeks, become either shorter or more unsaturated to decrease their melting point, thereby always allowing the fat to remain in a liquid state. This characteristic is particularly important because only liquid fat can be hydrolyzed and transported from the cells.

Fat cells can synthesize very small amounts of fatty acids and triglycerides from carbohydrates; this function supplements the synthesis of fat in the liver, as discussed later in the chapter.

Tissue Lipases Permit Exchange of Fat Between Adipose Tissue and the Blood. As discussed earlier, large quantities of lipases are present in adipose tissue. Some of these enzymes catalyze the deposition of cell triglycerides from the chylomicrons and lipoproteins. Others, when activated by hormones, split the triglycerides of fat cells to release free fatty acids. Because of the rapid exchange of fatty acids, the triglycerides in fat cells are renewed about once every 2 to 3 weeks, which means that the fat stored in the tissues today is not the same fat that was stored last month, thus emphasizing the dynamic state of storage fat.

Liver Lipids

The principal functions of the liver in lipid metabolism are to (1) degrade fatty acids into small compounds that can be used for energy; (2) synthesize triglycerides, mainly from carbohydrates, but to a lesser extent from proteins as well; and (3) synthesize other lipids from fatty acids, especially cholesterol and phospholipids.

Large quantities of triglycerides appear in the liver during (1) the early stages of starvation, (2) in diabetes mellitus, and (3) in any other condition in which fat instead of carbohydrates is being used for energy. In these conditions, large quantities of triglycerides are mobilized from the adipose tissue, transported as free fatty acids in the blood, and redeposited as triglycerides in the liver, where the initial stages of much of fat degradation begin. Thus, under normal physiological conditions, the total amount of triglycerides in the liver is determined to a great extent by the overall rate at which lipids are being used for energy.

The liver may also store large amounts of lipids in people who are obese or have *lipodystrophy*, a condition characterized by genetic deficiency of adipocytes or acquired atrophy of adipocytes due to medications (e.g., antiretroviral therapy for human immunodeficiency virus infection), autoimmune disorders, or other causes. In genetic or acquired lipodystrophy, excess fat that cannot be stored in adipose tissue accumulates in the liver and, to a lesser extent, in other tissues that normally store minimal amounts of lipids.

The liver cells, in addition to containing triglycerides, contain large quantities of phospholipids and cholesterol, which are continually synthesized by the liver. Also, the liver cells are much more capable of desaturating fatty acids than are other tissues, and thus liver triglycerides normally are much more unsaturated than the triglycerides of adipose tissue. This capability of the liver to desaturate fatty acids is functionally important to all tissues of the body because many structural elements of cells contain reasonable quantities of unsaturated fats, and their principal source is the liver. This desaturation is accomplished by a dehydrogenase in the liver cells.

Use of Triglycerides for Energy: Formation of Adenosine Triphosphate

The dietary intake of fat varies considerably in persons of different cultures, averaging as little as 10% to 15% of caloric intake in some Asian populations to as much as 35% to 50% of the calories in many Western populations. For many persons the use of fats for energy is therefore as important as the use of carbohydrates. In addition, many of the carbohydrates ingested with each meal are converted into triglycerides, stored, and used later in the form of fatty acids released from the triglycerides for energy.

Hydrolysis of Triglycerides Into Fatty Acids and Glycerol. The first stage in using triglycerides for energy is their hydrolysis into fatty acids and glycerol. Then, both the fatty acids and the glycerol are transported in the blood to the active tissues, where they will be oxidized to give energy. Almost all cells—with some exceptions, such as brain tissue and red blood cells—use fatty acids for energy.

Glycerol, upon entering the active tissue, is immediately changed by intracellular enzymes into *glycerol-3-phosphate*, which enters the glycolytic pathway for glucose breakdown and is thus used for energy. Before the fatty acids can be used for energy, they must be processed further in the mitochondria.

Entry of Fatty Acids Into Mitochondria. Degradation and oxidation of fatty acids occur only in mitochondria. Therefore, the first step for the use of fatty acids is their transport into the mitochondria using *carnitine* as a carrier. Once inside the mitochondria, fatty acids split away from carnitine and are degraded and oxidized.

Degradation of Fatty Acids to Acetyl Coenzyme A By Beta-Oxidation. Fatty acids are degraded in the mitochondria by progressive release of two-carbon segments in the form of *acetyl coenzyme A* (acetyl-CoA). This degradation process, which is shown in **Fig. 69.3**, is called *beta-oxidation* of fatty acids.

To understand the essential steps in the beta-oxidation process, note that in Equation 1 in **Fig. 69.3**, the first step is combination of the fatty acid molecule with coenzyme A (CoA) to form fatty acyl-CoA. In Equations 2, 3, and 4, the *beta carbon* (the second carbon from the right) of the fatty acyl-CoA binds with an oxygen molecule—that is, the beta carbon becomes oxidized.

Then, in Equation 5, the right-hand two-carbon portion of the molecule is split off to release acetyl-CoA into the cell fluid. At the same time, another CoA molecule binds at the end of the remaining portion of the fatty acid molecule, and thus a new fatty acyl-CoA molecule is formed; this time, however, the molecule is two carbon atoms shorter because of the loss of the first acetyl-CoA from its terminal end.

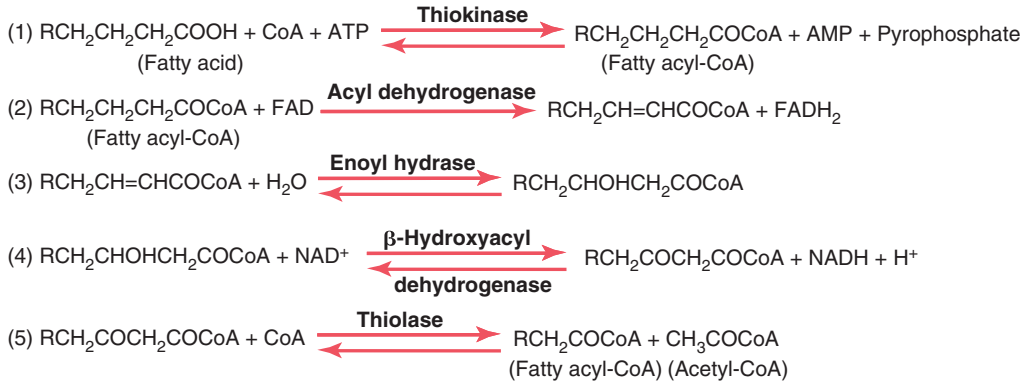

Figure 69.3 Beta oxidation of fatty acids to yield acetyl coenzyme A.

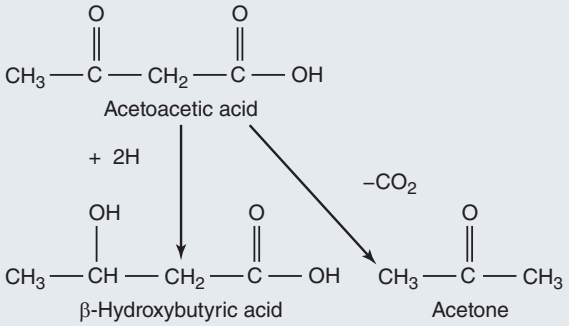
Next, this shorter fatty acyl-CoA enters into Equation 2 and progresses through Equations 3, 4, and 5 to release another acetyl-CoA molecule, thus shortening the original fatty acid molecule by another two carbons. In addition to the released acetyl-CoA molecules, four atoms of hydrogen are released from the fatty acid molecule at the same time, entirely separate from the acetyl-CoA.

Oxidation of Acetyl-CoA. The acetyl-CoA molecules formed by beta-oxidation of fatty acids in the mitochondria enter immediately into the *citric acid cycle* (see Chapter 68), combining first with oxaloacetic acid to form citric acid, which then is degraded into carbon dioxide and hydrogen atoms. The hydrogen is subsequently oxidized by the *chemiosmotic oxidative system of the mitochondria*, which was also explained in Chapter 68. The net reaction in the citric acid cycle for each molecule of acetyl-CoA is the following:

$$CH_3COCoA + \text{Oxaloacetic acid} + 3H_2O + ADP \xrightarrow{\text{Citric acid cycle}} 2CO_2 + 8H + HCoA + ATP + \text{Oxaloacetic acid}$$

Thus, after initial degradation of fatty acids to acetyl-CoA, their final breakdown is precisely the same as that of the acetyl-CoA formed from pyruvic acid during the metabolism of glucose. The extra hydrogen atoms are also oxidized by the same *chemiosmotic oxidative system of the mitochondria* that is used in carbohydrate oxidation, liberating large amounts of adenosine triphosphate (ATP).

Large Amounts of ATP Are Formed By Oxidation of Fatty Acids. Note in **Fig. 69.3** that the four separate hydrogen atoms released each time a molecule of acetyl-CoA is split from the fatty acid chain are released in the forms of reduced flavin adenine dinucleotide ($FADH_2$), reduced nicotinamide adenine dinucleotide (NADH), and H^+. Therefore, for every stearic fatty acid molecule that is split to form 9 acetyl-CoA molecules, 32 extra hydrogen atoms are removed. In addition, for each of the 9 molecules of acetyl-CoA that are subsequently degraded by the citric acid cycle, 8 more hydrogen atoms are removed, making another 72 hydrogen atoms. Thus, a total of 104 hydrogen atoms are eventually released by the degradation of each stearic acid molecule. Of this group, 34 are removed from the degrading fatty acids by flavoproteins and 70 are removed by nicotinamide adenine dinucleotide (NAD^+) as NADH and H^+.



These two groups of hydrogen atoms are oxidized in the mitochondria, as discussed in Chapter 68, but they enter the oxidative system at different points. Therefore, 1 molecule of ATP is synthesized for each of the 34 flavoprotein hydrogens, and 1.5 molecules of ATP are synthesized for each of the 70 NADH and H^+ hydrogens. This makes 34 plus 105, or a total of 139 molecules of ATP formed by the oxidation of hydrogen derived from each molecule of stearic acid. Another 9 molecules of ATP are formed in the citric acid cycle (separate from the ATP released by the oxidation of hydrogen), 1 for each of the nine acetyl-CoA molecules metabolized. Thus, a total of 148 molecules of ATP are formed during the complete oxidation of 1 molecule of stearic acid. However, 2 high-energy bonds are consumed in the initial combination of CoA with the stearic acid molecule, making a *net gain* of 146 molecules of ATP.

Formation of Acetoacetic Acid in the Liver and Its Transport in the Blood

A large share of the initial degradation of fatty acids occurs in the liver, especially when large amounts of lipids are being used for energy. However, the liver uses only a small proportion of the fatty acids for its own intrinsic metabolic processes. Instead, when the fatty acid chains have been split into acetyl-CoA, two molecules of acetyl-CoA condense to form one molecule of acetoacetic acid, which is then transported in the blood to the other cells throughout the body, where it is used for energy. The following chemical processes occur:

$$\underset{\text{Acetyl-CoA}}{2CH_3COCoA} + H_2O \underset{\text{Other cells}}{\overset{\text{Liver cells}}{\rightleftharpoons}} \underset{\text{Acetoacetic acid}}{CH_3COCH_2COOH} + 2HCoA$$

Part of the acetoacetic acid is also converted into *β-hydroxybutyric acid*, and minute quantities are converted into *acetone* in accord with the following reactions:

The acetoacetic acid, β-hydroxybutyric acid, and acetone diffuse freely through the liver cell membranes and are transported by the blood to the peripheral tissues. Here they again diffuse into the cells, where reverse reactions occur, and acetyl-CoA molecules are formed. These molecules, in turn, enter the citric acid cycle and are oxidized for energy, as already explained.

Normally, the acetoacetic acid and β-hydroxybutyric acid that enter the blood are transported so rapidly to the tissues that their combined concentration in the plasma seldom rises above 3 mg/dL. Yet, despite this small *concentration* in the blood, large *quantities* are actually transported, as is also true for free fatty acid transport. The rapid transport of both these substances results from their high solubility in the membranes of the target cells, which allows almost instantaneous diffusion into the cells.

Ketosis in Starvation, Diabetes, and Other Diseases. The concentrations of acetoacetic acid, β-hydroxybutyric acid, and acetone occasionally rise to levels many times normal in the blood and interstitial fluids; this condition is called *ketosis* because acetoacetic acid is a keto acid. The three compounds are called *ketone bodies*. Ketosis occurs especially as a consequence of starvation, in persons with diabetes mellitus, and sometimes even when a person's diet is composed almost entirely of fat. In all these states, essentially no carbohydrates are metabolized—in starvation and with a high-fat diet because carbohydrates are not available, and in diabetes because insulin is not available to cause glucose transport into the cells.

When carbohydrates are not used for energy, almost all the energy of the body must come from fat metabolism. We shall see later in the chapter that the unavailability of carbohydrates automatically increases the rate of removal of fatty acids from adipose tissues. In addition, several hormonal factors—such as increased secretion of glucocorticoids by the adrenal cortex, increased secretion of glucagon by the pancreas, and decreased secretion of insulin by the pancreas—further enhance removal of fatty acids from the fat tissues. As a result, large quantities of fatty acids become available (1) to the peripheral tissue cells to be used for energy and (2) to the liver cells, where much of the fatty acid is converted to ketone bodies.

The ketone bodies pour out of the liver to be carried to the cells. For several reasons, the cells are limited in the amount of ketone bodies that can be oxidized. The most important reason for this limitation is that one of the products of carbohydrate metabolism is *oxaloacetate*, which is required to bind with acetyl-CoA before it can be processed in the citric acid cycle. Therefore, deficiency of oxaloacetate derived from carbohydrates limits the entry of acetyl-CoA into the citric acid cycle, and when a simultaneous outpouring of large quantities of acetoacetic acid and other ketone bodies from the liver occurs, the blood concentrations of acetoacetic acid and β-hydroxybutyric acid sometimes rise to as high as 20 times normal, thus leading to extreme acidosis, as explained in Chapter 31.

The acetone that is formed during ketosis is a volatile substance, some of which is blown off in small quantities in the expired air of the lungs, thus giving the breath an acetone smell that is frequently used to diagnose ketosis.

Adaptation to a High-Fat Diet. When changing slowly from a carbohydrate diet to a diet almost entirely of fat, a person's body adapts to use far more acetoacetic acid than usual, and in this case, ketosis normally does not occur. For instance, in the Arctic (Alaska, Canada, and Greenland) indigenous population (Inuit), who sometimes live on a high-fat diet, ketosis does not usually develop. Undoubtedly, several factors enhance the rate of acetoacetic acid metabolism by the cells. After a few weeks, even the brain cells, which normally derive almost all their energy from glucose, can derive 50% to 75% of their energy from fats.

Synthesis of Triglycerides From Carbohydrates

Whenever a greater quantity of carbohydrates enters the body than can be used immediately for energy or stored in the form of glycogen, the excess is rapidly converted into triglycerides and stored in this form in the adipose tissue.

In humans, most triglyceride synthesis occurs in the liver, but minute quantities are also synthesized in the adipose tissue. The triglycerides formed in the liver are transported mainly in VLDLs to the adipose tissue, where they are stored.

Conversion of Acetyl-CoA Into Fatty Acids. The first step in the synthesis of triglycerides is conversion of carbohydrates into acetyl-CoA. As explained in Chapter 68, this conversion occurs during the normal degradation of glucose by the glycolytic system. Because fatty acids are actually large polymers of acetic acid, it is easy to understand how acetyl-CoA can be converted into fatty acids. However, synthesis of fatty acids from acetyl-CoA is not achieved by simply reversing the oxidative degradation described earlier. Instead, this occurs by the two-step process shown in **Fig. 69.4**, using *malonyl-CoA* and reduced nicotinamide adenine dinucleotide phosphate (NADPH) as the principal intermediates in the polymerization process.

Combination of Fatty Acids With α-Glycerophosphate to Form Triglycerides

Once the synthesized fatty acid chains have grown to contain 14 to 18 carbon atoms, they bind with glycerol to form triglycerides. The enzymes that cause this conversion are highly specific for fatty acids, with chain lengths of 14 carbon atoms or greater, a factor that controls the physical quality of the triglycerides stored in the body.

As shown in **Fig. 69.5**, the glycerol portion of triglycerides is furnished by α-glycerophosphate, which is another

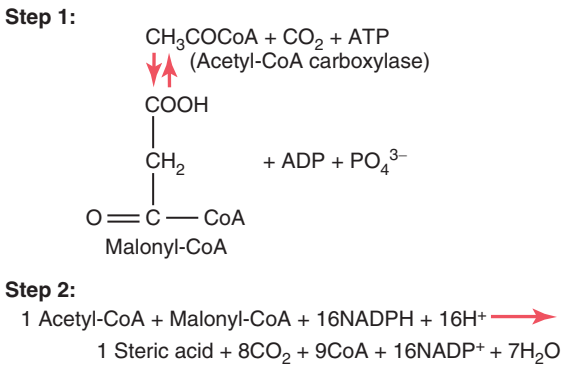


Figure 69.4 Synthesis of fatty acids.

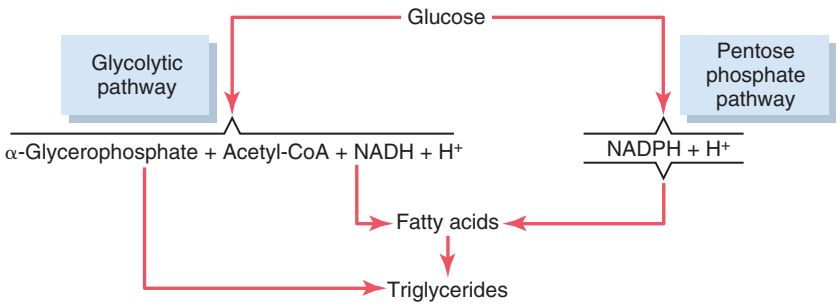

Figure 69.5 Overall schema for synthesis of triglycerides from glucose.

product derived from the glycolytic scheme of glucose degradation. This mechanism is discussed in Chapter 68.

Efficiency of Carbohydrate Conversion Into Fat. During triglyceride synthesis, only about 15% of the original energy in the glucose is lost in the form of heat; the remaining 85% is transferred to the stored triglycerides.

Importance of Fat Synthesis and Storage. Fat synthesis from carbohydrates is especially important for two reasons:

1. The ability of the different cells of the body to store carbohydrates in the form of glycogen is generally slight; a maximum of only a few hundred grams of glycogen can be stored in the liver, the skeletal muscles, and all other tissues of the body put together. In contrast, many kilograms of fat can be stored in adipose tissue. Therefore, fat synthesis provides a means by which the energy of excess ingested carbohydrates (and proteins) can be stored for later use. Indeed, the average person has almost 150 times as much energy stored in the form of fat as stored in the form of carbohydrate.
2. Each gram of fat contains almost two and a half times the calories of energy contained by each gram of glycogen. Therefore, for a given weight gain, a person can store several times as much energy in the form of fat as in the form of carbohydrate, which is exceedingly important when an animal must be highly motile to survive.

Failure to Synthesize Fats From Carbohydrates in the Absence of Insulin. In persons with serious, uncontrolled insulin-deficient diabetes mellitus (type 1 diabetes), fats are poorly synthesized, if at all, for the following reasons. First, when insulin is not available, glucose does not enter the fat and liver cells satisfactorily, so little of the acetyl-CoA and NADPH needed for fat synthesis can be derived from glucose. Second, lack of glucose in the fat cells greatly reduces the availability of α-glycerophosphate, which also makes it difficult for the tissues to form triglycerides.

Synthesis of Triglycerides From Proteins

Many amino acids can be converted into acetyl-CoA, as discussed in Chapter 70. The acetyl-CoA can then be synthesized into triglycerides. Therefore, when people have more proteins in their diets than their tissues can use as proteins, a large share of the excess is stored as fat.

Regulation of Energy Release From Triglycerides

Carbohydrates Are Preferred Over Fats for Energy When Excess Carbohydrates Are Available. When excess carbohydrates are available in the body, carbohydrates are used preferentially over triglycerides for energy. Several reasons exist for this "fat-sparing" effect of carbohydrates.

First, fats in adipose tissue cells are present in two forms: stored triglycerides and small quantities of free fatty acids. They are in constant equilibrium with each other. When excess *α-glycerophosphate* is present (which occurs when excess carbohydrates are available), the excess α-glycerophosphate binds the free fatty acids in the form of stored triglycerides. As a result, the equilibrium between free fatty acids and triglycerides shifts toward the stored triglycerides; consequently, only minute quantities of fatty acids are available to be used for energy. Because α-glycerophosphate is an important product of glucose metabolism, the availability of large amounts of glucose automatically inhibits the use of fatty acids for energy.

Second, when carbohydrates are available in excess, fatty acids are synthesized more rapidly than they are degraded. This effect is caused partially by the large quantities of acetyl-CoA formed from the carbohydrates and by the low concentration of free fatty acids in the adipose tissue, thus creating conditions appropriate for the conversion of acetyl-CoA into fatty acids.

An even more important effect that promotes conversion of carbohydrates to fats is the following: The first step, which is the rate-limiting step, in the synthesis of fatty acids is carboxylation of acetyl-CoA to form malonyl-CoA. The rate of this reaction is controlled primarily by the enzyme *acetyl-CoA carboxylase*, the activity of which is accelerated in the presence of intermediates of the citric acid cycle. When excess carbohydrates are being used, these intermediates increase, automatically causing increased synthesis of fatty acids.

Thus, an excess of carbohydrates in the diet not only acts as a fat-sparer but also increases fat stores. In fact, all the excess carbohydrates not used for energy or stored in the small glycogen deposits of the body are converted to fat for storage.

Acceleration of Fat Utilization for Energy in the Absence of Carbohydrates. All the fat-sparing effects of carbohydrates are lost and actually reversed when carbohydrates are not available. The equilibrium shifts in the opposite direction, and fat is mobilized from adipose cells and used for energy in place of carbohydrates.

Also important are several hormonal changes that take place to promote rapid fatty acid mobilization from adipose tissue. Among the most important of these hormonal changes is a marked decrease in pancreatic secretion of insulin caused by the absence of carbohydrates. This decrease in insulin not only reduces the rate of glucose utilization by the tissues but also decreases fat storage, which further shifts the equilibrium in favor of fat metabolism in place of carbohydrates.

Hormonal Regulation of Fat Utilization. At least seven of the hormones secreted by endocrine glands have significant effects on fat utilization. Some important hormonal effects on fat metabolism, in addition to *lack of insulin*, are noted here.

Probably the most dramatic increase that occurs in fat utilization is that observed during heavy exercise. This increase results almost entirely from release of *epinephrine* and *norepinephrine* by the adrenal medullae during exercise, as a result of sympathetic stimulation. These two hormones directly activate *hormone-sensitive triglyceride lipase*, which is present in abundance in the fat cells, and this activation causes rapid breakdown of triglycerides and mobilization of fatty acids. Sometimes the free fatty acid concentration in the blood of an exercising person rises as much as 8-fold, and the use of these fatty acids by the muscles for energy is correspondingly increased. Other types of stress that activate the sympathetic nervous system can also increase fatty acid mobilization and utilization in a similar manner.

Stress also causes large quantities of *adrenocorticotropic hormone* (ACTH) to be released by the anterior pituitary gland, which causes the adrenal cortex to secrete extra quantities of *glucocorticoids*. Both ACTH and glucocorticoids activate either the same hormone-sensitive triglyceride lipase as that activated by epinephrine and norepinephrine or a similar lipase. When ACTH and glucocorticoids are secreted in excessive amounts for long periods, as occurs in the endocrine condition called *Cushing syndrome*, fats are frequently mobilized to such a great extent that ketosis results. ACTH and glucocorticoids are then said to have a *ketogenic effect*.

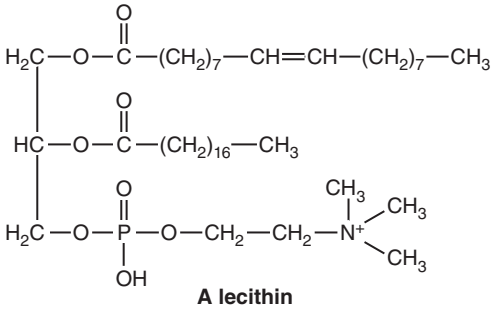
Growth hormone has an effect similar to but weaker than that of ACTH and glucocorticoids in activating hormone-sensitive lipase. Therefore, growth hormone can also have a mild ketogenic effect.

Thyroid hormone indirectly causes rapid mobilization of fat by increasing overall rate of energy metabolism in all cells of the body under the influence of this hormone. The resulting reduction in acetyl-CoA and other intermediates of both fat and carbohydrate metabolism in the cells is a stimulus to fat mobilization.

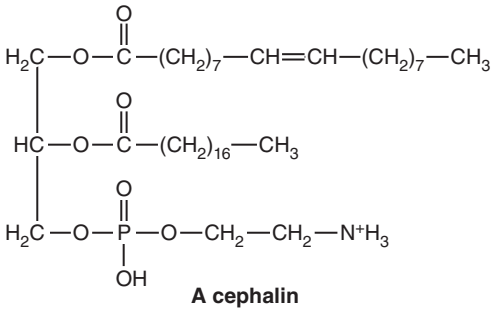
The effects of the different hormones on metabolism are discussed further in the chapters dealing with each hormone.

Obesity—Excess Deposition of Fat

Obesity is discussed in Chapter 72 in relation to dietary balances, but briefly, it is caused by the ingestion of greater amounts of food than can be used by the body for energy. The excess food, whether fats, carbohydrates, or proteins, is then stored almost entirely as fat in the adipose tissue, to be used later for energy. The ability of humans to store excess energy in adipose tissue is tremendous, with some people achieving body weights in excess of 500 kilograms (1100 pounds), mainly as a result of fat accumulation.



Several strains of rodents have been found in which *hereditary obesity* occurs. In at least one of these strains, the obesity is caused by ineffective mobilization of fat from the adipose tissue by tissue lipase, while synthesis and storage of fat continue normally. Such a one-way process causes progressive enhancement of the fat stores, resulting in severe obesity. Multiple genetic factors that influence brain feeding centers or pathways that control energy expenditure or that alter energy storage can also cause hereditary obesity in humans. However, monogenic (single gene) causes of human obesity are rare, as discussed in Chapter 72.



Phospholipids and Cholesterol

Phospholipids

The major types of body phospholipids are *lecithins, cephalins*, and *sphingomyelin;* their typical chemical formulas are shown in **Fig. 69.6**. Phospholipids always contain one or more fatty acid molecules and one phosphoric acid radical, and they usually contain a nitrogenous base. Although the chemical structures of phospholipids are somewhat variable, their physical properties are similar because they are all lipid soluble, transported in lipoproteins, and used throughout the body for various structural purposes, such as in cell membranes and intracellular membranes.

Formation of Phospholipids. Phospholipids are synthesized in essentially all cells of the body, although certain

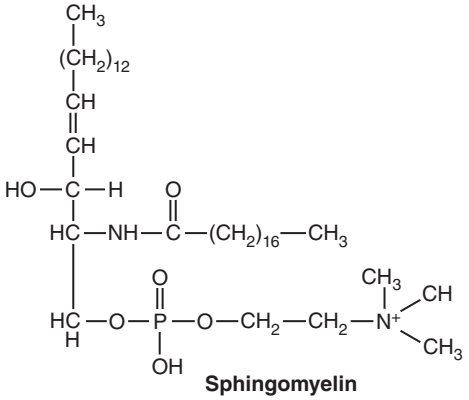


Figure 69.6 Typical phospholipids.

cells have a special ability to form great quantities of them. Probably 90% of phospholipids are formed in liver cells; substantial quantities are also formed by the intestinal epithelial cells during lipid absorption from the gut.

The rate of phospholipid formation is governed to some extent by the usual factors that control the overall rate of fat metabolism because when triglycerides are deposited in the liver, the rate of phospholipid formation increases. Also, specific chemical substances are needed for the formation of some phospholipids. For instance, *choline*, either obtained in the diet or synthesized in the body, is necessary for formation of lecithin, because choline is the nitrogenous base of the lecithin molecule. In addition, *inositol* is necessary for formation of some cephalins.

Specific Uses of Phospholipids. Phospholipids have several functions, including the following:

1. Phospholipids are an important constituent of lipoproteins in the blood and are essential for the formation and function of most of these lipoproteins; in the absence of phospholipids, serious abnormalities of transport of cholesterol and other lipids can occur.
2. Thromboplastin, which is necessary to initiate the clotting process, is composed mainly of one of the cephalins.
3. Large quantities of sphingomyelin are present in the nervous system; this substance acts as an electrical insulator in the myelin sheath around nerve fibers.
4. Phospholipids are donors of phosphate radicals when these radicals are necessary for different chemical reactions in the tissues.
5. One of the most important functions of phospholipids is participation in formation of structural elements—mainly membranes—in cells throughout the body, as discussed in the next section of this chapter in connection with a similar function for cholesterol.

Cholesterol

Cholesterol, the formula of which is shown in **Fig. 69.7**, is present in the normal diet, and it can be absorbed slowly from the gastrointestinal tract into the intestinal lymph. It is highly fat soluble but only slightly soluble in water. It is specifically capable of forming esters with fatty acids. Indeed, about 70% of the cholesterol in the lipoproteins of the plasma is in the form of cholesterol esters.

Formation of Cholesterol. Besides the cholesterol absorbed each day from the gastrointestinal tract, which is called *exogenous cholesterol*, an even greater quantity is formed in the cells of the body, called *endogenous cholesterol*. Essentially all the endogenous cholesterol that circulates in the lipoproteins of the plasma is formed by the liver, but all other cells of the body form at least some cholesterol, which is consistent with the fact that many of the membranous structures of all cells are partially composed of this substance.

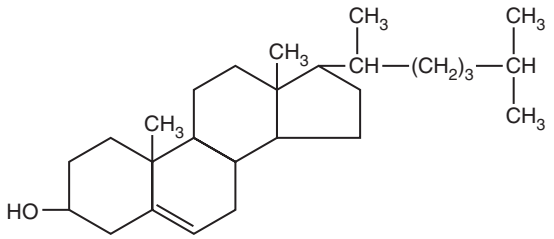

Figure 69.7 Cholesterol.

The basic structure of cholesterol is a sterol nucleus, which is synthesized entirely from multiple molecules of acetyl-CoA. In turn, the sterol nucleus can be modified by various side chains to form (1) cholesterol; (2) cholic acid, which is the basis of the bile acids formed in the liver; and (3) many important steroid hormones secreted by the adrenal cortex, the ovaries, and the testes (these hormones are discussed in later chapters).

Factors That Affect Plasma Cholesterol Concentration—Feedback Control of Body Cholesterol. Among the important factors that affect plasma cholesterol concentration are the following:

1. An increase in the *amount of cholesterol ingested each day* may increase the plasma concentration slightly. However, when cholesterol is ingested, the rising concentration of cholesterol inhibits the most essential enzyme for endogenous synthesis of cholesterol, 3-hydroxy-3-methylglutaryl CoA reductase, thus providing an intrinsic feedback control system to prevent an excessive increase in plasma cholesterol concentration. As a result, plasma cholesterol concentration *usually* is not changed upward or downward more than ±15% by altering the amount of cholesterol in the diet, although the response of individuals differs markedly.
2. A diet *high in saturated fat* increases blood cholesterol concentration 15% to 25%, especially when this diet is associated with excess weight gain and obesity. This increase in blood cholesterol results from increased fat deposition in the liver, which then provides increased quantities of acetyl-CoA in the liver cells for the production of cholesterol. Therefore, to decrease the blood cholesterol concentration, maintaining a normal body weight and consuming a diet low in saturated fat are even more important than maintaining a diet low in cholesterol.
3. Ingestion of fat containing highly *unsaturated fatty acids* usually depresses blood cholesterol concentration a slight to moderate amount. The mechanism of this effect is unknown, despite the fact that this observation is the basis of much present-day dietary strategy.
4. *Lack of insulin* or *thyroid hormone* increases the blood cholesterol concentration, whereas excess thyroid hormone decreases the concentration. These effects are probably caused mainly by changes in the degree of activation of specific enzymes responsible for the metabolism of lipids and overall metabolic rate.
5. *Genetic disorders* of cholesterol metabolism may greatly increase plasma cholesterol levels. For example, mutations of the *LDL receptor* gene prevent the liver from adequately removing the cholesterol-rich LDLs from the plasma. As discussed later, this phenomenon causes the liver to produce excessive amounts of cholesterol. Mutations of the gene that encodes *apolipoprotein B*, the part of the LDL that binds to the receptor, also cause excessive cholesterol production by the liver.

Specific Uses of Cholesterol in the Body. By far the most abundant nonmembranous use of cholesterol in the body is to form cholic acid in the liver. As much as 80% of cholesterol

is converted into cholic acid. As explained in Chapter 71, cholic acid is conjugated with other substances to form bile salts, which promote digestion and absorption of fats.

A small quantity of cholesterol is used by (1) the adrenal glands to form *adrenocortical hormones*, (2) the ovaries to form *progesterone* and *estrogen*, and (3) the testes to form *testosterone*. These glands can also synthesize their own sterols and then form hormones from them, as discussed in the chapters on endocrinology.

A large amount of cholesterol is precipitated in the corneum of the skin. This cholesterol, along with other lipids, makes the skin highly resistant to the absorption of water-soluble substances and to the action of many chemical agents because cholesterol and the other skin lipids are highly inert to acids and to many solvents that might otherwise easily penetrate the body. Also, these lipid substances help prevent water evaporation from the skin; without this protection, the amount of evaporation can be 5 to 10 liters per day (as occurs in patients with burns who have lost their skin) instead of the usual 300 to 400 milliliters.

Cellular Structural Functions of Phospholipids and Cholesterol—Especially for Membranes. The previously mentioned uses of phospholipids and cholesterol are of only minor importance in comparison with their function of forming specialized structures, mainly membranes, in all cells of the body. We discussed in Chapter 2 that large quantities of phospholipids and cholesterol are present in both the cell membrane and the membranes of the internal organelles of all cells. It is also known that the *ratio* of membrane cholesterol to phospholipids is especially important in determining the fluidity of cell membranes.

For membranes to be formed, substances that are not soluble in water must be available. In general, the only substances in the body that are not soluble in water (besides the inorganic substances of bone) are the lipids and some proteins. Thus, the physical integrity of cells everywhere in the body is based mainly on phospholipids, cholesterol, and certain insoluble proteins. The polar charges on the phospholipids also reduce the interfacial tension between the cell membranes and the surrounding fluids.

Another fact that indicates the importance of phospholipids and cholesterol for the formation of structural elements of the cells is the slow turnover rates of these substances in most nonhepatic tissues—turnover rates measured in months or years. For instance, their function in brain cells to provide memory processes is related mainly to their indestructible physical properties.

Atherosclerosis

Atherosclerosis is a disease of the large and intermediate-sized arteries in which fatty lesions called *atheromatous plaques* develop on the inside surfaces of the arterial walls. *Arteriosclerosis* is a general term that refers to thickened and stiffened blood vessels of all sizes.

One abnormality that can be measured very early in blood vessels that later become atherosclerotic is *damage to the vascular endothelium*. This damage, in turn, increases expression of adhesion molecules on endothelial cells and decreases their ability to release nitric oxide and other substances that help prevent adhesion of macromolecules, platelets, and monocytes to the endothelium. After damage to the vascular endothelium occurs, circulating monocytes and lipids (mostly LDLs) begin to accumulate at the site of injury (**Fig. 69.8A**). The monocytes cross the endothelium, enter the *intima* of the vessel wall, and differentiate to become *macrophages*, which then ingest and oxidize the

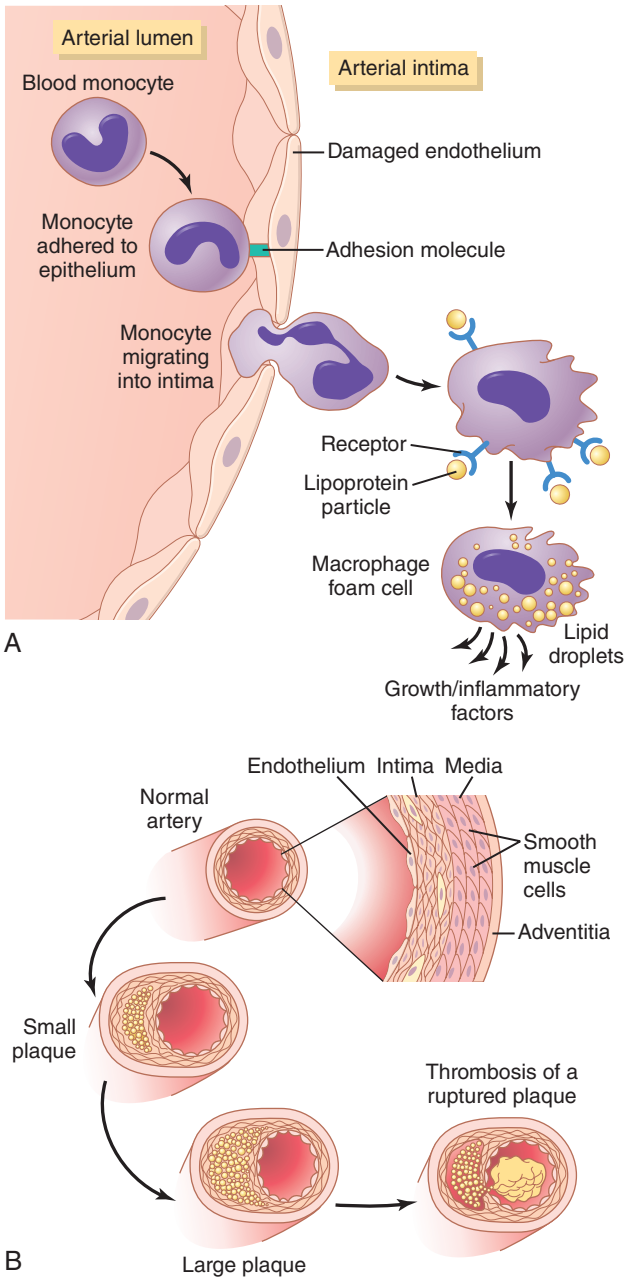

Figure 69.8 Development of atherosclerotic plaque. (A) Attachment of a monocyte to an adhesion molecule on a damaged endothelial cell of an artery. The monocyte then migrates through the endothelium into the intimal layer of the arterial wall and is transformed into a macrophage. The macrophage then ingests and oxidizes lipoprotein molecules, becoming a macrophage foam cell. The foam cells release substances that cause inflammation and growth of the intimal layer. (B) Additional accumulation of macrophages and growth of the intima cause the plaque to grow larger and accumulate lipids. Eventually, the plaque may occlude the vessel or rupture, causing the blood in the artery to coagulate and form a thrombus. *(Modified from Libby P. Inflammation in atherosclerosis.* Nature. *2002;420:868.)*

accumulated lipoproteins, giving the macrophages a foam-like appearance. These *macrophage foam cells* then aggregate on the blood vessel and form a visible *fatty streak*.

With time, the fatty streaks grow larger and coalesce, and the surrounding fibrous and smooth muscle tissues proliferate to form larger and larger plaques (see **Fig. 69.8B**). Also, the macrophages release substances that cause *inflammation* and further proliferation of smooth muscle and fibrous tissue on the inside surfaces of the arterial wall. The lipid deposits plus the cellular proliferation can become so large that the plaque bulges into the lumen of the artery and greatly reduces blood flow, sometimes completely occluding the vessel. Even without occlusion, the fibroblasts of the plaque eventually deposit extensive amounts of dense connective tissue; *sclerosis (fibrosis)* becomes so great that the arteries become stiff. Still later, calcium salts often precipitate with the cholesterol and other lipids of the plaques, leading to bony-hard calcifications that can make the arteries rigid tubes. Both of these later stages of the disease are often called "hardening of the arteries."

Atherosclerotic arteries lose most of their distensibility, and because of the degenerative areas in their walls, they are easily ruptured. Also, where the plaques protrude into the flowing blood, their rough surfaces can cause blood clots to develop, with resultant thrombus or embolus formation (see Chapter 37), leading to a sudden blockage of all blood flow in the artery.

Almost half of all deaths in the United States and Europe are due to vascular disease. About two-thirds of these deaths are caused by thrombosis of one or more coronary arteries. The remaining one-third are caused by thrombosis or hemorrhage of vessels in other organs of the body, especially the brain (causing strokes), but also the kidneys, liver, gastrointestinal tract, limbs, and so forth.

Roles of Cholesterol and Lipoproteins in Atherosclerosis

Increased Low-Density Lipoproteins. An important factor in causing atherosclerosis is a high blood plasma concentration of cholesterol in the form of LDLs. The plasma concentration of these high-cholesterol LDLs is increased by several factors, especially by eating highly saturated fat in the daily diet, obesity, and physical inactivity. To a much lesser extent, eating excess cholesterol may also raise plasma levels of LDLs.

Familial Hypercholesterolemia. In 80% to 90% of patients with *familial hypercholesterolemia*, the person inherits defective genes for the formation of LDL receptors on the membrane surfaces of the body's cells. In the absence of these receptors, the liver cannot absorb either IDL or LDL. Without this absorption, the cholesterol machinery of the liver cells goes on a rampage, producing new cholesterol, and is no longer responsive to the feedback inhibition of too much plasma cholesterol. As a result, the number of VLDLs released by the liver into the plasma increases immensely.

A much smaller percentage (~2%) of persons with familial hypercholesterolemia have gain of function mutations of the *PCSK9* gene, which encodes the enzyme *proprotein convertase subtilisin/kexin type 9*; this enzyme binds to the LDL receptor and induces a conformational change that leads to its destruction, thereby reducing LDL absorption by the liver and other cells and increasing plasma cholesterol markedly. Drugs that inhibit PCSK9 are now available to treat familial hypercholesterolemia, although they are still expensive and not widely used.

Patients with full-blown familial hypercholesterolemia may have blood cholesterol concentrations of 600 to 1000 mg/dL, levels that are 4 to 6 times normal. If untreated, many of these people die before age 50 years because of myocardial infarction or other sequelae of atherosclerotic blockage of blood vessels throughout the body.

Heterozygous familial hypercholesterolemia is relatively common and occurs in about 1 in 500 people. The more severe form of this disorder caused by homozygous mutations is much rarer, occurring in only about one of every million births on average.

Role of High-Density Lipoproteins in Preventing Atherosclerosis. Much less is known about the function of HDLs compared with that of LDLs. It is believed that HDLs can actually absorb cholesterol crystals that are beginning to be deposited in arterial walls. Animal experiments also suggest that HDL may have other actions that protect against atherosclerosis, such as inhibition of oxidative stress and prevention of inflammation in blood vessels. Whether or not these mechanisms are true, epidemiological studies indicate that when a person has a high *ratio* of high-density to low-density lipoproteins, the likelihood of developing atherosclerosis is greatly reduced. Yet, clinical studies with drugs that increase HDL levels have failed to demonstrate decreased risk for cardiovascular disease. Some studies even suggest that very high levels of HDL may, paradoxically, be associated with higher mortality risk in individuals with coronary artery disease. These discrepant results indicate the need for additional research on the basic mechanisms by which HDL may influence atherosclerosis and cardiovascular risk.

Other Major Risk Factors for Atherosclerosis

In some people with perfectly normal levels of cholesterol and lipoproteins, atherosclerosis still develops. Some of the factors that are known to predispose to atherosclerosis are (1) *physical inactivity* and *obesity*, (2) *diabetes mellitus*, (3) *hypertension*, (4) *hyperlipidemia*, and (5) *cigarette smoking*.

Hypertension, for example, increases the risk for atherosclerotic coronary artery disease by at least 2-fold. Likewise, persons with diabetes mellitus have, on average, more than a 2-fold increased risk of developing coronary artery disease. When hypertension and diabetes mellitus occur together, the risk for coronary artery disease is increased by more than 8-fold. When hypertension, diabetes mellitus, and hyperlipidemia are all present, the risk for atherosclerotic coronary artery disease is increased almost 20-fold, suggesting that these factors interact in a synergistic manner to increase the risk of developing atherosclerosis. In many overweight and obese patients, these three risk factors do occur together, greatly increasing their risk for atherosclerosis, which in turn may lead to heart attack, stroke, and kidney disease.

In early and middle adulthood, men are more likely to develop atherosclerosis than are women of comparable age, suggesting that male sex hormones might be atherogenic or, conversely, that female sex hormones might be protective.

Some of these factors cause atherosclerosis by increasing the concentration of LDLs in the plasma. Others, such as hypertension, lead to atherosclerosis by causing damage to the vascular endothelium and other changes in the vascular tissues that predispose to cholesterol deposition.

To add to the complexity of atherosclerosis, experimental studies suggest that *excess blood levels of iron* can lead to atherosclerosis, perhaps by forming free radicals in the blood that damage the vessel walls. About one-quarter of all people have a special type of LDL called lipoprotein(a), containing an additional protein, *apolipoprotein(a)*, that almost doubles the incidence of atherosclerosis. The precise mechanisms of these atherogenic effects have yet to be discovered.

Prevention of Atherosclerosis

The most important measures to protect against development of atherosclerosis and its progression to serious vascular disease are (1) maintaining a healthy weight, being physically active, and eating a diet that contains mainly unsaturated fat with a low cholesterol content; (2) preventing hypertension by maintaining a healthy diet and being physically active, or effectively controlling blood pressure with antihypertensive drugs if hypertension does develop; (3) effectively controlling blood glucose with insulin treatment or other drugs if diabetes develops; and (4) avoiding cigarette smoking.

Several types of drugs that lower plasma lipids and cholesterol have proved to be valuable in preventing atherosclerosis. Most of the cholesterol formed in the liver is converted into bile acids and secreted in this form into the duodenum; then, more than 90% of these same bile acids is reabsorbed in the terminal ileum and used over and over again in the bile. Therefore, any agent that combines with the bile acids in the gastrointestinal tract and prevents their reabsorption into the circulation can decrease the total bile acid pool in the circulating blood. As a result, far more of the liver cholesterol is converted into new bile acids. Thus, simply eating *oat bran*, which binds bile acids and is a constituent of many breakfast cereals, increases the proportion of liver cholesterol that forms new bile acids rather than forming new LDLs and atherogenic plaques. *Resin agents* can also be used to bind bile acids in the gut and increase their fecal excretion, thereby reducing cholesterol synthesis by the liver.

Another group of drugs called *statins* competitively inhibits *hydroxymethylglutaryl-coenzyme A* (HMG-CoA) *reductase*, a rate-limiting enzyme in the synthesis of cholesterol. This inhibition decreases cholesterol synthesis and increases LDL receptors in the liver, usually causing a 25% to 50% reduction in plasma levels of LDLs. The statins may also have other beneficial effects that help prevent atherosclerosis, such as attenuating vascular inflammation. These drugs are now widely used to treat patients who have increased plasma cholesterol levels.

In general, studies show that for each 1 mg/dL decrease in LDL cholesterol in the plasma, there is about a 2% decrease in mortality from atherosclerotic heart disease. Therefore, appropriate preventive measures are valuable in decreasing heart attacks.

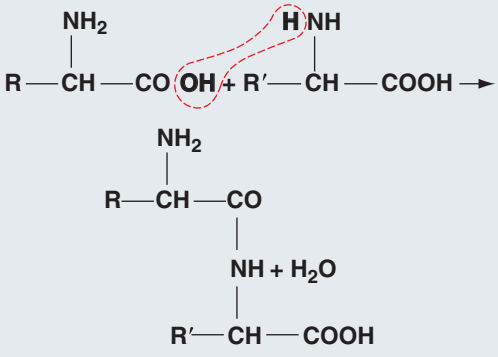
CHAPTER 70

Protein Metabolism

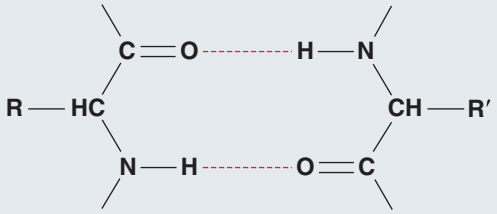
About three-quarters of the body solids are proteins. These proteins include structural proteins, enzymes, nucleoproteins, proteins that transport oxygen, proteins of the muscle that cause muscle contraction, and many other types that perform specific intracellular and extracellular functions throughout the body.



The basic chemical properties that explain the diverse functions of proteins are so extensive that they constitute a major portion of the entire discipline of biochemistry. For this reason, the current discussion is confined to a few specific aspects of protein metabolism that are important as background for other discussions in this text.

Basic Properties of Proteins

Amino Acids Are the Principal Constituents of Proteins



The principal constituents of proteins are amino acids. Twenty of these amino acids are present in the body proteins in significant quantities. **Fig. 70.1**, which shows the chemical formulas of these 20 amino acids, demonstrates that they all have two features in common; each amino acid has an acidic group (–COOH) and a nitrogen atom attached to the molecule, usually represented by the amino group ($–NH_2$).
